`RMS value`	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **`threshold value`** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: `Threshold`

- Default setting **`(_:3) Threshold`** = ***`0.050 A`***

The **`Threshold`** parameter allows you to set the threshold value of the ground current 3I0.

Parameter: `Pickup delay`

- Default setting **`(_:102) Pickup delay`** = ***`0.00 s`***

With the parameter **`Pickup delay`** you set whether pickup of the stage is to be delayed or not. If the transient cycle of the ground fault occurrence should not be evaluated, set a delay of 100 ms, for example.

Parameter: `Operate delay`

- Default setting **`(_:6) Operate delay`** = ***`0.30 s`***

The **`Operate delay`** parameter determines the time during which the pickup conditions must be met to issue the operate indication. The operate indication is issued when this time expires.

6.13.11 Non-Directional Y0 Stage

6.13.11.1 Description

In the **Directional sensitive ground-fault detection** function, the **Non-directional Y0 stage** also works on demand.

Logic

[lo_gfp_sy_0, 3, en_US]

Figure 6-264 Logic Diagram of the Non-Directional Y0 Stage

Measured Value V0, Method of Measurement

The device can measure the residual voltage at the broken-delta winding. The measured voltage VN is converted to a value with reference to the zero-sequence voltage V0. If the residual voltage is not available, the device calculates the zero-sequence voltage V0 from the measured phase-to-ground voltages V_A, V_B, and V_C using the defining equation.

The method of measurement processes the sampled voltage values and filters out the fundamental component numerically.

Measured Value 3I0, Method of Measurement

The function usually evaluates the sensitively measured ground current 3I0 via a core balance current transformer. Since the linearity range of the sensitive measuring input ends at approx. 1.6 A, for larger secondary ground currents, the function switches to the 3I0 current calculated from the phase currents. This results in a very large linearity and settings range.

The method of measurement processes the sampled current values and filters out the fundamental component numerically.

Depending on the connection type of the measuring point as well as the current terminal blocks used, different linearity and setting ranges result. You can find more information in section *Measured Value 3I0, Method of Measurement , Page 897*.

Y0

The fundamental-component values of V0 and 3I0 are used to calculate the admittance Y0 through the formula Y0 = 3I0/V0. This stage uses Y0 as a condition to recognize the ground fault.

Minimum 3I0 Threshold

To start the Y0 calculation, the IN/3I0 value must exceed a minimum 3I0 threshold. For protection-class current transformers, the threshold value is 30 mA ($I_{rated, sec}$ = 1 A) or 150 mA ($I_{rated, sec}$ = 5 A). For sensitive current transformers, the threshold value is 1 mA ($I_{rated, sec}$ = 1 A) or 5 mA ($I_{rated, sec}$ = 5 A).

Ground-Fault Detection, Pickup

If the absolute value of the zero-sequence voltage V0 exceeds the threshold value **`V0> threshold value`** and Y0 exceeds the threshold value **`Threshold Y0>`**, the stage recognizes the ground fault. If the threshold values remain exceeded during the **`Pickup delay`**, the stage picks up.

Blocking the Stage via Binary Input Signal

Blocking of the stage is possible externally or internally via the binary input signal *>Block stage*. In the event of blocking, the picked up stage will be reset.

Blocking the Stage in Case of Measuring-Voltage Failure

The stage can be blocked if a measuring-voltage failure occurs. In the event of blocking, the picked up stage will be reset.

The following blocking options are available for the stage:

- From inside on pick up of the **Measuring-voltage failure detection** function
- From an external source via the binary input signal *>open* of the function block **Voltage-transformer circuit breaker**, which links in the tripping of the voltage-transformer circuit breaker.

The **`Blk. by meas.-volt. failure`** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

Blocking of the Time Delay

You can use the binary input signal *>Block delay & op.* to prevent the start of the time delay and thus also the operate indication. A running time delay is reset. The pickup is indicated and a fault record is opened.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

The **`Blk. w. inrush curr. detect.`** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

6.13.11.2 Application and Setting Notes

Parameter: **Operate & flt.rec. blocked**

- Default setting **(_:2) Operate & flt.rec. blocked** = ***no***

You can block the operate indication, the fault recording, and the fault log with the **Operate & flt.rec. blocked** parameter. In this case, a ground-fault log is created instead of the fault log.

Parameter: **Blk. by meas.-volt. failure**

- Recommended setting value **(_:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and enabled.
- The binary input signal *>Open* of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker.

Parameter Value	Description
yes	The protection stage is blocked (= default setting). If V0 is calculated from the phase-to-ground voltages, Siemens recommends using the blocking.
no	The protection stage is not blocked. If V0 is obtained from the VN measurement of a broken-delta winding, Siemens recommends not using the blocking.

Parameter: **Blk. w. inrush curr. detect.**

- Default setting **(_:27) Blk. w. inrush curr. detect.** = ***no***

With the **Blk. w. inrush curr. detect.** parameter, you determine whether the operate is blocked during the detection of an inrush current.

Parameter: **V0> threshold value**

- Default setting **(_:101) V0> threshold value** = ***5.000 V***

The **V0> threshold value** parameter allows you to set the zero-sequence voltage sensitivity of the stage. The threshold value must be smaller than the minimum amount of the zero-sequence voltage V0 which must still be detected.

Parameter: **Threshold Y0>**

- Default setting **(_:102) Threshold Y0>** = ***2.00 mS***

With the parameter **Threshold Y0>**, you set the threshold value of the ground admittance Y0. If the ground admittance for the setting value is unknown, you can assume the following relation:

$$Y0 > k_s \frac{I_{c,line}}{3V_{ph-gnd}} + \frac{3I_{0\,min}}{V0>}$$

[fo_se_g_f_Y0, 2, en_US]

k_s	Factor, takes into account the ohmic components of the current (1.2 for overhead lines, 1.0 to 1.05 for cable systems)
$I_{c,line}$	Secondary capacitive ground-fault current for the protected line
V_{ph-gnd}	Secondary phase-to-ground voltage in the healthy case

$3I_{0min}$	Secondary ground current in the healthy case (resulting from transformer error), 5 mA to 10 mA (core balance current transformer), 50 mA to 100 mA (Holmgreen transformer)
V0>	Secondary pickup threshold of the residual voltage

Parameter: `Pickup delay`

- Default setting **`(_:103) Pickup delay`** = ***`0.00 s`***

With the parameter **`Pickup delay`**, you set whether pickup of the stage is to be delayed or not. If the transient cycle of the ground fault occurrence should not be evaluated, set a delay of 100 ms, for example.

Parameter: `Operate delay`

- Default setting **`(_:6) Operate delay`** = ***`0.30 s`***

The **`Operate delay`** parameter determines the time during which the pickup conditions must be met to issue the operate indication. The operate indication is issued when this time expires.

6.13.12 Non-Directional 3I0 Harmonic Stage

6.13.12.1 Description

The **Non-directional 3I0 harmonic stage** detects ground faults via the 3rd, 5th, or 7th harmonic component of the zero-sequence current 3I0.

Logic

[lo_3I0_harmonic, 2, en_US]

Figure 6-265 Logic Diagram of the Non-Directional 3I0 Harmonic Stage

Measured Value 3I0, Method of Measurement

The function usually evaluates the sensitively measured ground current 3I0 via a core balance current transformer. Since the linearity range of the sensitive measuring input ends at approx. 1.6 A, for larger secondary ground currents, the function switches to the 3I0 current calculated from the phase currents. This results in a very large linearity and settings range.

Depending on the connection type of the measuring point and on the current terminal blocks used, different linearity and setting ranges result. You can find more information in chapter *6.13.4.1 Description*.

The function uses the 3rd, 5th, or 7th harmonic component of the ground current 3I0 for detecting the ground fault. The specific harmonic component to be used is determined by the **Harmonic selection** setting.

Stabilization, Pickup

To avoid a wrong pickup in case of transient current peaks, the function uses the **Stabilization counter** parameter. If the magnitude of the zero-sequence harmonic current 3I0harm. exceeds the **3I0 harm. threshold**, the stabilization counter starts. If the 3I0harm. current keeps exceeding the **3I0 harm. threshold** for a specified number of measuring cycles, the stage picks up. You can define the specified number via the **Stabilization counter** parameter.

Pickup Extension

Considering the discontinuity of the 3I0harm. current, the *Pickup* signal does not drop out immediately after the 3I0harm. current falls below the **3I0 harm. threshold**.

When the 3I0harm. current falls below the **3I0 harm. threshold**, the timer **Pickup extension time** starts to hold the *Pickup* signal until the timer expires. The timer resets after the 3I0harm. current exceeds the **3I0 harm. threshold** again during the extension time.

Blocking the Stage via Binary Input Signal

You can block the stage externally or internally via the binary input signal *>Block stage*. In the event of blocking, the picked up stage will be reset.

Blocking the Time Delay

You can use the binary input signal *>Block delay & op.* to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated. Fault logging and fault recording take place.

Functional Measured Values

Values	Description	Primary	Secondary	% Referenced to
3I0 harm.	3rd, 5th, or 7th harmonic component of the ground current	A	A	Parameter **Rated current**

You can find the parameter **Rated current** in the **FB General** of the function group where the **Sensitive ground-fault detection** function is used. If the 3I0harm. current is smaller than 0.005 % of the rated secondary current, the functional measured value is displayed as ---.

6.13.12.2 Application and Setting Notes

Parameter: Harmonic selection

- Default setting **(_:201) Harmonic selection** = ***5th harmonic***

With the **Harmonic selection** parameter, you select to use the 3rd, 5th, or 7th harmonic component of the zero-sequence current 3I0 for detecting the ground fault.

Parameter: 3I0 harm. threshold

- Default setting **(_:202) 3I0 harm. threshold** = ***0.030 A***

With the **3I0 harm. threshold** parameter, you define the threshold value of the zero-sequence harmonic current 3I0harm. for detecting the ground fault.

This parameter needs to be set according to the experience from the specific network. The experience requires the analysis of permanent ground faults from the network. If such information is unavailable, Siemens recommends a rather low setting between 5 mA and 10 mA secondary.

Parameter: `Stabilization counter`

- Default setting **`(_:204) Stabilization counter`** = ***`4`***

With the **`Stabilization counter`** parameter, you define the number of measuring cycles in which the 3I0harm. current must keep exceeding the **`3I0 harm. threshold`** to meet the pickup condition. With this setting, you can optimize the pickup-condition reliability versus the pickup time.

For example, the **`Stabilization counter`** value is ***`4`***. Then, if the 3I0harm. current exceeds the **`3I0 harm. threshold`** and keeps exceeding the threshold for 4 measuring cycles, the stage picks up. The measuring cycle time is half of the network period. For 50 Hz, the cycle time is 10 ms. To avoid a false pickup due to CB switching operations, Siemens recommends using the default setting.

Parameter: `3I0 harm. dropout ratio`

- Default setting **`(_:203) 3I0 harm. dropout ratio`** = ***`0.60`***

With the **`3I0 harm. dropout ratio`** parameter, you define the dropout threshold for the **`3I0 harm. threshold`** parameter. Siemens recommends using the default setting.

Parameter: `Pickup extension time`

- Default setting **`(_:110) Pickup extension time`** = ***`0.00 s`***

With the **`Pickup extension time`** parameter, you define the time for extending the *Pickup* signal if the zero-sequence harmonic current 3I0harm. falls below the **`3I0 harm. threshold`**.

This extension time can be used to generate a stable pickup indication under fluctuating zero-sequence harmonics.

Parameter: `Operate delay`

- Default setting **`(_:6) Operate delay`** = ***`1.00 s`***

With the **`Operate delay`** parameter, you determine the time during which the pickup conditions must be met to issue the operate indication. The operate indication is issued when this time expires.

Parameter: `Operate & flt.rec. blocked`

- Default setting **`(_:2) Operate & flt.rec. blocked`** = ***`no`***

With the **`Operate & flt.rec. blocked`** parameter, you block the operate indication, the fault recording, and the fault log. In this case, a ground-fault log is created instead of the fault log.

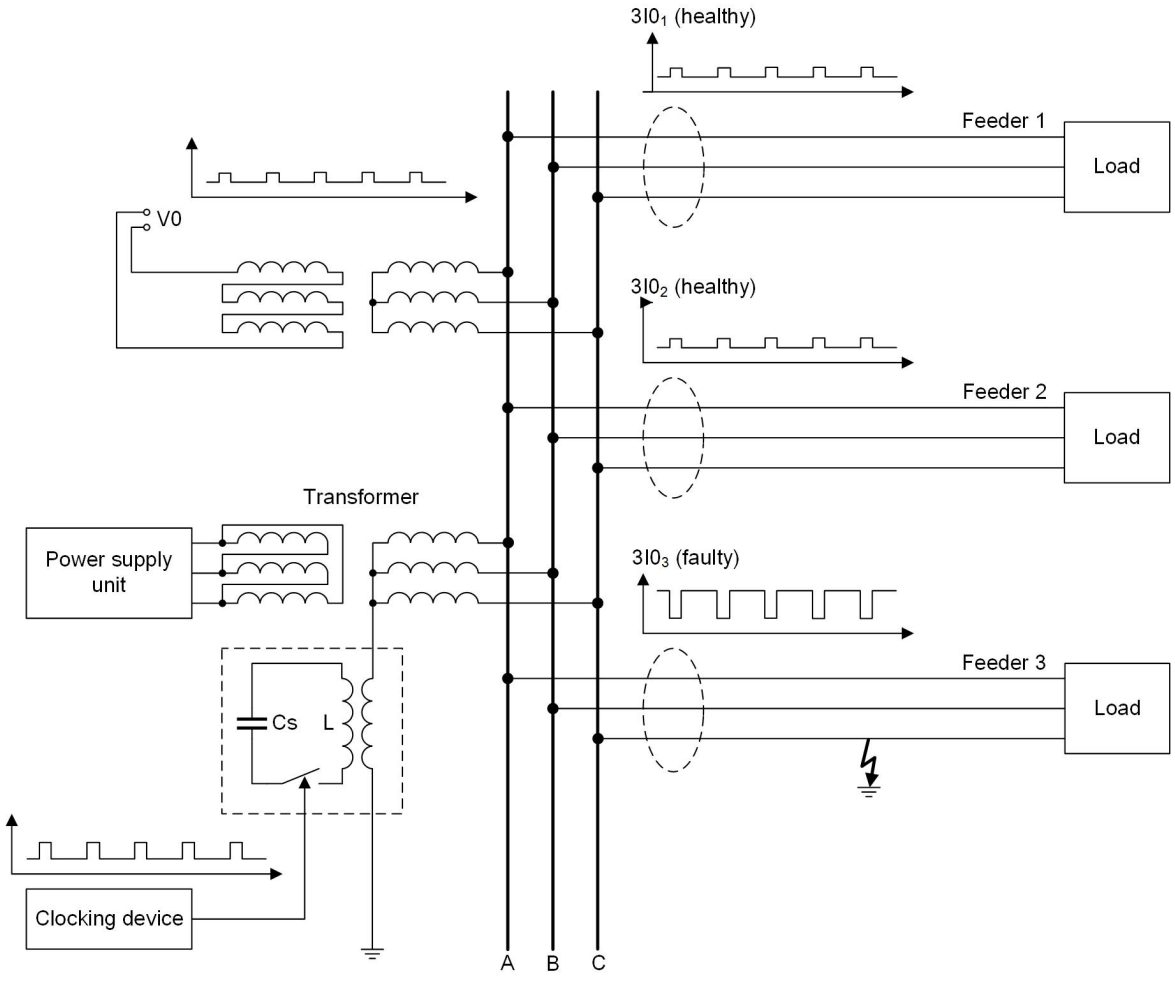
6.13.13 Pulse-Pattern Detection Stage

6.13.13.1 Description



Overview

The **Pulse-pattern detection** stage detects a faulty feeder during a permanent ground fault in overcompensated systems. This method is not reliably applicable to undercompensated systems.

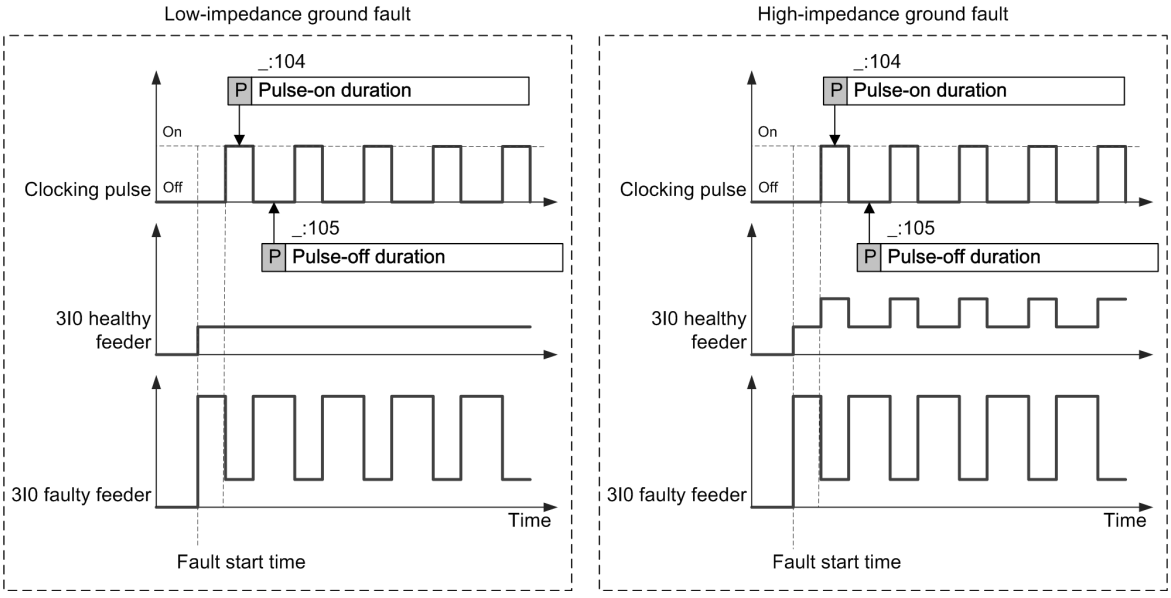
The following figure shows a simplified network that applies the pulse-pattern detection method.

The pulse pattern in the ground current 3I0 is generated by switching on and off a capacitor in parallel to the arc-suppression coil:

- When the capacitor is switched on, an additional capacitive ground current is generated and the 3I0 compensation changes.
- When the capacitor is switched off, the additional capacitive ground current is vanished and the 3I0 compensation returns to the normal state.

[dw_pulse detection network, 2, en_US]

Figure 6-266 Network that Uses the Pulse-Pattern Detection



Cs	Capacitance of the switched capacitor
L	Inductance of the arc-suppression coil

Pulse Pattern during a Ground Fault

The following figure shows the 3I0 pulse pattern in an overcompensated system for a low-impedance ground fault and a high-impedance ground fault.

- For low-impedance ground faults, the 3I0 pulse pattern exists only in the faulty feeder.
- For high-impedance ground faults, the pulse pattern is also present in the healthy feeders with lower amplitude but in phase opposition to the faulty feeder.

  Applying a different switch-on/switch-off duration allows distinguishing between faulty and healthy feeders in case of high-impedance ground faults.

[dw_pulse pattern in overcompensation network, 1, en_US]

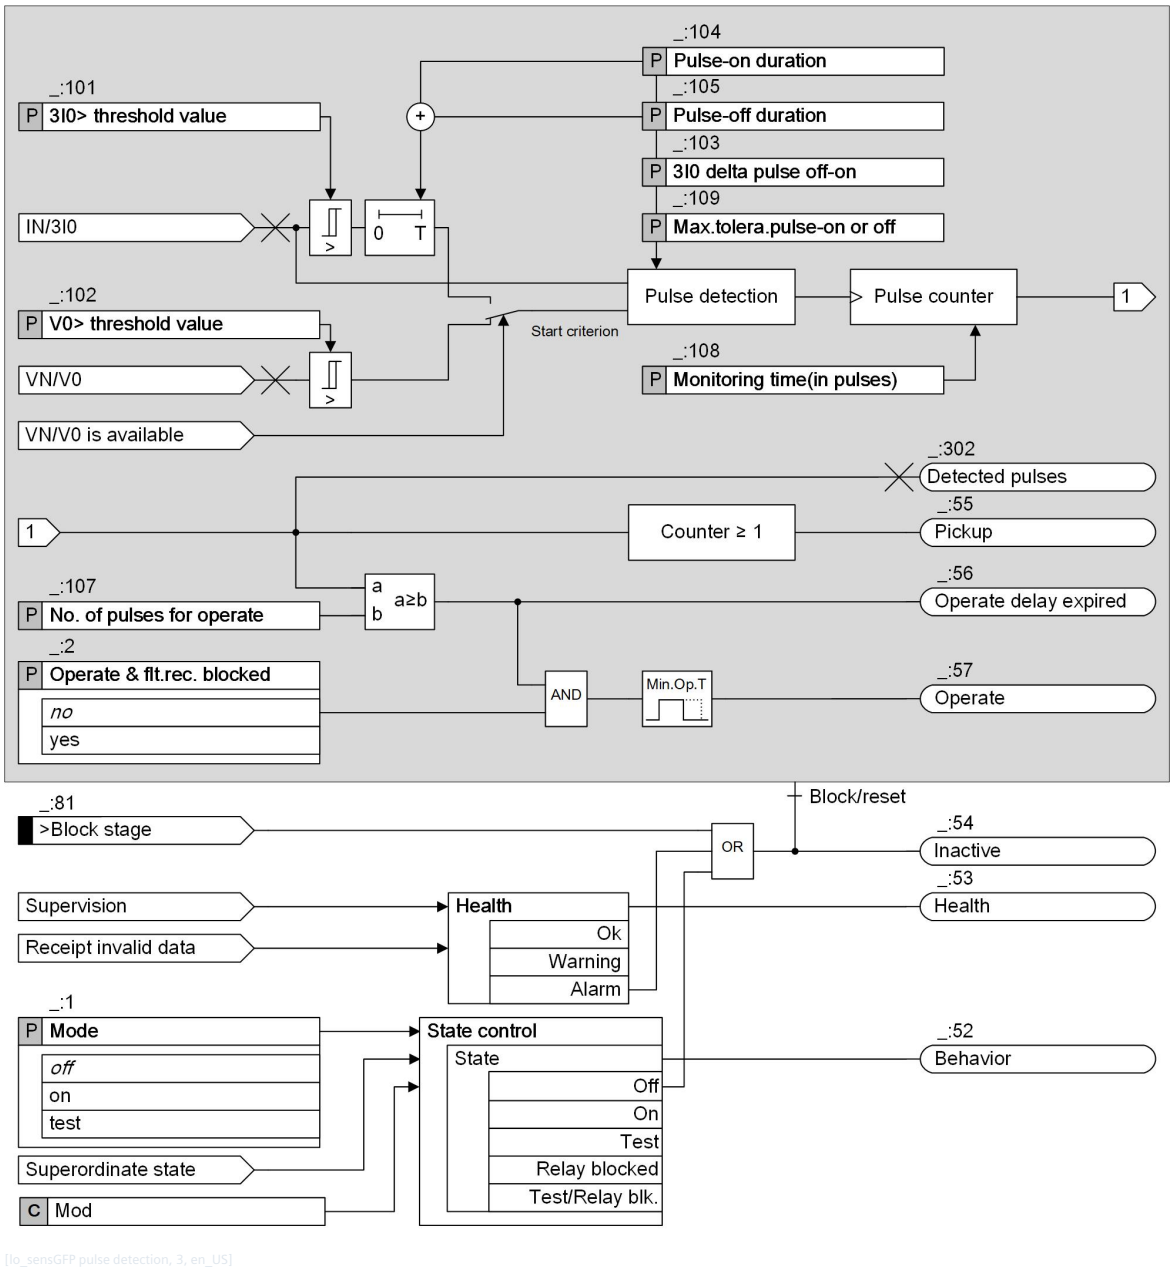


Figure 6-267 Current Pulse Pattern in the Overcompensated System

For the faulty feeder, the current pulse pattern is as follows:

- When the clocking pulse is on, the capacitor is switched on, the zero-sequence current 3I0 in the faulty feeder is reduced, and the corresponding current pulse pattern is off.
- When the clocking pulse is off, the capacitor is switched off, 3I0 in the faulty feeder is increased, and the current pulse pattern is on.

Clocking Pulse	Capacitor	3I0 in the Faulty Feeder	Current Pulse Pattern of the Faulty Feeder
On	On	Reduced	Off
Off	Off	Increased	On

Logic

[lo_sensGFP pulse detection, 3, en_US]

Figure 6-268 Logic Diagram of the Pulse-Pattern Detection Stage

Measured Value V0, Method of Measurement

The device can measure the residual voltage at the broken-delta winding. The measured voltage VN is converted to a value with reference to the zero-sequence voltage V0. If the residual voltage is not available to the device as a measurand, the zero-sequence voltage V0 is calculated from the measured phase-to-ground voltages V_A, V_B, and V_C using the defining equation.

This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.

Measured Value 3I0, Method of Measurement

The function usually evaluates the ground current 3I0 sensitively measured via a core balance current transformer. Since the linearity range of the sensitive measuring input ends at approx. 1.6 A, for larger secondary

ground currents, the function switches to the 3I0 calculated from the phase currents. This results in a very large linearity and settings range.

The method of measurement processes the sampled current values and filters out the fundamental component numerically.

Depending on the connection type of the measuring point as well as the current terminal blocks used, different linearity and setting ranges result. You can find more information in *Measured Value 3I0, Method of Measurement , Page 897*.

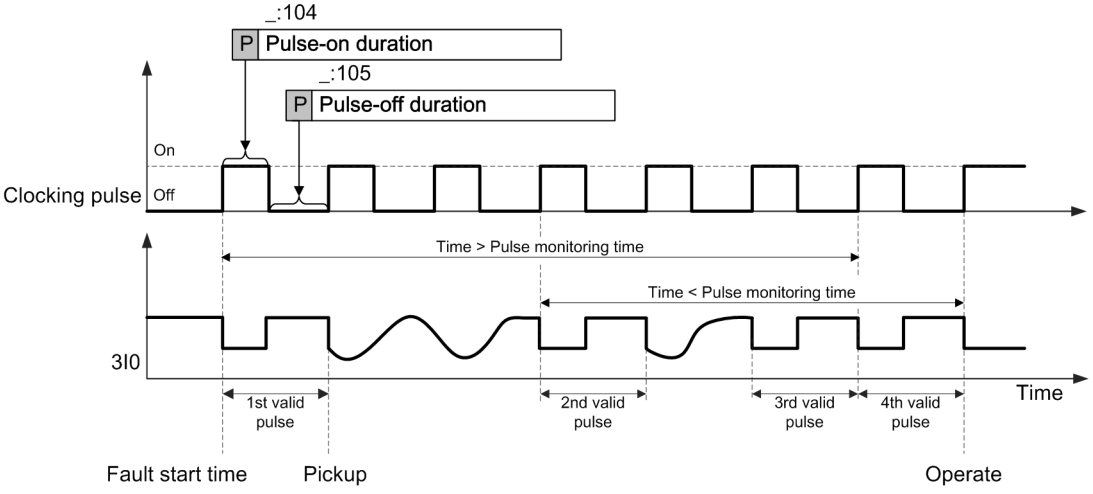
Pulse Detection, Pulse Counter

For this stage, voltage routing is optional and current routing is mandatory.

- If VN or V0 is available, the voltage is the only criterion for starting the pulse-detection logic. When the fundamental-component value of V0 exceeds the **V0> threshold value**, the pulse-detection logic is started.
- If VN or V0 is not available, the current is the only criterion for starting the pulse-detection logic. When the fundamental-component value of the zero-sequence current 3I0 exceeds the **3I0> threshold value**, the pulse-detection logic is started.

If the measured current pulse-off duration equals to the value of the **Pulse-on duration** parameter and the measured current pulse-on duration equals to the value of the **Pulse-off duration** parameter, a valid pulse is detected.

After the first valid pulse is detected, the pulse counter is started to count the number of pulses continuously until the stage resets.



Pickup, Operate

After the first valid pulse is detected, the stage picks up.

If the number of detected pulses within the pulse monitoring time reaches the setting of the **No. of pulses for operate** parameter, the stage operates. The pulse monitoring time is calculated via the following formula:

Pulse monitoring time = Value **Monitoring time(in pulses)** · (Value **Pulse-on duration** + Value **Pulse-off duration**)

For example, the value of the **No. of pulses for operate** parameter is ***3***, and the value of the **Monitoring time(in pulses)** is ***5***. Then the pickup and operate time diagram is as follows:

[dw_pulse pickup and operate, 1, en_US]

Figure 6-269 Pickup and Operate Time

- After the 3rd valid pulse is detected, the stage does not operate because the time between the 1st and the 3rd valid pulses is greater than the pulse monitoring time which is 5 clocking pulses.
- After the 4th valid pulse is detected, the stage operates because the time between the 2nd and the 4th valid pulses is within the pulse monitoring time which is 5 clocking pulses.

Dropout Delay

Switching on the capacitor usually causes 3I0 to decrease in the faulty feeder. This must not cause the stage to drop out. For that reason, a dropout delay is active for the sum of the **Pulse-on duration** and **Pulse-off duration** values.

Detected Pulses of the Ground Fault

The stage records the total number of detected pulses during the permanent ground fault. If the function resets or the operate condition is met, this number is issued via the signal *Detected pulses*.

Blocking the Stage via Binary Input Signal

You can block the stage externally or internally via the binary input signal *>Block stage*. In the event of blocking, the picked up stage will be reset.

6.13.13.2 Application and Setting Notes

Parameter: V0> threshold value

- Default setting **(_:102) V0> threshold value** = *30.000 V*

The **V0> threshold value** parameter allows you to set the zero-sequence (fundamental) voltage sensitivity of the stage. Set the threshold value smaller than the minimum absolute value of the zero-sequence voltage V0 that must still be detected.

If VN or V0 is not available, the **V0> threshold value** parameter is hidden and the **3I0> threshold value** parameter is visible and used.

Parameter: 3I0> threshold value

- Default setting **(_:101) 3I0> threshold value** = *0.200 A*

If VN or V0 is not available, the **3I0> threshold value** parameter is visible and used.

The **3I0> threshold value** parameter allows you to set the zero-sequence (fundamental) current sensitivity of the stage. Set the threshold value smaller than the minimum absolute value of the zero-sequence current 3I0 that must still be detected.

Parameter: Pulse-on duration, Pulse-off duration

- Default setting **(_:104) Pulse-on duration** = *1.00 s*
- Default setting **(_:105) Pulse-off duration** = *1.50 s*

With the **Pulse-on duration** and **Pulse-off duration** parameters, you define the switch-on and switch-off duration of the capacitor.

These values must be set according to the operation of the clocking device that determines the switch-on and switch-off duration of the capacitor. If you set these 2 parameters to the same or similar values, there is a risk of failure because the stage cannot distinguish the healthy and faulty feeders by only evaluating the ground current during a high-impedance ground fault.

Parameter: Max.tolera.pulse-on or off

- Default setting **(_:109) Max.tolera.pulse-on or off** = *0.15 s*

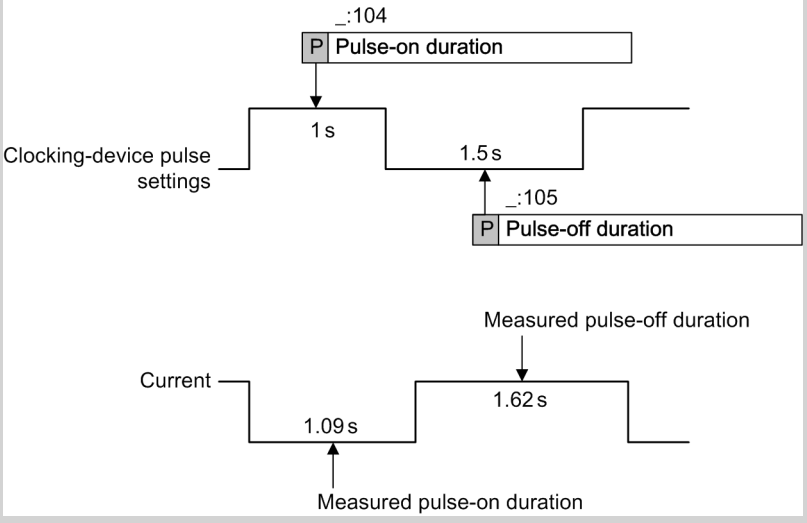
With the **Max.tolera.pulse-on or off** parameter, you define the tolerance for the measured pulse-on/pulse-off duration. The tolerance is the maximum deviation from the set values for the **Pulse-on duration** and **Pulse-off duration** parameters.

The recommended setting for this parameter is the maximum tolerance of the clocking device plus 40 ms (tolerance of the SIPROTEC 5 device). For the tolerance of the clocking device, you have to consider the tolerances of the pulse-on and pulse-off durations individually and select the larger tolerance of both.

EXAMPLE

Clocking device:

Set pulse-on duration for the clocking device	1.00 s
Max. tolerance pulse-on duration of the clocking device	70 ms
Set pulse-off duration for the clocking device	1.50 s
Max. tolerance pulse-off duration of the clocking device	110 ms
Larger tolerance of both	110 ms



Tolerance to be set:

Tolerance of the SIPROTEC 5 device	40 ms
Total tolerance to be set	110 ms + 40 ms = 150 ms

Consequently, you must set the respective device settings as:

- **`Pulse-on duration`** = 1.00 s
- **`Pulse-off duration`** = 1.50 s
- **`Max.tolera.pulse-on or off`** = 0.15 s

The following figure shows the measured pulse durations which are within the maximum stated tolerances of the example.

[dw_tolerance, 1, en_US]

If you have no information about the tolerance of the clocking device, you can carry out a test recording while the clocking device is in operation. From the test recording, you can read the inaccuracy of the pulse-on/ pulse-off durations. Add a safety margin of 20 ms on the read inaccuracy and consider this as the maximum tolerance of the clocking device. For the setting, add another 40 ms for the tolerance of the SIPROTEC 5 device.

Parameter: `3I0 delta pulse off-on`

- Default setting **`(_:103) 3I0 delta pulse off-on`** = ***`10 %`***

With the **3I0 delta pulse off-on** parameter, you define the minimum percentage value of the ground-current delta between the capacitor switched-on and capacitor switched-off states to detect the pulse pattern. That is, to detect the pulse pattern, the following condition must be met:

$$\frac{3I0_{\text{switched-off}} - 3I0_{\text{switched-on}}}{3I0_{\text{switched-off}}} \cdot 100\ \% \ \geq\ 3I0\ \text{delta pulse off-on}$$

[fo_delta ratio, 1, en_US]

To prevent minor current fluctuations from leading to a maloperation of the function, the setting of the **3I0 delta pulse off-on** parameter cannot be less than 2 %.

The setting of the **3I0 delta pulse off-on** parameter can be calculated with the following formula:

$$3I0\ \text{delta pulse off-on}\ =\ \frac{K_f C_s}{\frac{1}{\omega^2 L} - 3(C_{0\Sigma} - C_{0i})} \cdot\ 100\ \%$$

[fo_3I0_delta_pulse_off-on, 1, en_US]

Where

K_f	Safety factor Siemens recommends applying the factor 0.6 to also detect high-impedance ground faults.
C_s	Capacitance of the switched capacitor
ω	Angular frequency, which equals to 2πf, where f is the power frequency
L	Inductance of the arc-suppression coil
$C_{0\Sigma}$	Zero-sequence capacitance of the whole network
C_{0i}	Zero-sequence capacitance of the protected feeder

EXAMPLE

K_f	0.6
C_s	$1.1 \cdot 10^{-6}$ F
ω	314 rad/s
L	0.577 H
$C_{0\Sigma}$	$5.4297 \cdot 10^{-6}$ F
C_{0i}	$1.5502 \cdot 10^{-6}$ F

Then the setting of the **3I0 delta pulse off-on** parameter is calculated as follows:

$$3I0\ \text{delta pulse off-on}\ =\ \frac{0.6 \cdot 1.1 \cdot 10^{-6}}{\frac{1}{314^2 \cdot 0.577} - 3(5.4297 \cdot 10^{-6} - 1.5502 \cdot 10^{-6})} \cdot\ 100\ \% \ = 11\ \%$$

[fo_delta calculate, 1, en_US]

If the network information for the setting calculation is not available, Siemens recommends using the default setting of ***10 %***.

Parameter: No. of pulses for operate, Monitoring time(in pulses)

- Default setting **(_:107) No. of pulses for operate** = ***3***
- Default setting **(_:108) Monitoring time(in pulses)** = ***5***

With the **No. of pulses for operate** parameter, you determine the number of pulses to be detected within the pulse monitoring time, so that the stage operates.

With the **Monitoring time(in pulses)** parameter, you define the pulse monitoring time, which is calculated via the following formula:

Pulse monitoring time = Value **`Monitoring time(in pulses)`** · (Value **`Pulse-on duration`** + Value **`Pulse-off duration`**)

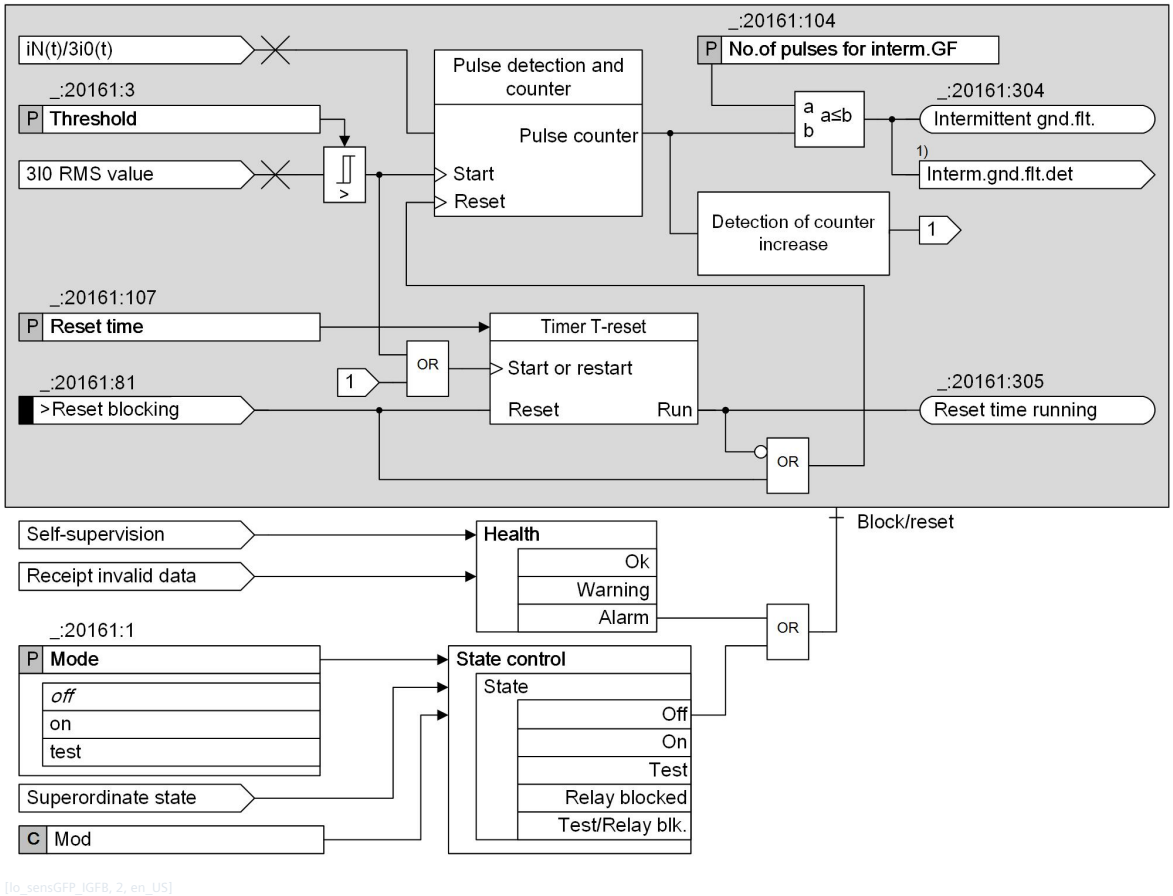
6.13.14 Intermittent Ground-Fault Blocking Stage



6.13.14.1 Description

Most functions designed for the detection of permanent ground faults may show a disadvantageous behavior in case of intermittent ground faults. An example of these functions is the **3I0> stage with cos φ or sin φ measurement**. In case of an intermittent ground fault, these functions may cause a flood of information due to continuously exceeding and dropping below thresholds. Also short-term wrong directional results are possible due to the nature of the intermittent signals. To avoid this disadvantage, these functions should be blocked in case of intermittent grounds faults.

The **Intermittent ground-fault blocking** stage detects and classifies a ground fault as intermittent and sends a blocking signal to the following stages:

- Directional **3I0> stage with cos φ or sin φ measurement**
- Directional **3I0> stage with φ(V0, 3I0) measurement**
- Directional **Y0> stage with G0 or B0 measurement**
- Directional **stage with phasor measurement of a harmonic**

Logic

[lo_sensGFP_IGFB, 2, en_US]

Figure 6-270 Logic Diagram of the Intermittent Ground-Fault Blocking Stage

(1) This signal is sent to the protection stages described in the preceding sections.

Measured Value 3I0

The algorithm evaluates the true RMS value of the ground current to ensure that ground-current pulses are considered.

You can find more information about possible connection types and measuring angles in chapter *Measured Value 3I0, Method of Measurement , Page 897*.

Pulse Counting and Intermittent Ground-Fault Indication

If the true RMS value of 3I0 exceeds the **Threshold** value, the current-pulse (current-peak) detection takes place. During the ongoing intermittent ground fault, all current pulses are counted.

If the pulse count reaches the threshold value set in the parameter **No.of pulses for interm.GF**, the signal *Intermittent gnd.flt.* is issued. At once, the internal signal *Interm.gnd.flt.det* is sent to the following stages:

- Directional **3I0> stage with cos φ or sin φ measurement**
- Directional **3I0> stage with φ(V0, 3I0) measurement**
- Directional **stage with phasor measurement of a harmonic**
- Directional **Y0> stage with G0 or B0 measurement**

If the **Blk.by interm.gnd.flt.** parameter in one of these stages is set to ***yes***, the stage is blocked.

Reset Time for the Definition of the Interval between Independent Ground Faults

If there is a large interval between independent ground faults or if the ground fault extinguishes and does not restrike within a large time, an intermittent ground fault can be considered as definitely disappeared.

The interval between ground faults is monitored with the reset time. If a ground fault occurs, the **Timer T-reset** with the setting **Reset time** is launched. Each new ground-current pulse restarts the **Reset time** with its initial value. If the **Timer T-reset** expires, that is, if no new ground fault was detected during that period, all memories and the stage logics are reset.

The **Timer T-reset** thus determines the time during which the next ground fault must occur to be processed yet as an intermittent ground fault in connection with the previous fault. A ground fault that occurs later is considered as a new ground-fault event.

Start and Reset Conditions of the Timer T-reset

The **Timer T-reset** is started if one of the following conditions is fulfilled:

- The true RMS value of 3I0 exceeds the **Threshold** value.
- A new pulse is detected. That is, with each new pulse, the timer starts again with its initial value.

The **Timer T-reset** can be reset via the binary input signal *>Reset blocking*.

Reset Conditions of the Counter and the Protection-Stage Blocking

The whole stage, including the counter and protection-stage blocking signal, is reset if one of the following conditions is fulfilled:

- The **Timer T-reset** expires.
- The binary input signal *>Reset blocking* is activated.

6.13.14.2 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:20161:3) Threshold** = ***1.000 A***

With the parameter **Threshold**, you set the intermittent ground-fault pickup threshold. This setting must be coordinated with the applied protection stage for detecting a permanent ground fault, which shall be blocked for an intermittent fault, for example, the **3I0> stage with cos φ or sin φ measurement**.

The parameter **Threshold** must be set to the same value as the respective **3I0> threshold value** of the protection stage. For example, in case of the **3I0> stage with cos φ or sin φ measurement**, the value from the parameter **(_:12601:101) 3I0> threshold value** must be applied for the parameter **Threshold**. It is not required to set a lower value than the respective **3I0> threshold value** of the protection stage.

If the **3I0> threshold value** of the protection stage is set to a higher value than the setting range for the parameter **Threshold**, set the maximum setting value for the parameter **Threshold**.

Parameter: No.of pulses for interm.GF

- Default setting **(_:20161:104) No.of pulses for interm.GF** = ***3***

With the parameter **No.of pulses for interm.GF**, you set the total number of pulse counts at which the ground fault is considered to be intermittent. Siemens recommends using the default setting.

Parameter: Reset time

- Default setting **(_:20161:107) Reset time** = ***5.00 s***

With the parameter **Reset time**, you define the minimum time between 2 adjacent ground faults/impulses. If the time is larger than the **Reset time**, the intermittent ground fault is considered as disappeared. This can mean that the ground fault has disappeared or that the intermittent ground fault has changed to a static ground fault. The function resets and a blocking is cleared.

Siemens recommends using the default setting.

6.14 Echo and Tripping in the Event of Weak Infeed

6.14.1 Overview of Functions

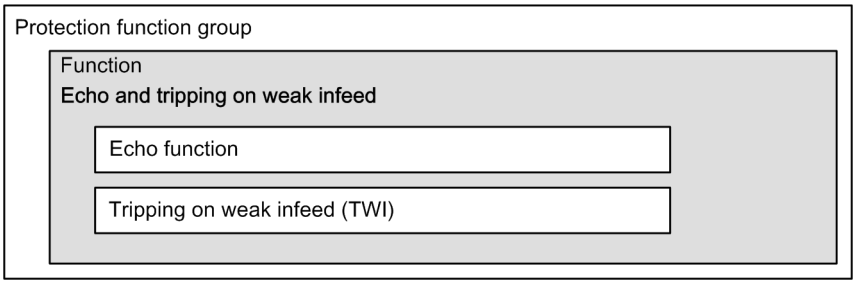
The **Echo and tripping on weak infeed** function is used to support the teleprotection schemes for distance protection and ground-fault protection. Its use is only advisable, therefore, if you are using an appropriate teleprotection scheme.

In the following situations, a permissive overreach transfer trip (permissive overreach transfer trip scheme, directional comparison and directional unblock method) does not receive a release signal from the opposite line end:

- Lines with single-side infeed, from the end of the line without infeed
- Neutral-point grounding at only one line end, from the end of the line without zero-sequence current
- From the line end with no or weak infeed

To accelerate tripping at both ends of the line in these situations, the **Echo and tripping on weak infeed** function supports the Echo function and the TWI function (TWI = tripping on weak infeed).

To trip the end of the line with a strong infeed, the echo function can be implemented at the end of the line with a weak infeed. In the absence of pickup at one end of the line, the echo function sends the received signal back to the other end of the line as an echo, so that the trip command can be enabled there.

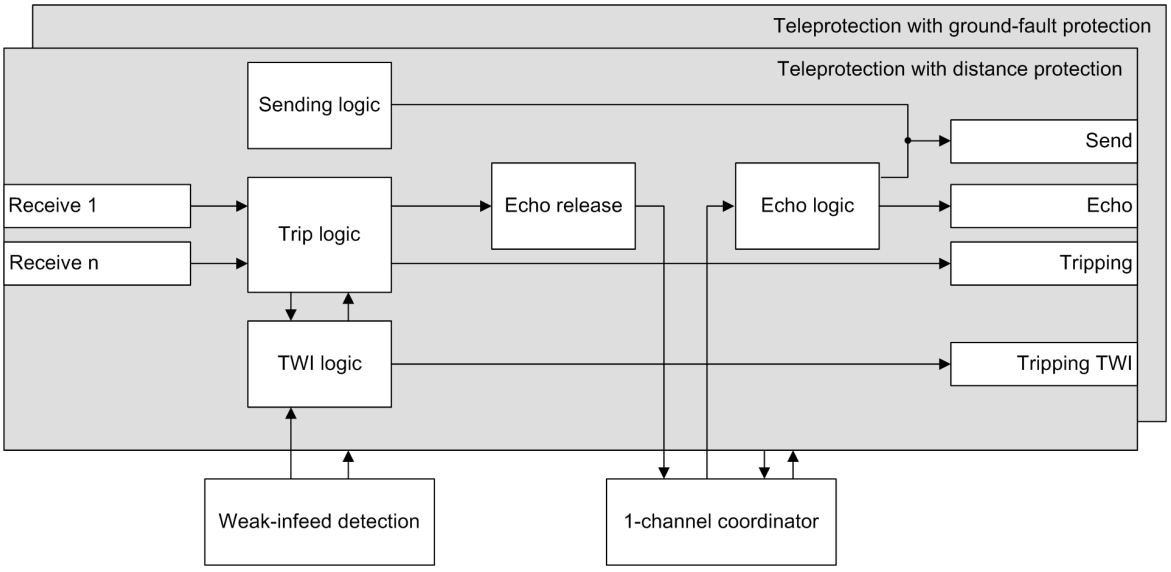


The Echo function can also be used to test the signal connection between the protection devices in the context of permissive underreach transfer trip.

You can also use the TWI function to trip the end of the line with missing or weak infeed. You can use the TWI function together with permissive overreach transfer trips and permissive underreach transfer trip.

Please note that the function must not be used in conjunction with blocking methods.

6.14.2 Structure of the Function



The **Echo and tripping on weak infeed** function comprises the subfunctions shown in the following figure. The function is used in the function group **Line**.

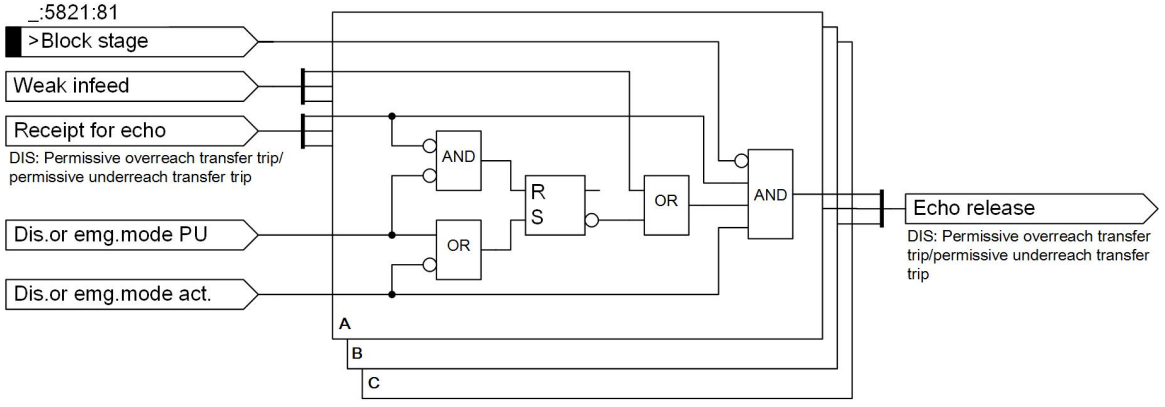
[dwwnstru-070311-01.tif, 1, en_US]

Figure 6-271 Structure/Embedding of the Function

The 2 subfunctions **Echo** and **Tripping on weak infeed** receive control signals from the teleprotection scheme for distance protection and ground-fault protection in the local device, see the following figure.

[dwwnfblk-070311-01.tif, 1, en_US]

Figure 6-272 Function Blocks

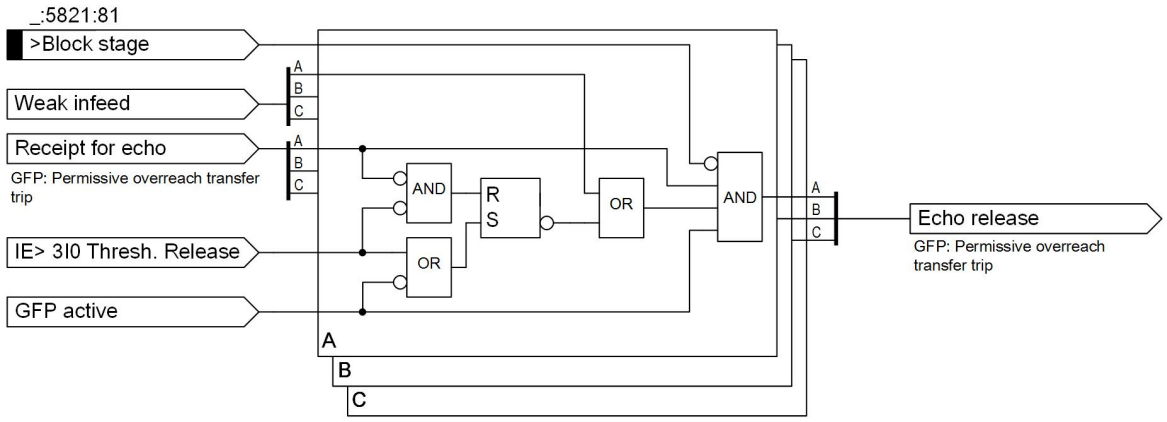


In the following, the individual function blocks are described.

6.14.3 Echo Function

In the absence of pickup at one end of the line, the echo function sends the received signal back to the other end of the line as an echo, so that the trip command can be released there.

Echo Release

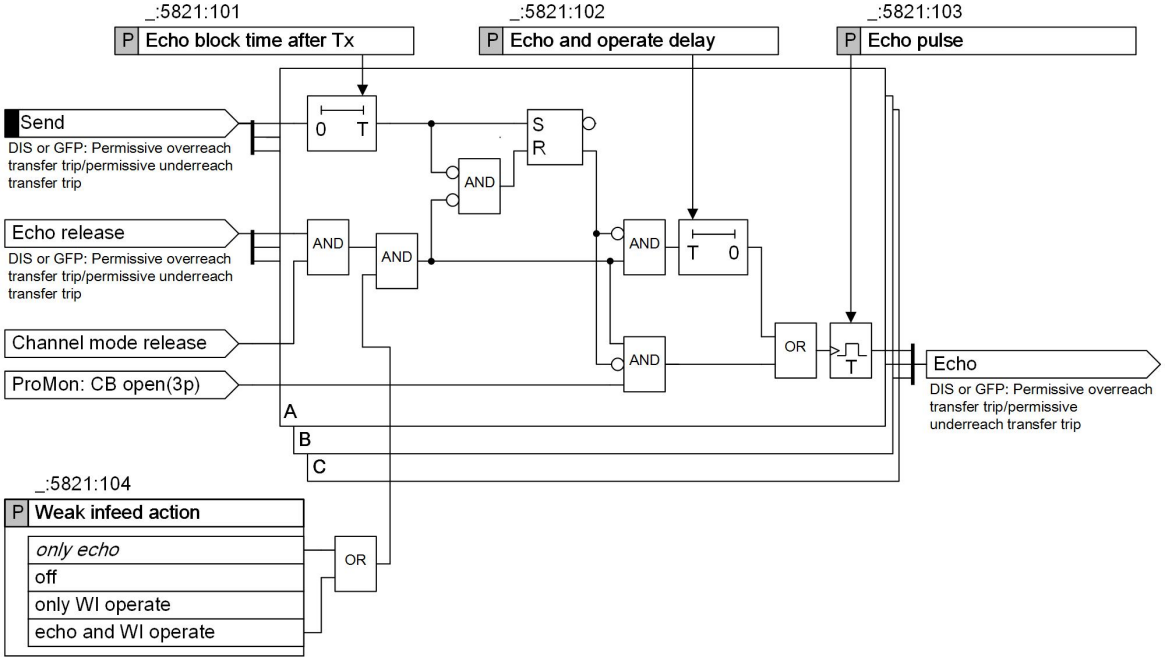


The release signal for the echo function in the teleprotection with distance protection is generated as follows:

[lodisecf-070311-01.tif, 1, en_US]

Figure 6-273 Release Logic for the Echo Function with Distance Protection

The release signal for the echo function in the teleprotection scheme with ground-fault protection is generated as follows:



[loeksecf-070311-01.tif, 2, en_US]

Figure 6-274 Release Logic for the Echo Function with Ground-Fault Protection

Echo Logic

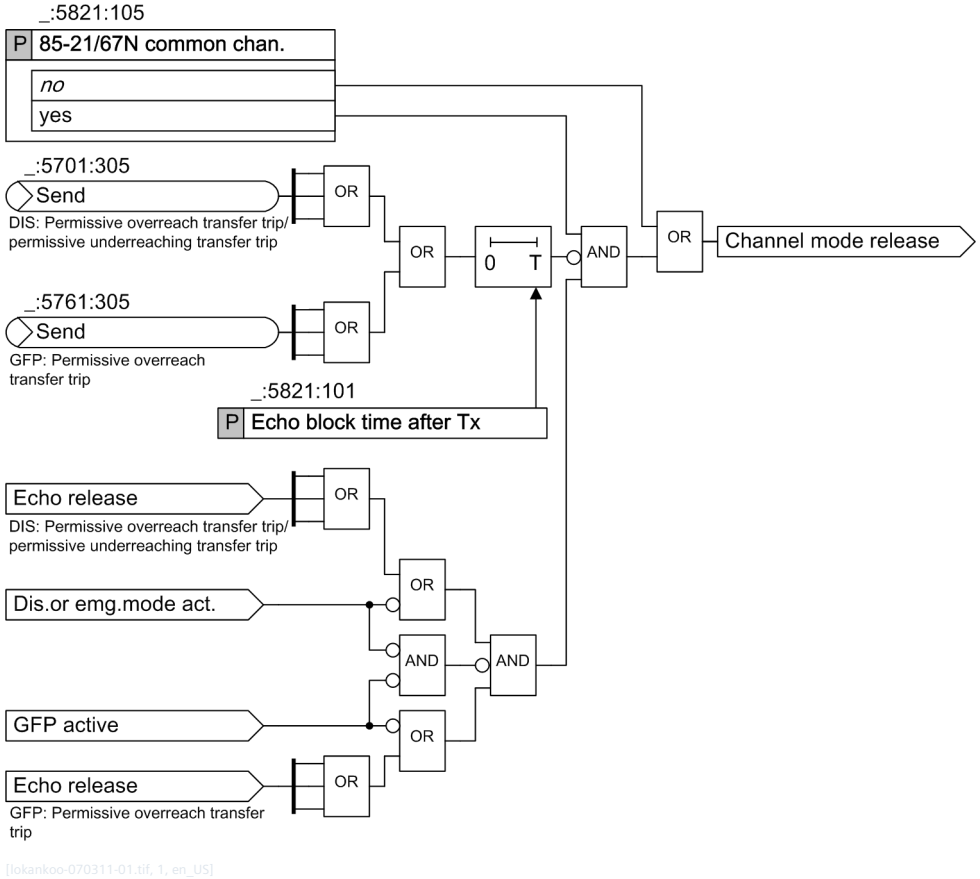
There are 2 structurally identical echo logics assigned to the functions Distance protection and Ground-fault protection. The echo logic is shown in the following figure.

[lodisecl-070311-01.tif, 1, en_US]

Figure 6-275 Logic Diagram for the Echo Function

The time delay **(_:5821:102) Echo and operate delay** takes effect when the echo release for distance protection or ground-fault protection is set. This time delay is necessary if the pickup time for the protection function at the weak line end is higher for a reverse fault or if the protection function picks up later due to unfavorable short circuit or ground-current distribution. The echo is transmitted at the end of the time delay. If the circuit breaker at the line end without infeed is 3-pole open, the echo time delay is not necessary. The echo time delay is bypassed.

You can set the length of the echo pulse with the **(_:5821:103) Echo pulse** parameter.



The circuit-breaker switch position is signaled centrally by the process monitor.

A new echo cannot be transmitted for at least 50 ms (default setting of the parameter **(_:5821:101) Echo block time after Tx**) once the echo pulse has been released, or for the duration of the send signal

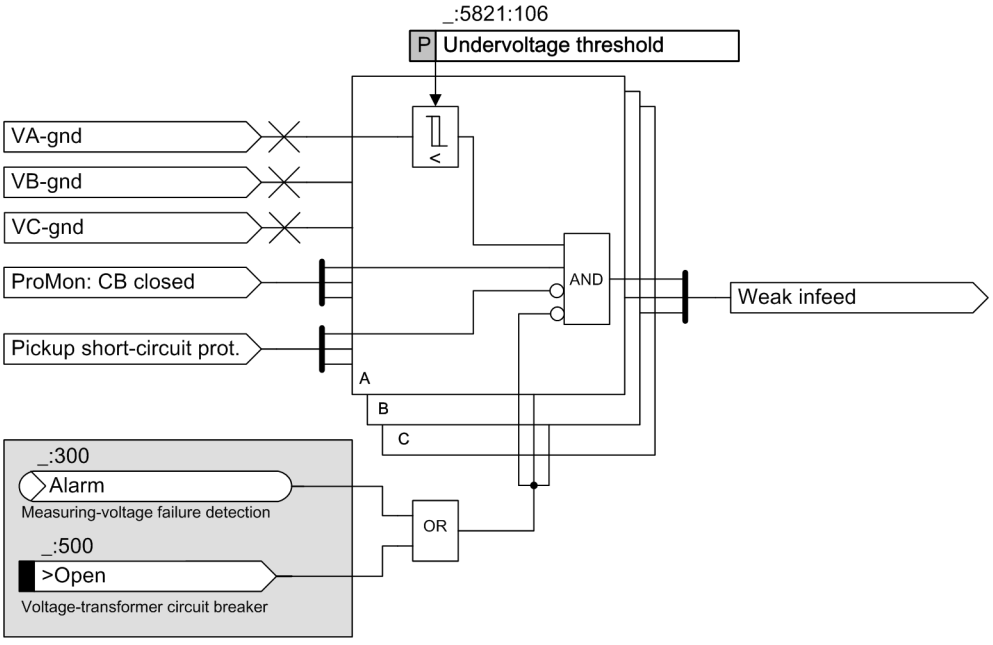
associated with the release method currently in use. This prevents the echo from being repeated immediately after the line is disconnected.

Common Communication Channel

If the teleprotection scheme with distance protection and ground-fault protection are used in parallel and a common communication channel is used for the send signals, it is no longer possible at the remote end of the line to tell whether the original echo signal is coming from distance protection or from ground-fault protection. The 1-channel coordinator ensures that an echo is only transmitted if an echo release is pending for both protection functions: in other words, if neither protection function picks up.

[lokankoo-070311-01.tif, 1, en_US]

Figure 6-276 Logic of the 1-Channel Coordinator

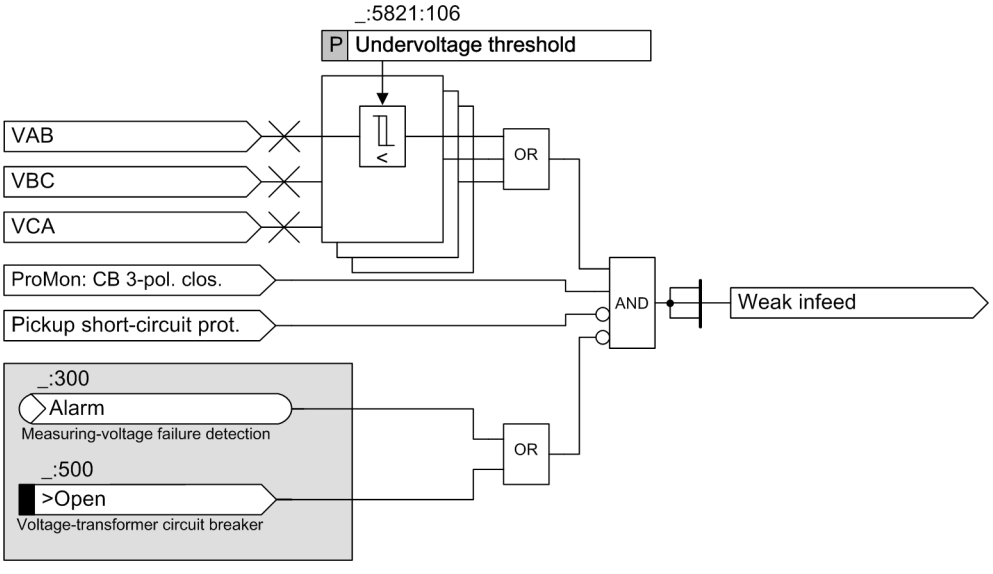


Detection of Weak Infeed

If there is a short-circuit, it has to be assumed that there is only a low voltage at the end of the line with weak infeed, as the weak short-circuit current can only induce a low voltage drop in the short-circuit loop. If there is no infeed, the loop voltage is close to zero. For this reason, tripping with weak infeed depends on the measured undervoltage **V<**. The measured undervoltage also makes it possible to the determine the faulty phase.

For supply systems with grounded neutral point, detection of the weak infeed is phase-selective. The infeed is assumed to be weak in the absence of pickup in the appropriate phase and if undervoltage (**(_:5821:106) Undervoltage threshold** parameter) is detected when the circuit breaker is closed. The information about the circuit-breaker position is supplied by the process monitor.

NOTE



If no circuit-breaker auxiliary contacts are routed and there is an operating condition without current flow, the logic of the process monitor cannot detect the circuit-breaker position. In such cases, you can influence the behavior of the logics in *Figure 6-277* and *Figure 6-278* with the parameter **`CB closed on I=0`** (see *6.14.5 Application and Setting Notes*).

[loasephe-070311-01.tif, 1, en_US]

Figure 6-277 Detection of Weak Infeed for Phase-to-Ground Voltages (Grounded Systems)

For systems with isolated or resonant-grounded neutral point, the phase-to-phase voltages are used as the criteria for undervoltage detection. Phase-selective detection of weak infeed is not possible.

[loasephp-170912-01.tif, 1, en_US]

Figure 6-278 Detection of Weak Infeed for Phase-to-Phase Voltages (Isolated or Resonant-Grounded Systems)

6.14.4 Tripping on Weak Infeed (TWI Function)

The TWI function is used to trip the circuit breaker at the end of the line with missing or weak infeed.

Logic for TWI

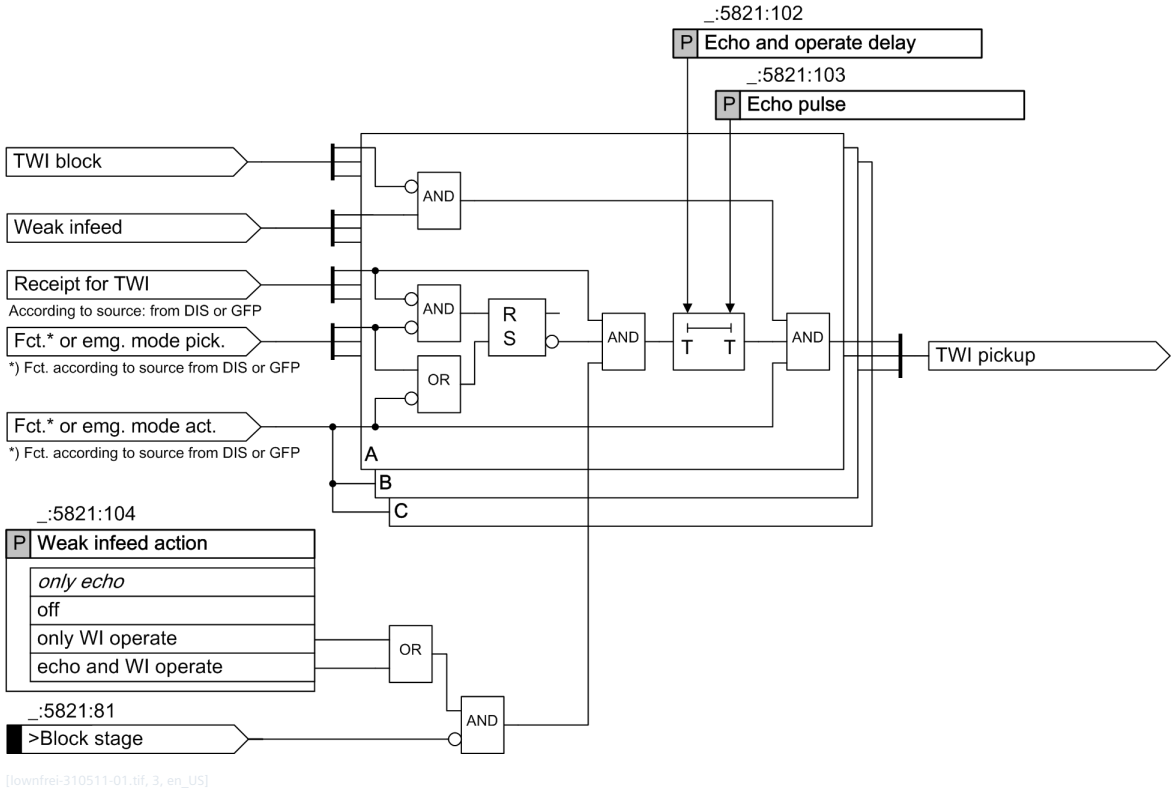


Figure 6-279 Release Logic for Tripping on Weak Infeed

If a weak infeed is detected and a receive signal from the teleprotection scheme for distance protection or ground-fault protection is pending at the same time, phase-selective TWI pickup is triggered. On TWI pickup, the trip logic of the associated method triggers the trip signal.

TWI pickup and thus tripping can be delayed with the parameterizable time **(_:5821:102) Echo and operate delay**. TWI pickup is also delayed by the release time **(_:5821:103) Echo pulse**. Synchronization between echo and TWI is achieved by both functions using the same time parameters.

The TWI function can be blocked via the phase-selective signals *TWI block*. This prevents false pickups, for example, due to switch-off processes on the line in question or on the parallel line. All phases not picked up for a 3-pole TWI operate are blocked for 250 ms. If another protection function trips, all 3 phases are blocked for 250 ms. In the event of a cleared reverse pickup of 1 phase of the corresponding function (depending on the source of Dis or EF), all 3 phases are blocked for 50 ms.

6.14.5 Application and Setting Notes

To select the function **Echo and tripping on weak infeed**, use the function library with DIGSI.

The function is designed for cooperation with permissive underreach transfer trip and permissive overreach transfer trips. The function must not be used in conjunction with blocking methods.

The function contains the following parameters:

Parameter: Weak infeed action

- Recommended setting value **(_:5821:104) Weak infeed action** = ***only echo***

The basic operating mode is set with the **Weak infeed action** parameter.

Parameter Value	Description
only echo	The echo function is active. There is no tripping on short circuits with missing or weak infeed.
off	A missing or weak infeed does not induce echo or tripping.
echo and WI operate	The echo function and tripping on short circuits with missing or weak infeed are active.
only WI operate	Only tripping on short circuits with missing or weak infeed is active.

Parameter: 85-21/67N common chan.

- Default setting **(_:5821:105) 85-21/67N common chan.** = ***no***

If distance protection and ground-fault protection are using the same communication channel and generate an echo independently of one another, you must set the **85-21/67N common chan.** parameter to ***yes*** to avoid unwanted tripping.

Parameter: Echo and operate delay

- Recommended setting value **(_:5821:102) Echo and operate delay** = ***0.04 s***

The length of the echo time delay **Echo and operate delay** must be set so that different pickup response times for distance-protection functions or ground-fault protection functions at all line ends cannot lead to an unwanted echo if faults occur outside the system.

Parameter: Echo pulse

- Recommended setting value **(_:5821:103) Echo pulse** = ***0.05 s***

The echo pulse duration **Echo pulse** can be adapted to transmission system conditions. It must be long enough to ensure that the receive signal is detected even if the movement delays of the protection and transmission devices at the ends of the line are not the same.

Parameter: Echo block time after Tx

- Recommended setting value **(_:5821:101) Echo block time after Tx**= ***0.05 s***

To avoid an infinite echo between the ends of the line, a new echo cannot be sent for a period of **(_:5821:101) Echo block time after Tx** after an echo signal has been sent. An infinite echo could otherwise be triggered by interference coupling on the signal path, for example. The echo is also blocked for this time once distance protection or ground-fault protection has been sent.

Parameter: Undervoltage threshold

- Default setting **(_:5821:106) Undervoltage threshold** = ***25,000 V***

This parameter is relevant only if you are using the TWI function (tripping on missing or weak infeed).

The upper limit for this threshold value **Undervoltage threshold** must be below the minimum voltage expected during operation. The maximum voltage drop to be expected at the end of the line with weak infeed if there is a short circuit on the line to be protected, at which distance protection might no longer pick up, applies as the lower limit.

In systems with grounded neutral point, phase-to-ground voltages apply as reference values; in systems with isolated or resonant-grounded neutral point, phase-to-phase voltages apply.

Parameter: CB closed on I=0

- Default setting **(_:5821:108) CB closed on I=0** = ***no***

With the **CB closed on I=0** parameter, you can influence the behavior of the logic for echo and tripping in the event of weak infeed, when no circuit-breaker auxiliary contacts are routed and there is an operating

condition without current flow. In such operating conditions, the logic of the process monitor is unable to detect the circuit-breaker position.

Parameter Value	Description
no	When you set the parameter **CB closed on I=0** = ***no***, the logics work to detect the weak infeed into the *Figure 6-277* and *Figure 6-278*, as if the circuit breaker were open. In this case, no *Weak infeed* is detected and tripping at weak infeed is not possible.
yes	When you set the parameter **CB closed on I=0** = ***yes***, the logics work to detect the weak infeed into *Figure 6-277* and *Figure 6-278* as if the circuit breaker were closed. In this case, the *Weak infeed* is detected and tripping at weak infeed is possible.

If the circuit-breaker auxiliary contacts are routed, or current flow is detected, the circuit-breaker switch position is detected based on this information.

You can find more detailed information in *6.14.3 Echo Function* in *Detection of Weak Infeed, Page 972*.

6.15 Distance Protection

6.15.1 Overview of Functions

The **Distance protection** (ANSI 21, 21N) function is available in 2 variants:

- Distance protection for grounded systems with 3-phase tripping
- Distance protection for isolated/resonant-grounded systems with 3-phase tripping

NOTE

This section explains the basic design of the distance protection function. Descriptions of the 5 listed functions can be found in the line protection manual (C53000-G5000-C010).

- Distance protection with reactance method (RMD)
- Teleprotection with distance protection
- Teleprotection with ground-fault protection
- Echo and tripping in the event of weak infeed
- Automatic reclosing function

NOTE

When using line distance protection functions in transformer differential protection, the current-transformer requirements of the line protection must be considered. You can find these in the line protection manual (C53000-G5040-C010).

6.15.2 Distance Protection for Grounded Systems

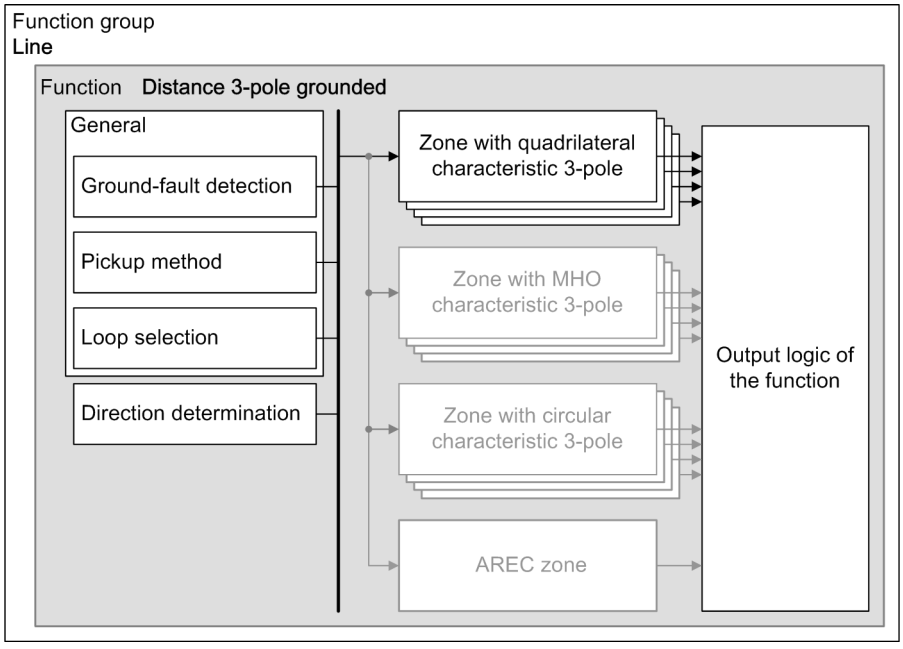
6.15.2.1 Overview of Functions

The function **Distance protection for grounded systems** (ANSI 21 N):

- Is a form of selective short-circuit protection for lines and cables supplied from one or more end(s) in radial, looped or meshed systems,
- Used as backup protection for busbars, transformers and other lines
- Works only in systems with grounded neutral point
- Trips 3-phase
- Suitable for use in all voltage levels

6.15.2.2 Structure of the Function

The function **Distance protection for grounded systems** can be placed in function groups that provide voltage and current measured values as well as line parameters.



The function **Distance protection for grounded systems** consists of the following blocks:

- General
- Pickup method
- Distance zones (preconfigured quadrilateral characteristic)
- Output logic 3-phase

The function **Distance protection for grounded systems** is preconfigured with 4 zones at the factory. The zones are structured identically. In the function **Distance protection for grounded systems**, a maximum of

16 zones with quadrilateral characteristic curve and 16 zones with MHO characteristic curve can be operated simultaneously.

The following figure shows the structural principles of the function **Distance protection for grounded systems**.

[dwstrg3p-090212-01.tif, 1, en_US]

Figure 6-280 Structure/Embedding of the Function

Mode of Operation

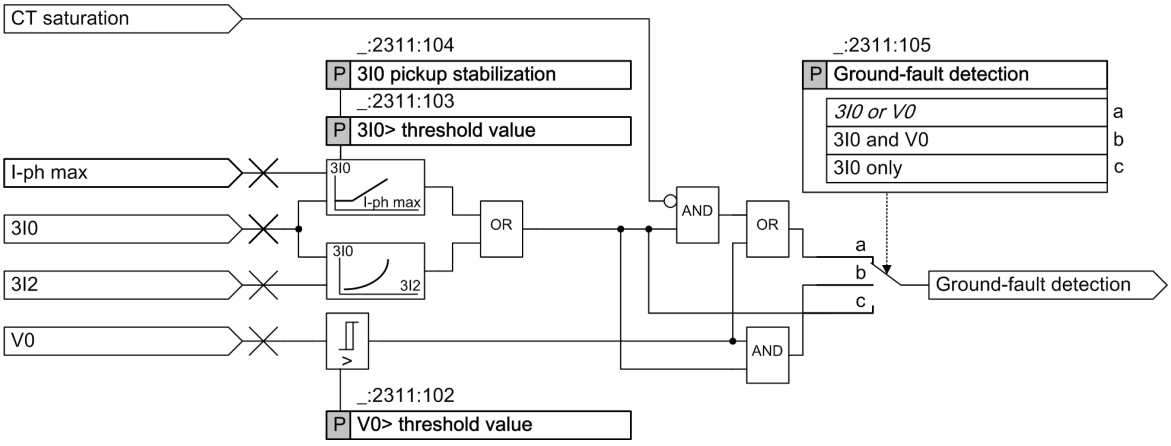
Ground-fault detection determines whether a ground fault has occurred. The pickup method releases the measurement loops. The impedance is calculated for the released loops. The calculated impedance is assigned to the operate curves (quadrilateral, MHO or circular characteristic) of the zones.

In the **Impedance pickup** method, the load cutout is then analyzed and the apparent impedances eliminated. For all picked up loops, the direction to the short-circuit location is then determined. The loop selection determines for which of the picked up loops assignment in the defined zones is done. The loop elimination removes all loops that are no longer picked up after direction determination and querying the load cutout. For the picked up loops, the time delay in the zone logic is started. The zone logic forms the pickup and trip signals of the loops and phases for the zone. The output logic processes the pickup and trip signals of the zones and forms the pickup and trip signals of the distance protection.

Ground-Fault Detection

Ground-fault detection checks whether a ground fault has occurred. If a ground fault has occurred, the measuring elements for the phase-to-ground loops are released.

For ground-fault detection, the following criteria are available:



- Monitoring of the zero-sequence current $3I_0$
- Monitoring of the ratio of the zero-sequence current and negative-sequence current ($3I_0/3I_2$)
- Monitoring of the zero-sequence voltage V_0

Current and voltage criteria complement one another (see *Figure 6-281*). If the ratio of zero-sequence impedance to positive-sequence impedance is greater, zero voltage increases. If the ratio of zero-sequence impedance to positive-sequence impedance is small, the ground current increases. The **`Ground-fault detection`** parameter determines the criterion used to perform ground fault recognition.

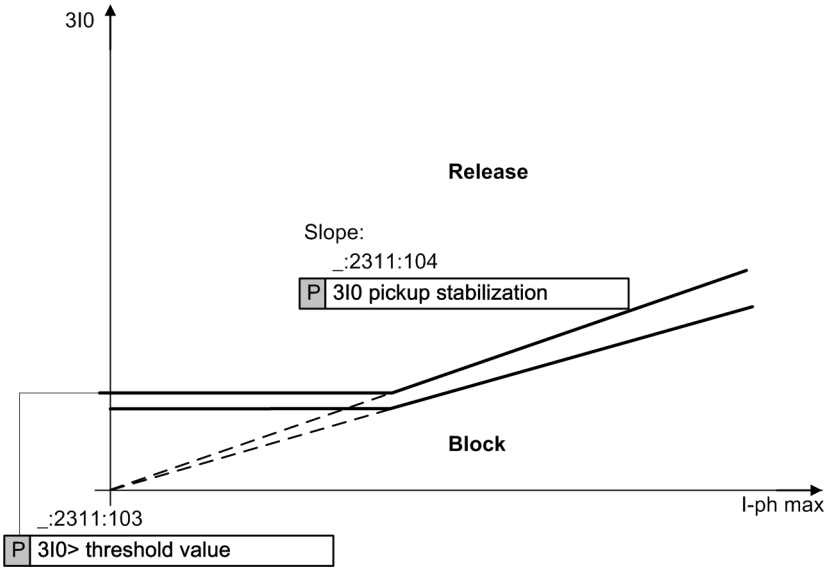
If a phase current leads to current-transformer saturation, the voltage criterion **must** be met for ground-fault detection. Uneven saturation of current transformers can lead to a secondary zero-sequence current without

a primary zero-sequence current flowing. Automatic scanning of the voltage criterion in the event of current-transformer saturation prevents unwanted ground-fault detections.

Ground-fault detection alone does not lead to the general pickup of the distance protection; it only controls other pickup modules. Ground-fault detection is also not indicated on its own.

[loerdfeh-240511-01.tif, 1, en_US]

Figure 6-281 Logic of Ground-Fault Detection for Grounded Systems



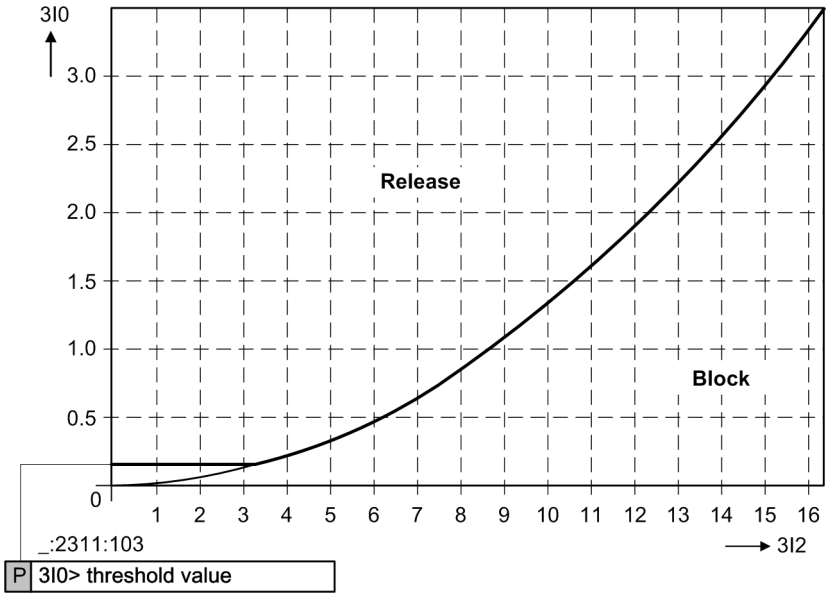
Ground-Fault Detection: Zero-Sequence Current $3I_0$

The zero-sequence current criterion monitors the fundamental component of the sum of phase currents for exceeding a settable value (parameter **`3I0> threshold value`**).

The residual-current criterion is stabilized against unwanted pickup for the following cases:

- Zero-sequence currents due to unbalanced load conditions
- zero-sequence currents in the event of faults without ground contact due to differing saturation of phase-current transformers
- For detected current-transformer saturation (see *Figure 6-281*)

Figure 6-282 shows the pickup characteristic of the residual-current criterion. As phase currents increase, the actual pickup value rises automatically. The dropout threshold is about 95 % of the pickup value.



[dwklerds-060611-01.tif, 1, en_US]

Figure 6-282 Zero-Sequence Current Criterion: Pickup Characteristic

Ground-Fault Detection: Zero-Sequence Current/Negative-Sequence Current ($3I_0/3I_2$)

For long, highly loaded lines, high load currents can lead to destabilization of the residual-current criterion (see *Figure 6-282*). For the detection of ground faults, the load-independent negative-sequence current criterion is extended. In addition to the zero-sequence current, the ratio of zero-sequence current to negative-sequence current is also monitored. In a 1-phase short circuit, the negative-sequence current I_2 is approximately as high as the zero-sequence current I_0. If the ratio of zero-sequence current to negative-sequence current exceeds a preset limit, the criterion is released. The zero-sequence current/negative-sequence current criterion is stabilized for high negative-sequence currents using a parabolic characteristic. *Figure 6-283* shows the connection. A prerequisite for release of the zero-sequence current/negative-sequence current criterion is a minimum current of $0.2 \cdot I_{rated}$ for $3I_0$.

[dwkdi0i2-140611-01.tif, 1, en_US]

Figure 6-283 I0/I2 Criterion: Pickup Characteristic

Ground-Fault Detection: Zero-Sequence Voltage V_0

The zero voltage is monitored for exceeding a set value (parameter **`V0> threshold value`**). The dropout threshold is about 95 % of the pickup value. In grounded systems, monitoring of the zero voltage can be used as an additional ground-fault criterion.

Pickup Method

The pickup method selects the fault loops to be measured. The following pickup methods are available:

- Impedance pickup
- Overcurrent pickup
- V-/I pickup
- V-/I-φ pickup

Impedance pickup is preconfigured as the pickup method. You can use different pickup methods in parallel.

Zone Assignment

The calculated impedance phasors for the fault loops are assigned to the zones. For each zone, an operate curve is defined in the R-X plane. The following operate curves are available:

- Quadrilateral characteristic
- MHO characteristic curve

You can find the description of operate curves in the chapters *6.15.6 Zone with Quadrilateral Characteristic Curve* and *6.15.8 Zone with MHO Characteristic Curve*.

Direction Determination

You can define for each zone whether the zone should work ***forwards***, ***backwards***, or ***non-directional***. For directional zones, you define the direction in the R-X plane. When assigning the impedance phasors in the R-X plane, the direction is then additionally analyzed. The description can be found in chapter *6.15.4 Direction Determination*.

Loop Selection in the Grounded System

In systems with effective or low-impedance grounded neutral point, each contact of a phase with ground is a short-circuit-like process. The closest protection equipment must switch off the fault immediately.

For double ground-fault protection, 2 phase-to-ground loops generally pick up. If both ground faults are in the same direction, this can also lead to pickup in the associated phase-to-phase loop. The **Loop select. with ph-ph-g** parameter is used to restrict analysis to certain loops.

In a 3-phase short circuit, all phase-to-phase loops generally pick up. In this case, the 3 phase-to-phase loops are analyzed. If a ground fault is detected, the phase-to-ground loops are also analyzed.

Output Logic

The output logic of the function **Distance protection for grounded systems** links the output indications of the zones and forms the group trip signal of the function.

You can find the description of the output logic in chapter *6.15.11 Output Logic of the Distance Protection*.

Influence of the Inrush-Current Detection

If the device is equipped with the **Inrush-current detection** function, the distance protection can be stabilized against tripping due to transformer-inrush currents. In case of interaction with the inrush-current detection the following configurations are possible:

- Blocking of the pickup for the overcurrent pickup method, V-/I-pickup and V-/I-/ϕ-pickup
- Blocking of individual distance zones
- Blocking of the pickup during impedance pickup by blocking the external distance zone(s)

The **Inrush-current detection** can be configured individually for the blocking of the mentioned pickup methods and distance zones. In case of blocking, the distance zone that is linked to the inrush-current detection or the pickup method will not pick up. The function **Inrush-current detection** signals the blocking through a corresponding indication. Once the blocking drops out and the pickup condition for the respective method or the linked distance zone is met, the pickup is signaled and the corresponding time delay will start. After that time, the operate indication will be generated. Only if the central function **Inrush-current detection** (see section *6.68.1 Inrush-Current Detection*) is in effect can the blocking be set.

6.15.2.3 Application and Setting Notes - General Settings

Set the following settings under **General** in the function **Distance protection for grounded systems**. The setting values are valid for all zones in the distance protection.

Parameter: Zone timer start

- Recommended setting value **(_:2311:110) Zone timer start** = ***on dist. pickup***

The **Zone timer start** parameter is used to determine the time at which the time delays of the zones start.

Parameter Value	Description
on dist. pickup	If the time delays of all zones start simultaneously, select this setting. If the fault type or measurement loop selection changes, all time delays continue to run. Siemens recommends using this setting.
on zone pickup	The time delay for the zone starts with zone pickup. If you need to coordinate the function with other distance or overcurrent protection functions, select this setting.

Parameter: Dist. characteristic angle

- Default setting **(_:2311:107) Dist. characteristic angle** = ***85.0°***

The **Dist. characteristic angle** parameter allows you to set the inclination angle of the distance protection characteristic curve (see *Figure 6-297*). The inclination angle set here for the distance protection characteristic curve applies to all zones in the function.

Siemens recommends setting the **Dist. characteristic angle** parameter to the line angle.

EXAMPLE:

Calculate the line angle from the data of the positive-sequence impedance on the line to be protected:

$$Z_1 = R_L + jX_L = (0.025 + j0.21)\Omega$$

[fo1 line angle, 1, en_US]

$$\text{Line angle} = \arctan\left(\frac{X_L}{R_L}\right)$$

[fo2 line angle, 1, en_US]

$$\text{Line angle} = 83.2°$$

[fo3 line angle, 1, en_US]

If you need to coordinate the function with other equipment, you can also set the inclination angle of the distance protection characteristic differently.

Parameter: Ground-fault detection

- Recommended setting value **(_:2311:105) Ground-fault detection** = ***3I0 or V0***

The **Ground-fault detection** parameter determines the criteria used to perform ground-fault detection.

Parameter Value	Description
3I0 or V0	If either the zero-sequence current criterion (3I0>) or the zero-sequence voltage criterion (V0>) leads to ground-fault detection, select this setting. For grounded systems, the OR operation of the criteria 3I0> and V0> is a reliable criterion for ground-fault detection. The criteria complement one another. For a weak infeed, the zero-sequence current is low and the zero-sequence voltage high. For a strong infeed, the conditions are reversed. Siemens recommends this setting for grounded systems.
3I0 and V0	If you wish to use both criteria for ground-fault detection (logical AND operation of zero-sequence current and zero-sequence voltage criteria), select this setting.
3I0 only	If only the zero-sequence current criterion is to be used for ground-fault detection, select this setting.

Parameter: 3I0> threshold value

- Recommended setting value **(_:2311:103) 3I0> threshold value** = ***0.10 A***

The **3I0> threshold value** parameter is used to define the zero-sequence current limit for ground-fault detection.

The parameter **3I0> threshold value** must be set to a value less than the lowest expected ground current in ground faults on the protected feeder. For the distance protection to trigger for external remote faults as backup protection, set the **3I0> threshold value** parameter to a more sensitive value than that necessary for internal faults. Siemens recommends keeping the setting value of ***0.10°A***.

Parameter: V0> threshold value

- Recommended setting value **(_:2311:102) V0> threshold value** = ***1.66 V***

The **V0> threshold value** parameter is used to define the zero-sequence voltage limit for ground-fault detection.

For ground faults in a grounded system, there is a zero-sequence voltage. The zero-sequence voltage drops as the distance between the fault location and the measuring point increases. Siemens recommends maintaining a default setting of ***1.66 V***. If power-system unbalances can cause higher zero-sequence voltages to occur during operation, you can increase the default setting.

Parameter: 3I0 pickup stabilization

- Recommended setting value **(_:2311:104) 3I0 pickup stabilization** = ***0.10***

The **3I0 pickup stabilization** parameter is used to set the inclination of the 3I0> characteristic curve for ground-fault detection.

Power-system unbalance (for example, untwisted lines) and current-transformer errors can cause a zero-sequence current flow at the protection device in the case of higher phase currents, even if there is no ground fault. The **3I0 pickup stabilization** parameter is used to avoid unwanted ground activation. If no extreme power-system unbalance and unusually large current-transformer errors are expected, Siemens recommends keeping the default value of ***0.10***.

Parameter: Loop select. with ph-ph-g

- Default setting **(_:2311:108) Loop select. with ph-ph-g** = ***block leading phase***

The **Loop select. with ph-ph-g** parameter is used to determine which loops will be analyzed by the distance protection in the event of double ground faults. You can restrict the analysis to certain loops. If you wish to restrict analysis to certain loops, they must have the same direction.

In the case of a bilateral infeed to one common fault resistance with respect to ground, the phase-to-ground loop of the leading phase tends to overreach, that is, the leading phase-to-ground loop is measured too small. If you set the parameter **Loop select. with ph-ph-g** = ***block leading phase***, these loops will not be analyzed.

The following table shows which loops are analyzed for different settings of the **Loop select. with ph-ph-g** parameter:

Parameter Value	Picked Up Loops	Analyzed Loop(s)
block leading phase	A-gnd, B-gnd, A-B B-gnd, C-gnd, B-C A-gnd, C-gnd, C-A	B-gnd, A-B C-gnd, B-C A-gnd, C-A
block lagging phase	A-gnd, B-gnd, A-B B-gnd, C-gnd, B-C A-gnd, C-gnd, C-A	A-gnd, A-B B-gnd, B-C C-gnd, C-A
all	A-gnd, B-gnd, A-B B-gnd, C-gnd, B-C A-gnd, C-gnd, C-A	A-gnd, B-gnd, A-B B-gnd, C-gnd, B-C A-gnd, C-gnd, C-A

Parameter Value	Picked Up Loops	Analyzed Loop(s)
ph-ph only	A-gnd, B-gnd, A-B	A-B
	B-gnd, C-gnd, B-C	B-C
	A-gnd, C-gnd, C-A	C-A
ph-gnd only	A-gnd, B-gnd, A-B	A-gnd, B-gnd
	B-gnd, C-gnd, B-C	B-gnd, C-gnd
	A-gnd, C-gnd, C-A	A-gnd, C-gnd

In a double line, ground faults may occur simultaneously on both lines. To avoid blocking of the internal fault loop, you must set the parameter **Loop select. with ph-ph-g** to ***ph-gnd only*** or ***all*** for this application. To ensure the selectivity of protection, reduce the range of the underreaching zone.

Parameter: Parallel-line compensat.

- Default setting: **(_:2311:106) Parallel-line compensat.** = ***no***

The **Parallel-line compensat.** parameter is used to determine for double circuit lines whether you wish to take into account the influence of the coupling impedance on the loop impedance or not.

NOTE

You see the parameter **Parallel-line compensat.** only if the ground current of the parallel line is available in the **Line** function group. To do this, connect the measuring point **I-1ph** (ground current of the parallel line) to the **Line** function group in DIGSI 5.

NOTE

The following parameters will be visible only if you are working with MHO characteristic curves:

- **Mem. polarization(ph-g)**
- **Mem. polarization(ph-ph)**
- **Cross polarization(ph-g)**
- **Cross polarization(ph-ph)**

The parameters apply to all MHO zones!

Parameter: Mem. polarization(ph-g)

- Default setting **(_:2311:111) Mem. polarization(ph-g)** = ***15.0*** **%**

With the **Mem. polarization(ph-g)** parameter, you can specify the degree of polarization with a buffered voltage for phase-to-ground loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Mem. polarization(ph-g)** parameter to ***0.0*** **%**.

Parameter: Mem. polarization(ph-ph)

- Default setting **(_:2311:112) Mem. polarization(ph-ph)** = ***15.0*** **%**

With the **Mem. polarization(ph-ph)** parameter, you can specify the degree of polarization with a buffered voltage for phase-to-phase loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Mem. polarization(ph-ph)** parameter to ***0.0*** **%**.

Parameter: Cross polarization(ph-g)

- Default setting **(_:2311:113) Cross polarization(ph-g)** = ***15.0*** **%**

With the **Cross polarization(ph-g)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-ground loops. This parameter influences the extension of the MHO charac-

teristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Cross polarization(ph-g)** parameter to ***0.0 %***.

Parameter: Cross polarization(ph-ph)

- Default setting **(_:2311:114) Cross polarization(ph-ph)** = ***15.0 %***

With the **Cross polarization(ph-ph)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-phase loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Cross polarization(ph-ph)** parameter to ***0.0 %***.

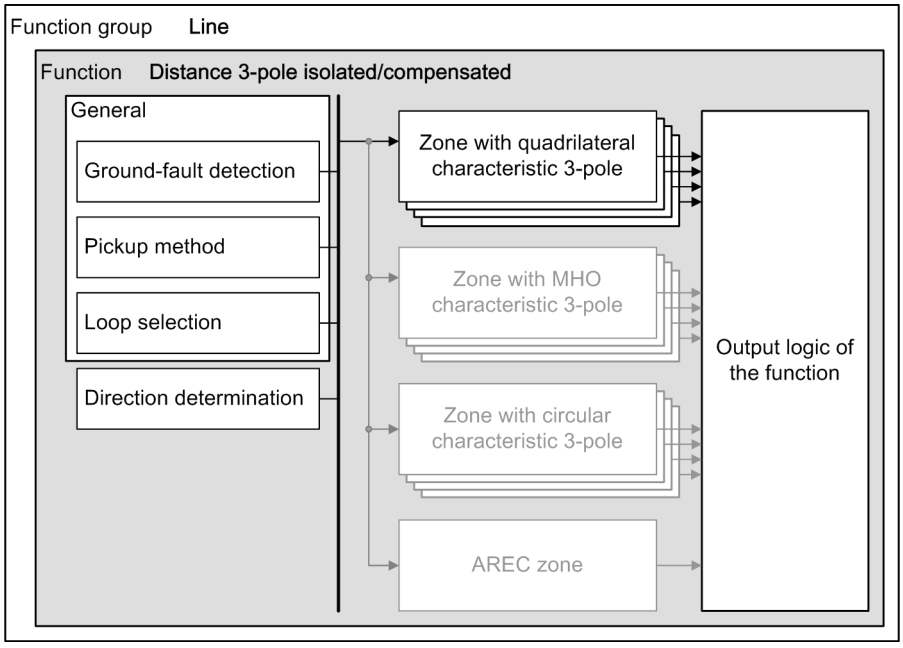
6.15.3 Distance Protection for Isolated/Resonant-Grounded Systems

6.15.3.1 Overview of Functions

The function **Distance protection for isolated or resonant-grounded systems** (ANSI 21 N):

- Is a form of selective short-circuit protection for lines and cables supplied from one or more end(s) in radial, looped or meshed systems,
- Works only in isolated or resonant-grounded systems via an arc-suppression coil
- Trips 3-phase
- Suitable for use in all voltage levels

6.15.3.2 Structure of the Function



The function **Distance protection for isolated or resonant-grounded systems** can be placed in function groups that provide voltage and current measured values as well as line parameters.

The function **Distance protection for isolated or resonant-grounded systems** consists of the following blocks:

- General information
- Pickup method
- Distance zones (preconfigured quadrilateral characteristic)
- AREC zones (not preconfigured)
- Output logic 3-phase

The function **Distance protection for isolated or resonant-grounded systems** is preconfigured with 4 zones at the factory. The zones are structured identically. In the function **Distance protection for isolated or resonant-grounded systems**, maximum of 16 zones with quadrilateral characteristic curves and 16 zones with MHO characteristic curves can be operated simultaneously.

The following figure shows the structural principles of the function **Distance protection for isolated or resonant-grounded systems**.

[dwstriso-090212-01.tif, 1, en_US]

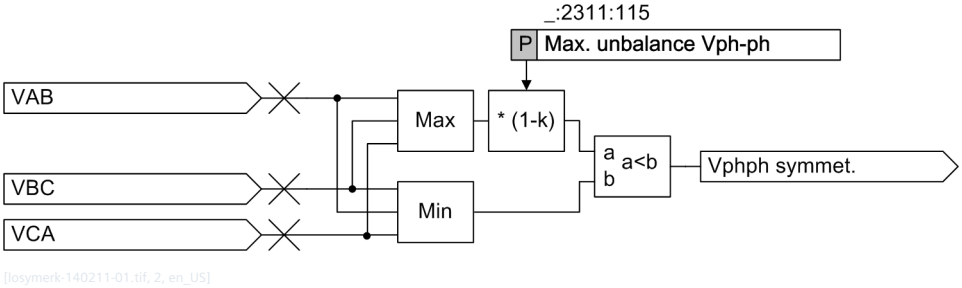
Figure 6-284 Structure/Embedding of the Function

Mode of Operation

Ground-fault detection determines whether a ground fault has occurred. The pickup method releases the measurement loops. The impedance is calculated for the released loops. The calculated impedance is assigned to the operate curves (quadrilateral, MHO, or circular characteristic [46]) of the zones. In the **Impedance pickup** method, the load cutout is then analyzed and the apparent impedances eliminated. For all picked up loops, the direction to the short-circuit location is then determined. The loop selection determines for which of the picked up loops assignment in the defined zones is done. The loop elimination removes all loops that are no longer picked up after direction determination and querying the load cutout. For the picked up loops, the time delay in the zone logic is started. The zone logic forms the pickup and trip signals of the loops and phases for the zone. The output logic processes the pickup and trip signals of the zones and forms the pickup and trip signals of the distance protection.

Ground-Fault Detection

Ground-fault detection checks whether a ground fault has occurred. If a ground fault has occurred, the measuring elements for the phase-to-ground loops are released.



For ground-fault detection, the following criteria are available:

- Monitoring of the zero-sequence current $3I_0$
- Monitoring of the ratio of the zero-sequence current and negative-sequence current ($3I_0/3I_2$)
- Monitoring of the zero-sequence voltage V_0
- Monitoring of the balance of phase-to-phase voltages

In isolated/resonant-grounded systems, the pickup of ground-fault detection is unwanted for simple ground faults. In the event of 1-phase pickup, a simple ground fault is initially presumed. So that the starting oscillation upon occurrence of the ground fault does not lead to unwanted pickup of the function, the pickup is suppressed for a settable time. After the **`Delay 1-phase pickup`** time has expired, the pickup is released. This is necessary so that the distance protection can still detect a double ground fault with a base point on a stub-end feeder. If phase-to-phase voltages are unbalanced, a double ground fault can be assumed. In that case, pickup is released immediately. The balance criterion prevents unwanted pickup for a simple ground

[46] in preparation

fault or unbalanced load conditions (see *Figure 6-285*). The **`Max. unbalance Vph-ph`** parameter specifies the maximum permitted unbalance for the load case, or in the event of a simple ground fault.

[losymerk-140211-01.tif, 2, en_US]

Figure 6-285 Balance Detection for Phase-to-Phase Voltages

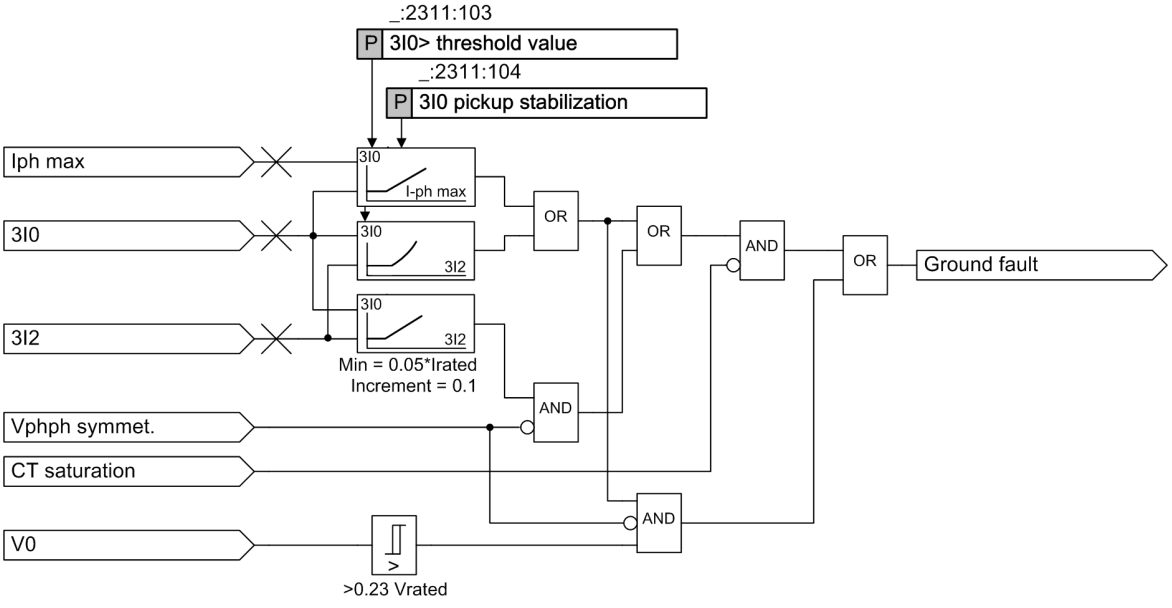


Figure 6-286 shows the logic of the ground-fault detection in isolated or resonant-grounded systems.

If the following conditions are met, the ground-fault detection responds for double ground faults with very low ground currents:

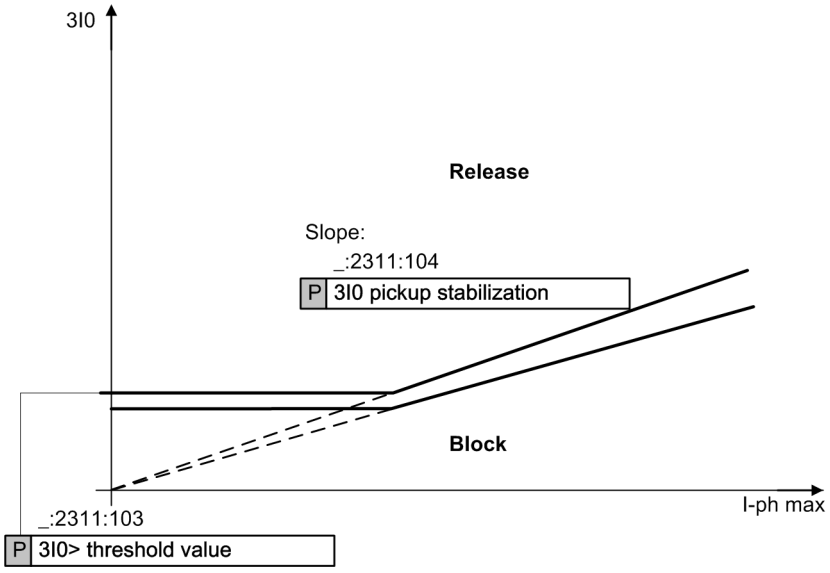
- The zero-sequence current is 10 % of the measured negative-sequence current I_2
- The zero-sequence current is at least 5 % of the secondary rated current
- The phase-to-phase voltages are unbalanced

Monitoring of the balance in phase-to-phase voltages prevents unwanted pickup in the event of simple ground faults.

Only for current-transformer saturation, the zero-sequence voltage criterion is taken into account for the release of the ground-fault detection for double ground faults. If V0 exceeds the firmly set threshold of 0.23 V · V_{rated}, the zero-sequence voltage criterion is released.

[loisolie-140211-01.tif, 1, en_US]

Figure 6-286 Ground-Fault Detection in Isolated or Resonant-Grounded Systems



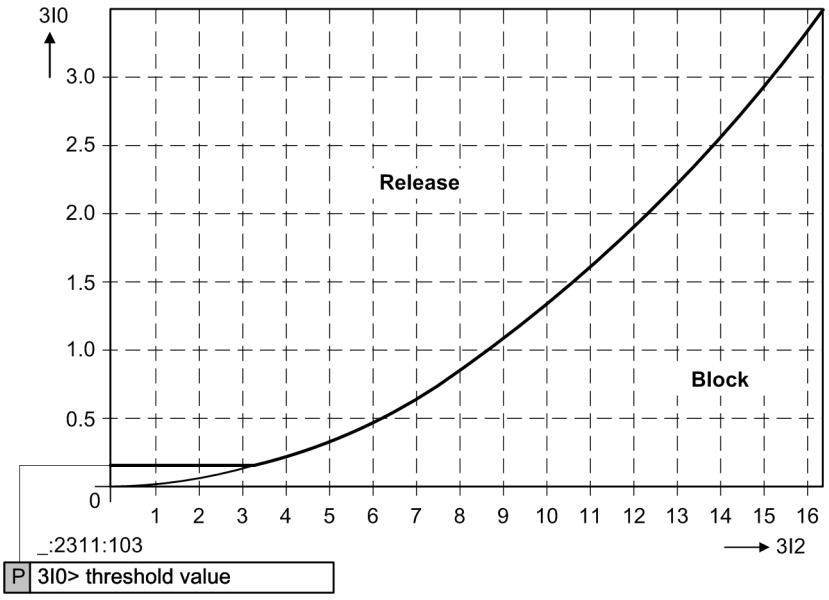
Ground-Fault Detection: Zero-Sequence Current $3I_0$

The zero-sequence current criterion monitors the fundamental component of the sum of phase currents for exceeding a settable value (parameter **`3I0> threshold value`**).

The zero-sequence current criterion is stabilized against unwanted pickup for the following cases:

- Zero-sequence currents due to unbalanced load conditions
- Zero-sequence currents in the event of faults without ground contact due to differing saturation of phase-current transformers
- For detected current-transformer saturation (see *Figure 6-286*)

Figure 6-287 shows the pickup characteristic of the zero-sequence current criterion. As phase currents increase, the actual pickup value rises automatically. The dropout threshold is about 95 % of the pickup value.



[dwklerds-060611-01.tif, 1, en_US]

Figure 6-287 Zero-Sequence Currents Criterion: Pickup Characteristic:

Ground-Fault Detection: Zero-Sequence Current/Negative-Sequence Current ($3I_0/3I_2$)

For long lines, high load currents can lead to destabilization of the residual-current criterion (see *Figure 6-287*). For the detection of double ground faults, the load-independent negative-sequence current criterion is extended. In addition to the zero-sequence current, the ratio of zero-sequence current to negative-sequence current is also monitored. If the ratio of zero-sequence current to negative-sequence current exceeds a preset limit, the criterion is released. The zero-sequence current/negative-sequence current criterion is stabilized for high negative-sequence currents using a parabolic characteristic. *Figure 6-288* shows the connection. A prerequisite for release of the zero-sequence current/negative-sequence current criterion is a minimum current of $0.2 \cdot I_{rated}$ for $3I_0$.

[dwkli0i2-140611-01.tif, 1, en_US]

Figure 6-288 I0/I2 Criterion: Pickup Characteristic

Ground-Fault Detection: Zero-Sequence Voltage V_0

Only for current-transformer saturation, the zero-sequence voltage criterion is taken into account for the release of the ground-fault detection for double ground faults. If V0 exceeds the firmly set threshold of 0.23 V V_{rated}, the zero-sequence voltage criterion is released.

Pickup Method

The pickup method selects the fault loops to be measured. The following pickup methods are available:

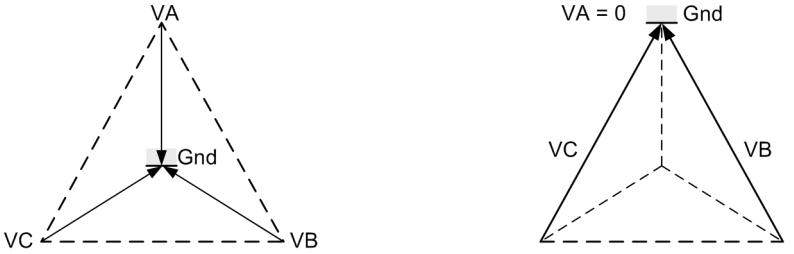
- Impedance pickup
- Overcurrent pickup
- V-/I pickup
- V-/I-φ pickup

Impedance pickup is preconfigured as the pickup method. You can use different pickup methods in parallel.

Zone Assignment

The calculated impedance phasors for the fault loops are assigned to the zones. For each zone, an operate curve is defined in the R-X plane. The following operate curves are available:

- Quadrilateral characteristic (preconfigured)
- MHO characteristic curve



You can find the description of operate curves in the chapters *6.15.6 Zone with Quadrilateral Characteristic Curve* and *6.15.8 Zone with MHO Characteristic Curve*.

Direction Determination

You can define for each zone whether the zone should work ***forwards***, ***backwards***, or ***non-directional***. For directional zones, you define the direction in the R-X plane. When assigning the impedance phasors in the R-X plane, the direction is then additionally analyzed. The description can be found in chapter *6.15.4 Direction Determination*.

Loop Selection for Double Faults in Isolated/Resonant-Grounded Systems

In isolated or resonant-grounded systems, no short-circuit-like currents flow in the event of a 1-phase-to-ground fault. There is only a shift of the voltage triangle (see *Figure 6-289*). For system operation, this state is not an immediate danger. In the entire galvanically connected system, the voltage of the phase affected by the ground fault is approximately 0 V. Thus each load current gives an impedance of approximately 0 Ω. The distance protection may not respond in this case. A 1-phase phase-to-ground pickup without ground-current pickup is thus prevented.

a) Healthy power system, without ground fault

b) Ground fault in phase A

[dwerdslu-100611-01.tif, 1, en_US]

Figure 6-289 Ground Fault in the Non-Grounded System

If a ground fault occurs, a significant starting current can flow in an extended resonant-grounded system. This can result in a pickup of the ground-current pickup. Special measures must be taken to prevent unwanted pickups when a ground fault occurs.

Specify a uniform double ground-fault preference for the galvanically contiguous system. This specifies which fault will be switched off.

For a double ground fault in the isolated or resonant-grounded system, it is enough to switch off one base point. The 2nd fault can remain in the system as a simple ground fault. Specify a uniform double ground-fault preference for the galvanically contiguous system. This specifies which fault will be switched off. The **`Phase preferen. (ph-ph-g)`** parameter is used to define the order of preference. The following double ground-fault preferences can be selected.

Setting for Parameter `Phase preferen. (ph-ph-g)`	Principle of Preference
C(A) acyclical	Acyclical C before A before B
A(C) acyclical	Acyclical A before C before B
B(A) acyclical	Acyclical B before A before C
A(B) acyclical	Acyclical A before B before C
C(B) acyclical	Acyclical C before B before A
B(C) acyclical	Acyclical B before C before A
C(A) cyclical	Cyclical C before A before B before C
A(C) cyclical	Cyclical A before C before B before A

In the 8 preference cases, a ground fault will be switched off according to the preference program. The 2nd fault remains as a simple ground fault in the system and can be detected using the **Ground-fault detection** function.

Influence of the Inrush-Current Detection

If the device is equipped with the **Inrush-current detection** function, the distance protection can be stabilized against tripping due to transformer-inrush currents. In case of interaction with the inrush-current detection the following configurations are possible:

- Blocking of the pickup for the overcurrent pickup method, V-/I-pickup and V-/I-/ϕ-pickup
- Blocking of individual distance zones
- Blocking of the pickup during impedance pickup by blocking the external distance zone(s)

The **Inrush-current detection** can be configured individually for the blocking of the mentioned pickup methods and distance zones. In case of blocking, the distance zone that is linked to the inrush-current detection or the pickup method will not pick up. The function **Inrush-current detection** signals the blocking through a corresponding indication. Once the blocking drops out and the pickup condition for the respective method or the linked distance zone is met, the pickup is signaled and the corresponding time delay will start. After that time, the operate indication will be generated. Only if the central function **Inrush-current detection** (see section *6.68.1 Inrush-Current Detection*) is in effect can the blocking be set.

6.15.3.3 Application and Setting Notes - General Settings

Parameter: Zone timer start

- Recommended setting value **(_:2311:110) Zone timer start** = ***on dist. pickup***

The **Zone timer start** parameter is used to determine the time at which the time delays of the zones start.

Parameter Value	Description
on dist. pickup	If the time delays of all zones start simultaneously, select this setting. If the fault type or measurement loop selection changes, all time delays continue to run. Siemens recommends using this setting.
on zone pickup	The time delay for the zone starts with zone pickup. If you need to coordinate the function with other distance or overcurrent protection functions, select this setting.

Parameter: Dist. characteristic angle

- Default setting **(_:2311:107) Dist. characteristic angle** = ***85.0°***

The **Dist. characteristic angle** parameter allows you to set the inclination angle of the distance protection characteristic curve (see *Figure 6-297*). The inclination angle set here for the distance protection characteristic curve applies to all zones in the function.
Siemens recommends setting the **Dist. characteristic angle** parameter to the line angle.

EXAMPLE:

Calculate the line angle from the data of the positive-sequence impedance (Z_1) on the line to be protected in the following way:

$$Z_1 = R_L + jX_L = (0.025 + j0.21)\Omega$$

[fo1 line angle, 1, en_US]

$$\text{Line angle} = \arctan\left(\frac{X_L}{R_L}\right)$$

[fo2 line angle, 1, en_US]

$$\text{Line angle} = 83.2°$$

[fo3 line angle, 1, en_US]

If you need to coordinate the function with other equipment, you can also set the inclination angle of the distance protection characteristic differently.

Parameter: 3I0> threshold value

- Recommended setting value **(_:2311:103) 3I0> threshold value** = ***0.10 A***

The **3I0> threshold value** parameter is used to define the zero-sequence current limit for ground-fault detection.

Determine the maximum ground current for a simple ground fault. Set the parameter **3I0> threshold value** to a slightly higher value.

Parameter: 3I0 pickup stabilization

- Recommended setting value **(_:2311:104) 3I0 pickup stabilization** = ***0.10***

The **3I0 pickup stabilization** parameter is used to set the inclination of the 3I0> characteristic curve for ground-fault detection.

Power-system unbalance (for example, untwisted lines) and current-transformer errors can cause a zero-sequence current flow at the protection device in the case of higher phase currents, even if there is no ground fault. The **3I0 pickup stabilization** parameter is used to avoid unwanted ground activation. If no extreme power-system unbalance and extraordinary current-transformer faults are expected, Siemens recommends keeping the recommended setting value of ***0.10***.

Parameter: Delay 1-phase pickup

- Default setting **(_:2311:108) Delay 1-phase pickup** = ***0.04 s***

The **Delay 1-phase pickup** parameter is used to delay pickup in the event of simple ground faults in the isolated/resonant-grounded system for the duration of the transient.

In resonant-grounded systems (neutral point grounding through an arc-suppression coil), when a ground fault occurs, it leads to non-system-frequency transients. The starting oscillation can lead to pickup of the I0> criterion. The **Delay 1-phase pickup** parameter is used to delay the pickup.

Parameter: Phase preferen. (ph-ph-g)

- Default setting **(_:2311:116) Phase preferen. (ph-ph-g)** = ***C (A) acyclic***

The **Phase preferen. (ph-ph-g)** parameter is used to define the order of preference for double ground faults.

The following table shows which loops are analyzed for different settings of the **Phase preferen. (ph-ph-g)** parameter:

Parameter Value	Picked Up Loop(s)	Analyzed Loop(s)
C (A) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	A-gnd C-gnd C-gnd
A (C) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	A-gnd C-gnd A-gnd
B (A) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	B-gnd B-gnd A-gnd
A (B) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	A-gnd B-gnd A-gnd
C (B) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	B-gnd C-gnd C-gnd
B (C) acyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	B-gnd B-gnd C-gnd
C (A) cyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	A-gnd B-gnd C-gnd

Parameter Value	Picked Up Loop(s)	Analyzed Loop(s)
A (C) cyclic	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	B-gnd C-gnd A-gnd
all	A-gnd, B-gnd, (A-B) B-gnd, C-gnd, (B-C) A-gnd, C-gnd, (C-A)	A-gnd, B-gnd B-gnd, C-gnd C-gnd; A-gnd

If you wish to switch off both base points of a ground fault, set the parameter **Phase preferen. (ph-ph-g)** = ***all***.

Parameter: Max. unbalance Vph-ph

- Default setting **(_:2311:115) Max. unbalance Vph-ph** = ***25 %***

The parameter **Max. unbalance Vph-ph** can be used to specify the maximum permitted unbalance for phase-to-phase voltages in the healthy condition. Determine the setting value for the specific application.

NOTE

The following parameters will be visible only if you are working with MHO characteristic curves:

- **Mem. polarization(ph-g)**
- **Mem. polarization(ph-ph)**
- **Cross polarization(ph-g)**
- **Cross polarization(ph-ph)**

The parameters apply to all MHO zones!

Parameter: Mem. polarization(ph-g)

- Default setting (:_2310:_111) **Mem. polarization(ph-g)** = ***15.0 %***

With the **Mem. polarization(ph-g)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-ground loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Mem. polarization(ph-g)** parameter to ***0.0 %***.

Parameter: Mem. polarization(ph-ph)

- Default setting (:_2310:_112) **Mem. polarization(ph-ph)** = ***15.0 %***

With the **Mem. polarization(ph-ph)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-phase loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Mem. polarization(ph-ph)** parameter to ***0.0 %***.

Parameter: Cross polarization(ph-g)

- Default setting (:_2310:_113) **Cross polarization(ph-g)** = ***15.0 %***

With the **Cross polarization(ph-g)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-ground loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Cross polarization(ph-g)** parameter to ***0.0 %***.

Parameter: Cross polarization(ph-ph)

- Default setting (:_2310:_114) **Cross polarization(ph-ph)** = ***15.0 %***

With the **Cross polarization(ph-ph)** parameter, you can specify the degree of polarization with an external-fault voltage for phase-to-phase loops. This parameter influences the extension of the MHO characteristic curve depending on the source impedance. If you wish to work with the basic characteristic curve without extension, set the **Cross polarization(ph-ph)** parameter to ***0.0 %***.

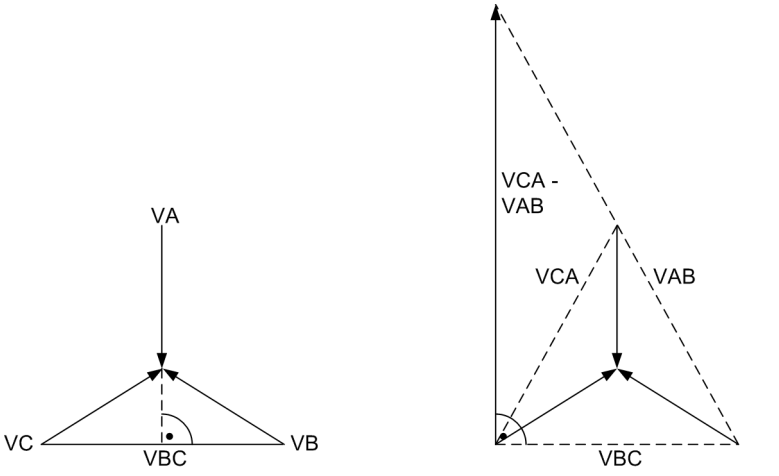
6.15.4 Direction Determination

To determine the direction of a short circuit, an impedance phasor is used for each loop.



Different methods are implemented for direction determination. The function selects the most appropriate method depending on the available input variables when a short circuit occurs.

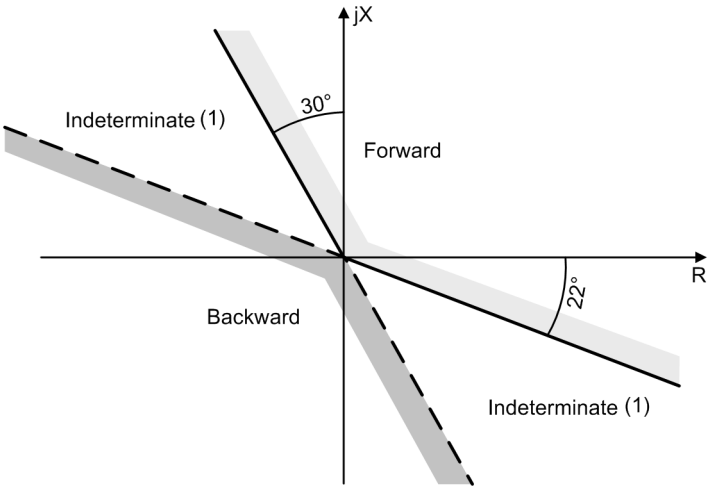
The following factors during short-circuit occurrence influence, for example, the method selection:

- Existing measurands
- Existing storage capacities
- Current system constellation

The following table shows the different input variables of the methods and their properties:

Input Variables for Direction Determination	Feature
Current, actual short-circuit voltage	This method determines the ratio between the instantaneous voltage phasor and the instantaneous current phasor. The calculated impedance provides information on the direction of the short circuit. The method functions with all short-circuit types and is loop-selective.
Saved, actual short-circuit voltage	The method determines the ratio between the saved voltage phasor and the instantaneous current phasor. The voltage phasor adapted to the instantaneous phase situation is used. The calculated impedance provides information on the direction of the short circuit. It is the preferred application for series-compensated systems. The method functions with all short-circuit types and is loop-selective.

Input Variables for Direction Determination	Feature
Current quadrature voltage	The method determines the ratio between the instantaneous healthy voltage phasor turned by 90° and the instantaneous current phasor.  a) Phase-to-ground loop (A-gnd) b) Phase-to-phase loop (phsBC) Figure 6-290 Direction Determination with Quadrature Voltages The calculated impedance provides information on the direction of the short circuit. The method functions only with 1-phase and 2-phase short circuits without ground contact and is loop-selective.
Saved quadrature voltage	The method determines the ratio between the saved healthy voltage phasor turned by 90° and the instantaneous current phasor. The calculated impedance provides information on the direction of the short circuit. The method functions only with 1-phase and 2-phase short circuits without ground contact and is loop-selective.
Delta variables	Direction determination works with static delta variables. The method uses the delta phasors of current and voltage. The delta phasors of current and voltage are calculated from the difference between the instantaneous measured phasor and the phasor saved before the fault. The ratio between the delta voltage phasor and the delta current phasor provides information on the direction of the short circuit. The method functions with all short-circuit types and is loop-selective.
Symmetrical components	The direction determination is based on the symmetrical components. • The direction determination with zero-sequence variables determines the zero-sequence impedance from the voltage and current phasors of the zero-sequence system. The calculated impedance provides information on the direction of the short circuit. The method functions only with short circuits with ground contact and is not loop-selective. • The direction determination with negative-sequence variables determines the negative-sequence impedance from the voltage and current phasors of the negative-sequence system. The calculated impedance provides information on the direction of the short circuit. It is the preferred application for short circuits during power swing. It functions only with unbalanced short circuits and is not loop-selective.



Direction-Characteristic Curve

The theoretical steady-state direction-characteristic curve is shown in *Figure 6-291*.

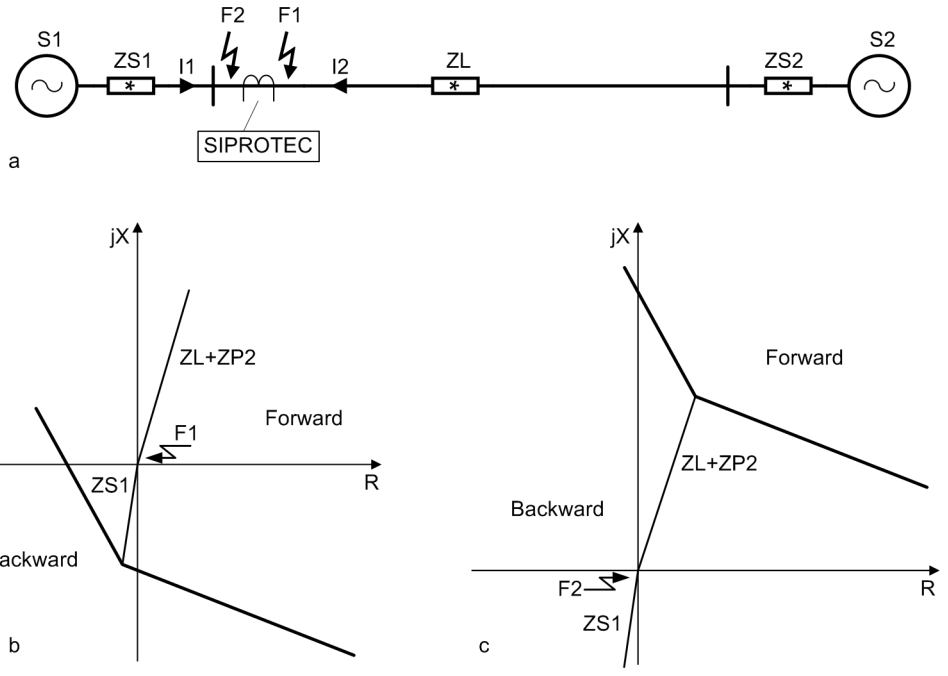
If buffered voltages are used, the following factors influence the position of the direction-characteristic curve:

- Source impedance
- Power transported on the line before occurrence of the short circuit

For this reason, the direction-characteristic curve (forwards) has a reserve distance to the limits of the 1st quadrant in the R-X diagram:

[dw_ritgkl, 2, en_US]

Figure 6-291 Direction-Characteristic Curve in the R-X Diagram



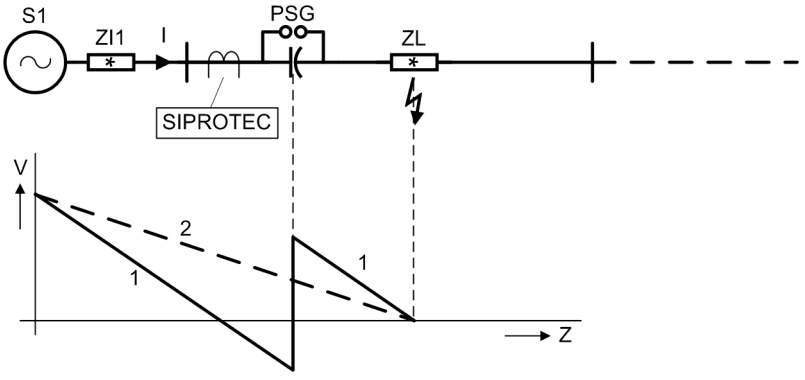
(1) Also valid for non-directional

Since each zone can be set to **forward**, **backward**, or **non-directional**, different direction-characteristic curves are used for **forward** and **backward**. A non-directional zone has no direction-characteristic curve. The entire tripping range applies to it.

Features of Direction Determination

The theoretical steady-state direction-characteristic curve in *Figure 6-291* applies to actual short-circuit voltages.

Figure 6-292 shows the direction-characteristic curve, taking the source impedance into consideration for external short-circuit or buffered voltages (without load transport). Since these voltages are equal to the corresponding generator voltage E, and they also do not change after the short circuit occurs, the direction-characteristic curve appears in the impedance diagram shifted by the source impedance ZS1 = E1/I1. For fault location F1 (*Figure 6-292*a), the short circuit lies in the forward direction, and the source impedance is in the backward direction. For all fault locations up to directly where the device is installed (current transformer), there is a consensus for forward (*Figure 6-292*b). If the current reverses, the orientation of the direction-characteristic curve changes suddenly (*Figure 6-292*c). A reversed current I2 now flows through the measuring point (current transformer). The source impedance ZS2 + ZL determines the value of I2. During load transport on the line, the direction-characteristic curve can also rotate by the load angle.



[dwrspeiu-140211-01.tif, 1, en_US]

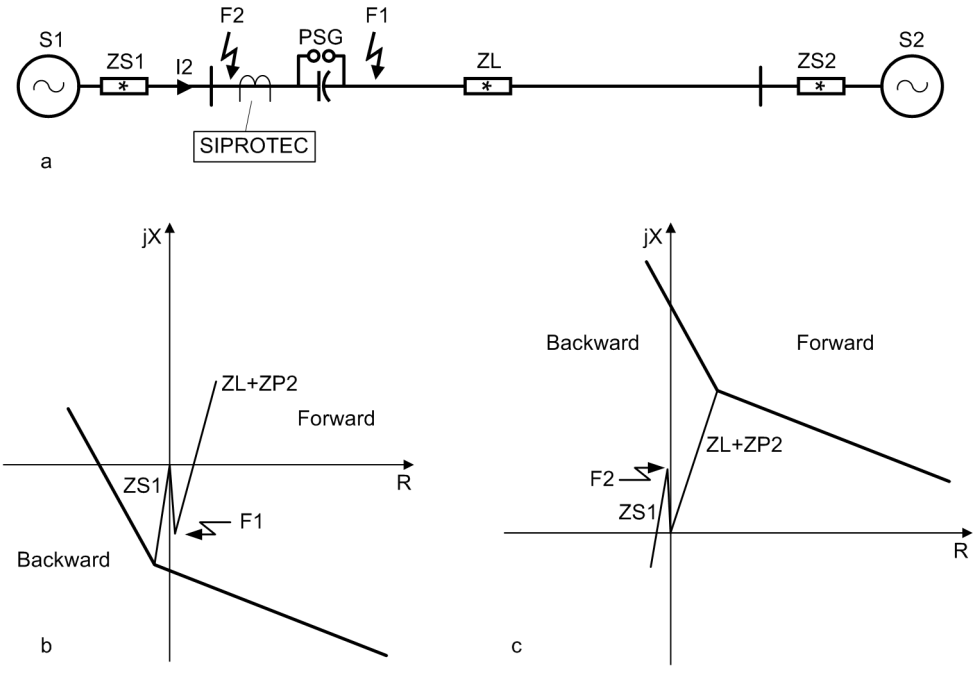
Figure 6-292 Direction-Characteristic Curve with Quadrature or Buffered Voltages

Direction Determination for Series-Compensated Lines

The direction-characteristic curves and their shift by the source impedance also apply for lines with series capacitors. For a short circuit upstream of the local series capacitor, however, the short-circuit voltage reverses if the protective spark gap SF has not picked up (see *Figure 6-293*).

[dwrserko-140211-01.tif, 1, en_US]

Figure 6-293 Voltage Characteristic for a Short Circuit Upstream of a Series Capacitor



(1) Without pickup of the protective spark gap

(2) With pickup of the protective spark gap

The distance protection thus senses a false fault direction. But in this case as well, direction measurement is correct due to the use of buffered voltages (see *Figure 6-294*a).

For direction determination, the voltage before the occurrence of the fault is used. Thus the peaks of the direction-characteristic curves, depending on the source impedance and load conditions before occurrence of the fault, appear shifted so far that the capacitor reactance does not lead to apparent reversal of direction (*Figure 6-294*b). The capacitor reactance is always lower than the source reactance.

If the short circuit is downstream of the capacitor – thus in reverse direction from where the device is installed (current transformer) – the peaks of the direction-characteristic curve are shifted in the other direction (*Figure 6-294*c). This also ensures a correct direction determination in this case.

[dwrklser-140211-01.tif, 1, en_US]

Figure 6-294 Direction-Characteristic Curves for Series-Compensated Lines

So that the direction determination for lines with series compensation functions correctly, you must set the parameter **`Series compensation`** = ***`yes`*** in the **Line** function group.

6.15.5 Pickup Method: Impedance Pickup

6.15.5.1 Description

In impedance pickup, the phase currents are monitored. If the phase currents exceed the set **`Min. phase-current thresh`**, the impedances between the phase-to-phase loops are calculated. If a ground fault is detected, the impedances of the phase-to-ground loops are also calculated.

Impedance pickup includes the elimination of apparent impedance and – if activated – monitoring of the load cutout.

Healthy Loops

In impedance pickup, all 6 line loops are calculated. Here, the short-circuit currents and voltages of short-circuited lines also influence the impedances of the healthy loops. For an A-gnd fault, for example, the short-circuit current in line A also influences the measured values in measurement loops A-B and C-A. The ground current is also measured in loops B-gnd and C-gnd. Together with load currents flowing, so-called "apparent impedances" occur in the healthy loops. These have nothing to do with the actual troubleshooting.

These apparent impedances in the healthy loops are typically greater than the fault impedance of the short-circuit loop. The healthy loops contain only part of the short-circuit current, and always have a higher voltage than the faulty loop. They are therefore of no significance for the zone selectivity of the protection.

In addition to zone selectivity, phase selectivity is also important. Phase selectivity includes the identification of the faulty phase, the generation of phase-selective indications, and the possibility of executing a 1-pole automatic reclosing function (AREC). Depending on the infeed conditions, short circuits near the station may have the result that the healthy loops see the short circuit at a greater distance, but they still see it within a tripping area. This case leads to a disconnection without the option of a 1-pole AREC. The 3-pole disconnection of the line then results.

Inspecting the loops reliably assures zone and phase selectivity. Loops are inspected in 2 steps.

- From the calculated loop impedance and their partial impedances (phase or ground), a replication of the line is first simulated.
- If the replication is plausible, the corresponding loop activation is categorized as valid.

If the impedances of more than one loop lie within the zone range, the smallest is still declared valid. Furthermore, all loops are declared valid whose impedance is greater than the lowest impedance by not more than 50 %. Loops with greater impedances are eliminated. The exception is any loop declared plausible in the first step. These can then no longer be eliminated.

This eliminates healthy apparent impedances on the one hand, but on the other hand simultaneously detects unbalanced multiphase short circuits and multiple faults correctly. The loops found valid are converted into phase information. This allows the pickup to be signaled in a phase-selective manner.

Load Cutout

For long lines with high loads, there is a risk that the load impedance will be reflected in the operate curve of the distance protection. For operate curves with high R segments, a load cutout can be configured that eliminates unwanted pickups due to overload. The load cutout (see *Figure 6-295* can be configured for phase-to-phase loops and for phase-to-ground loops.

The parameters are explained in chapter *6.15.5.2 Application and Setting Notes*.

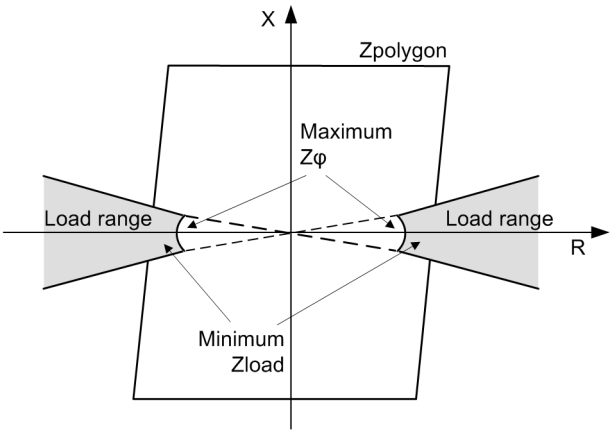
6.15.5.2 Application and Setting Notes

Parameter: Min. phase-current thresh

- Recommended setting value **(_:101) Min. phase-current thresh** = ***0.10 A***

Set the **Min. phase-current thresh** parameter to a very sensitive value (10 % of I_{rated}). If the minimum phase current is exceeded, the distance protection calculates the impedance. The sensitive setting allows you to ensure the backup function of the distance protection in case of remote faults in other feeders. If the minimum phase current in some short circuits – depending on system conditions – is not exceeded, you will have to take special measures for the weak infeed. Siemens recommends using the default setting **Min. phase-current thresh** = ***0.10 A***.

Load Cutout



The load cutout can be set using the following parameters:

- Default setting **(_:102) Use ph-g load cutout** = ***Yes***
- Default setting **(_:103) R load cutout (ph-g)** = ***20.000 Ω***
- Default setting **(_:104) Angle load cutout (ph-g)** = ***45.0°***
- Default setting **(_:105) Use ph-ph load cutout** = ***Yes***
- Default setting **(_:106) R load cutout (ph-ph)** = ***25.000 Ω***
- Default setting **(_:107) Angle load cutout (ph-ph)** = ***45.0°***

The load cutout is set separately for phase-to-ground loops (ph-gnd) and phase-to-phase loops (ph-ph). Using the parameters **Use ph-g load cutout** and **Use ph-ph load cutout**, you specify whether the load range is cut out of the impedance level or not. The load cutout parameters are visible only if you set the parameters **Use ph-g load cutout** = ***yes*** and **Use ph-ph load cutout** = ***yes*** .

Since there is no zero-sequence current in the load, load conditions cannot lead to a ground pickup. In the event of a 1-pole tripping of neighboring circuits, there may simultaneously be a ground pickup and an increased load current. For these cases, the load cutout must be set for the ground characteristic.

In the impedance level, the load range must be separate from the tripping area of the distance zone. The zone may only respond under fault conditions, not under load conditions. For the specific application, calculate the smallest load impedance and the greatest load impedance angle under heavy load (see *Figure 6-295*).

[dwlastke-140211-01.tif, 1, en_US]

Figure 6-295 Load Cutout

The values should be set a little smaller (about 10 %) than the minimum load impedance expected. The minimum load impedance results at maximum load current and minimum operating voltage.

EXAMPLE

Calculation of load-cutout parameters in balanced load conditions

110-kV overhead line, 150 mm^2, with the data:

Maximum transmittable power	
P_{max}	= 100 MVA
I_{max}	= 525 A
Minimum operating voltage	
V_{min}	= 0.9 V_{rated}
Current transformer	600 A/5 A
Voltage transformer	110 kV/0.1 kV

The primary minimum load impedance is then calculated as follows:

$$R_{Lprim} = \frac{V_{min}}{I_{max}} = \frac{0.9 \cdot 110\ kV}{525\ A \cdot \sqrt{3}} = 108.9\ \Omega$$

[fo_ltber1-210514, 1, en_US]

The secondary minimum load impedance is then:

$$R_{Lsec} = \frac{Ratio_I}{Ratio_U} \cdot R_{Lprim} = \frac{600\ A/5\ A}{110\ kV/0.1\ kV} \cdot 108.9\ \Omega = 11.9\ \Omega$$

[fo_ltber2-210514, 1, en_US]

With a safety margin of 10 %, the following setting values result for setting the primary and secondary values:
Primary: **`R load cutout (ph-ph)`** = 108.9 Ω or
Secondary: **`R load cutout (ph-ph)`** = 11.9 Ω

Set the opening angle of the load cutout (parameters **`Angle load cutout (ph-ph)`** and **`Angle load cutout (ph-g)`**) greater (approx. 5°) than the maximum occurring load angle (corresponding to the minimum power factor cos φ).

EXAMPLE

Minimum power factor under heavy load $(\cos \varphi_{max})_{min} = 0.8$

$\varphi_{max} = 36.9°$

Setting value **`Angle load cutout (ph-ph)`** $= \varphi_{max} + 5° = 41.9°$

You can find additional setting notes in *Example application high voltage overhead line* in *6.15.5.2 Application and Setting Notes*

When, with double lines, 2 line systems are on a single tower, there is a significant coupling between the 2 line systems. In the event of a 1-pole tripping of neighboring circuits, increased load currents and coupled ground currents can cause a ground pickup. This pickup can be prevented by separate setting of the load cutout for phase-to-ground loops.

During the 1-pole dead time on the parallel line, a significant ground current flows on the intact line. This ground current is caused by the coupling in the zero-sequence system. The ground current during the 1-phase pause on the parallel line must be considered when setting the **`R load cutout (ph-g)`** parameter.

EXAMPLE

Calculation of the load-cutout parameters for an application on a double line

This example applies to a double line with zero-sequence system coupling of both line systems and 1-pole tripping on one system in the double line.

The set values for the load cutout parameters are calculated for a 400-kV overhead line with the following data:

220-km double line on one tower (zero-sequence system coupling of both line systems)

Maximum power flow per line with both lines in operation:

P_{max}	= 1200 MVA
I_{max}	= 1732 A
Minimum operating voltage V_{min}	= 0.9 V_{rated}
Current transformer	2000 A/5 A
Voltage transformer	400 kV/100 V
Parameter **`kr`**	= 1.54

The minimum load impedance results in:

$$Z_{L\ prim} = \frac{V_{min}}{\sqrt{3} \cdot I_{max}} = \frac{0.9 \cdot 400\ kV}{\sqrt{3} \cdot 1732\ A} = 120\ \Omega$$

[fo_zl prim, 1, en_US]

This calculated value applies to phase-to-phase loops. For double lines, the 1-pole dead time on the parallel line must also be considered for phase-to-ground loops. During the 1-pole dead time, the load current on the intact line increases. At the same time, a load current flows in the ground path on the parallel line in the 1-pole dead time. Calculate the minimum load impedance for phase-to-ground loops with the load current in the ground path. For the calculation in this example, this ground current is given as a value relative to the load current I_{max}.

For the ratio of Ignd on the healthy line to I_{max} in the 1-phase pause on the parallel line, the following value is assumed:

$$\frac{I_{gnd\ 1phase\ Pause}}{I_{max}} = 0.4$$

[fo_je 1pol imax, 1, en_US]

The line length as well as the source impedance and line impedance have an influence on this ratio. If you cannot determine the value using a power-system simulation, you can assume the following approximate values:

Long lines (about 200 km)	$I_{gnd1pol:Pause}/I_{max}$: approximately 0.4
Short lines (about 25 km)	$I_{gnd1pol:Pause}/I_{max}$: approximately 0.6

The minimum load impedance for phase-to-ground loops results in the following for the calculation example:

$$R_{L\ prim\ (ph-gnd)} = \frac{R_{L\ prim}}{1 + \frac{I_{gnd\ 1phase\ \ Pause}}{I_{max}} \cdot (1 + kr)} = \frac{120\ \Omega}{1 + 0.4 \cdot (1 + 1.54)} = 59.5\ \Omega$$

[fo_rl prim L-E, 1, en_US]

When parameterizing using PC and DIGSI, you can select to enter the values as the primary or secondary variables. Conversion into secondary values yields:

$$R_{L\ sec} = \frac{Ratio_I}{Ratio_V} \cdot R_{L\ prim} = \frac{2000\ A/5\ A}{400\ kV/0.1\ kV} \cdot 120\ \Omega = 12\ \Omega$$

[fo_rl sek, 1, en_US]

$$R_{L\ sec\ (ph-gnd)} = \frac{Ratio_I}{Ratio_V} \cdot R_{L\ prim\ (ph-gnd)} = \frac{2000\ A/5\ A}{400\ kV/0.1\ kV} \cdot 59.5\ \Omega = 5.95\ \Omega$$

[fo_rl sek L-E, 1, en_US]

With a safety margin of 10%, these settings are used:

R load cutout (ph-ph)	= 108 Ω	(primary)	= 10.8 Ω	(secondary)
R load cutout (ph-g)	= 53.5 Ω	(primary)	= 5.35 Ω	(secondary)

The opening angle of the load cutout, as in the 1st example for the single line, is calculated using the minimum power factor.

6.15.6 Zone with Quadrilateral Characteristic Curve

6.15.6.1 Description

Logic of a Zone

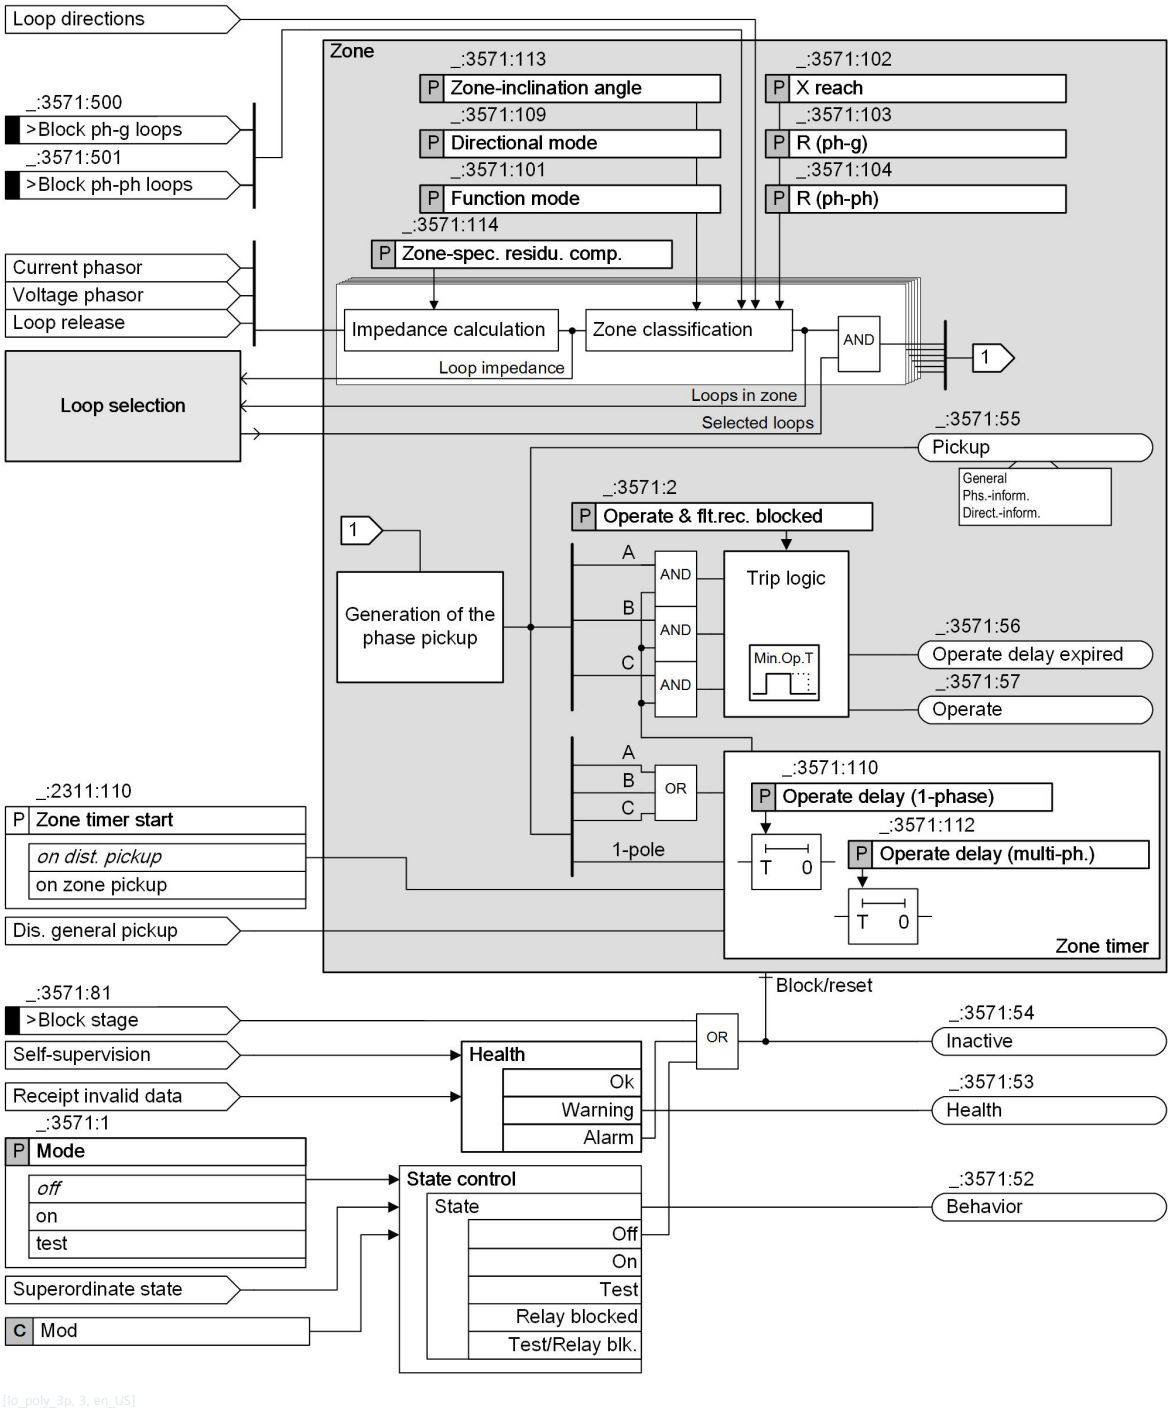

Figure 6-296 Logic Diagram of a Zone with a Quadrilateral Characteristic Curve

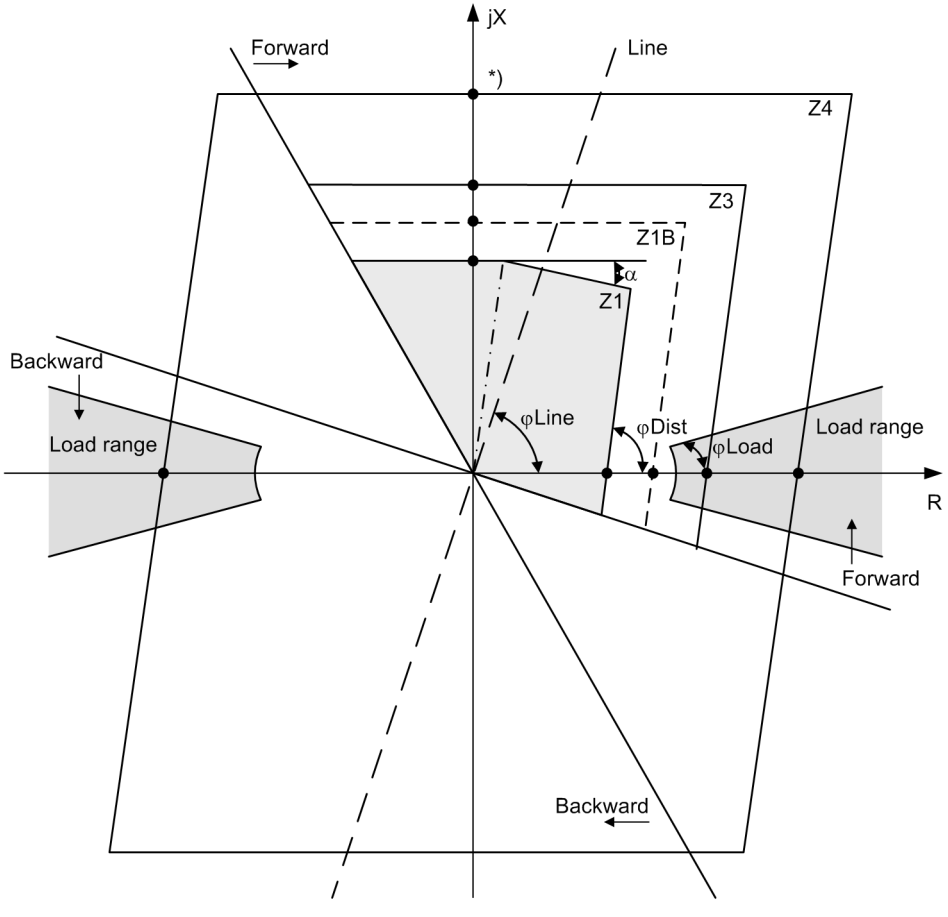
Mode of Operation

The zone handles the following tasks:

- Impedance calculation from the measured current and voltage values
- Placement of the impedance into the zone
- Generation of pickup and tripping for the zone



If the fault impedance of a loop lies well within the operating polygon of a distance zone, and the direction of the impedance phasor matches the directionality of the zone, the zone picks up. The loop information is converted into phase-selective pickup indications. The phase-selective pickup indications of the zones are processed further in the output logic of the distance protection and by external additional functions (for example, teleprotection scheme). The output logic of the distance protection is described in chapter *6.15.11 Output Logic of the Distance Protection*.

Operating Polygon

The quadrilateral characteristic (operating polygon) of the zone is an inclined parallelogram in the R-X plane. The operating polygon is defined by the parameters **`X reach`**, **`R (ph-ph)`**, **`R (ph-g)`** and **`Zone-inclination angle`**.

To stabilize the polygon limits, the characteristics have a hysteresis of 5 %. If the fault impedance lies within a polygon, the limits are increased by 5 % in all directions.

The following figure shows an example with 4 zones for the distance protection with quadrilateral operate curve.

*) Setting values are marked by points

[dwklpoly-060611-01.tif, 1, en_US]

Figure 6-297 Operate Curve with Quadrilateral Characteristic

NOTE

You can rename or delete the zones in DIGSI. You can also add additional zones from the DIGSI function library.

6.15.6.2 Impedance Calculation

There is an impedance measuring element available for each of the 6 possible phase loops A-gnd, B-gnd, C-gnd, A-B, B-C, C-A.

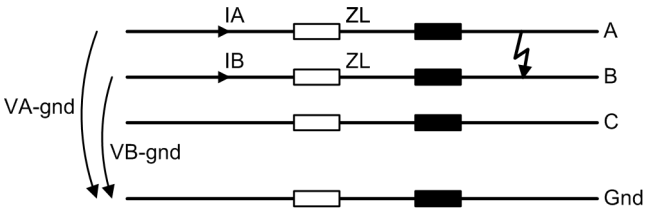
A jump detection synchronizes all calculations to the occurrence of the fault. Synchronization enables minimum and repeatable operate times to be achieved. If another fault occurs during analysis, the impedances are calculated using the current cyclical measurands. The analysis thus always works with the measurands of the current fault condition.

Impedance Calculation for Phase-to-Phase Loops

For calculation of a phase-to-phase loop, for example, for a 2-phase A-B short circuit (*Figure 6-298*), the loop equation is:

$$\underline{I}_A \cdot \underline{Z}_L - \underline{I}_B \cdot \underline{Z}_L = \underline{V}_{A-gnd} - \underline{V}_{B-gnd}$$

[foflschl-160909-01.tif, 1, en_US]



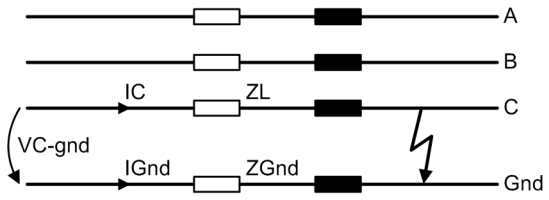
with

$\underline{V}, \underline{I}$	(complex) measurands
$\underline{Z}_L = R + jX$	(complex) line impedance

The line impedance is calculated as follows:

$$\underline{Z}_L = \frac{\underline{V}_{A-gnd} - \underline{V}_{B-gnd}}{\underline{I}_A - \underline{I}_B}$$

[folimped-240609-01.tif, 1, en_US]



[dwllschl-140211-01.tif, 1, en_US]

Figure 6-298 Short Circuit of a Phase-to-Phase Loop

As long as one of the lines involved is switched off, for example, during the 1-pole dead time of the automatic reclosing, the phase-to-phase loops involved are not calculated. During the 1-pole dead time of the automatic reclosing in A, for example, the loops A-B and C-A are blocked. This prevents an incorrect measurement with undefined measurands. The process monitor in the **Line** function group observes the state of the automatic reclosing and provides the blocking signal.

Impedance Calculation for Phase-to-Ground Loops

For calculation of a phase-to-ground loop, it must be considered that the impedance of the ground-return path generally does not match the impedance of the phases. This is the case, for example, for an C-gnd (*Figure 6-299*) short circuit.

[dwleschl-140211-01.tif, 1, en_US]

Figure 6-299 Short Circuit of a Phase-to-Ground Loop

The voltage $V_{C\text{-}gnd}$, the phase current I_C, and the ground current I_{gnd} of the faulty loop are measured.

$$V_{C-gnd} = I_C \cdot \left(R_{ph} + jX_{ph}\right) - I_{gnd} \cdot \left(kr \cdot R_{ph} + j\left(kx \cdot X_{ph}\right)\right)$$

[fofeschl-150909-01.tif, 1, en_US]

The impedance at the location of the fault is calculated as:

$$R_{C-gnd} = \frac{V_{C-gnd}}{I_C} \cdot \frac{\cos(\varphi_V - \varphi_{ph}) - \frac{I_{gnd}}{I_C} \cdot kx \cdot \cos(\varphi_V - \varphi_{gnd})}{1 - (kx + kr) \cdot \frac{I_{gnd}}{I_C} \cdot \cos(\varphi_{gnd} - \varphi_{ph}) + kr \cdot kx \cdot \left(\frac{I_{gnd}}{I_C}\right)^2}$$

[foreform-240609-01.tif, 1, en_US]

and

$$X_{C-gnd} = \frac{U_{C-gnd}}{I_C} \cdot \frac{\sin(\varphi_V - \varphi_{ph}) - \frac{I_{gnd}}{I_C} \cdot kr \cdot \sin(\varphi_V - \varphi_{gnd})}{1 - (kx + kr) \cdot \frac{I_{gnd}}{I_C} \cdot \cos(\varphi_{gnd} - \varphi_{ph}) + kr \cdot kx \cdot \left(\frac{I_{gnd}}{I_C}\right)^2}$$

[foxeform-240609-01.tif, 1, en_US]

with

$V_{C\text{-}gnd}$	Short-circuit voltage phasor
I_C	Short-circuit current phasor (phase C)
I_{gnd}	Ground-fault current phasor
φ_V	Phase angle of the short-circuit voltage
φ_{ph}	Phase angle of the short-circuit current (phase C)
φ_{gnd}	Phase angle of the ground-fault current

The factors $Kr = R_{gnd}/R_{ph}$ and $Kx = X_{gnd}/X_{ph}$ depend only on the line constants and not on the distance to the fault.

NOTE

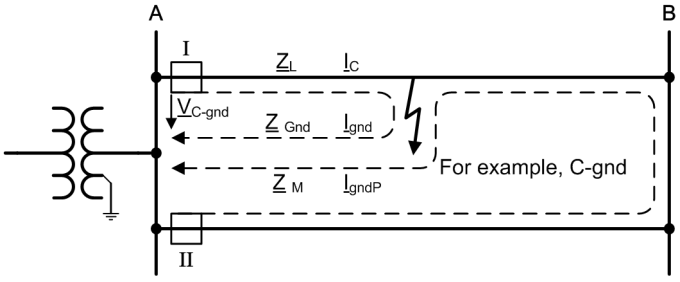
In the impedance calculation, the factors **Kr** and **Kx** are used for residual compensation. If you enter the grounding resistance factors in the format **k0** with **Phi(k0)**, they are automatically converted into **Kr** and **Kx**. Conversion is performed under consideration of the line angle. For this reason, pay attention to the correct setting of the line angle in the general data of the **Line** function group (parameter **(_:9001:108) Line angle**).

As long as one of the phases involved is switched off, for example, during the 1-pole dead time of the automatic reclosing, the phase-to-ground loops involved are not calculated. During the 1-pole dead time in the automatic reclosing in C, the C-gnd loop is blocked, for example. This prevents an incorrect measurement

with undefined measurands. The process monitor observes the state of the automatic reclosing and provides the blocking signal.

Measured-Value Correction for Parallel Lines

For double lines, both line systems are influenced by mutual coupling impedances (see *Figure 6-300*). With ground faults, errors in the results of the impedance calculation occur unless particular measures are taken. You can therefore effectively connect parallel-line compensation. This takes the ground current of the parallel line into consideration in the line equation, compensating for the coupling influence. This ground current must be applied to the device for this purpose. The loop equation in this case is similar to that of *Figure 6-299*:



$$\underline{I}_C \cdot \underline{Z}_L - \underline{I}_{gnd} \cdot \underline{Z}_{gnd} - \underline{I}_{gndP} \cdot \left(\underline{Z}_{0M}/3\right) = \underline{V}_{C-gnd}$$

[fofokpl1-150909-01.tif, 1, en_US]

$$\underline{I}_C \cdot \left(R_L + jX_L\right) - \underline{I}_{gnd} \cdot \left(kr \cdot R_L + j\,kx \cdot X_L\right) - \underline{I}_{gndP} \cdot \left(kmR \cdot R_L + j\,kmX \cdot X_L\right) = \underline{V}_{C-gnd}$$

[fofokpl2-150909-01.tif, 1, en_US]

I_{gndP} is the ground current of the parallel line. The ratios $R_{0M}/3R_{ph}$ and $X_{0M}/3X_{ph}$ are line constants that result from the geometry of the double line and the suitability of the grounding.

[dweksdol-140211-01.tif, 2, en_US]

Figure 6-300 Ground Fault on a Double Line

Without parallel-line compensation, the ground current of the parallel line typically results in the under-reaching of the distance protection (the loop impedance seen by the distance protection appears to be larger). If both lines end on different busbars and the grounding point is on a remote busbar (at B in *Figure 6-300*), overreach can result.

The parallel-line compensation applies only to faults on the line to be protected. Compensation may not be carried out for faults on the parallel line, since it would cause significant overreach. At installation point II in *Figure 6-300*, there must be no compensation for this fault situation.

The device thus receives an additional ground-current balance to perform a cross-comparison of the ground currents in both lines. The compensation is only connected for those line ends where the ground current of the parallel line is less than that of the end's own line. In example *Figure 6-300*, Ignd is greater than Ignd-P: There is compensation in I in that ZM · Ignd-P is coupled in; in II there is no compensation.

6.15.6.3 Application and Setting Notes

Parameter: Blocked if diff.prot.active

- Recommended setting value **`(_:121) Blocked if diff.prot.active`** = ***no***

The **`Blocked if diff.prot.active`** parameter is visible only when the **Line differential protection** function is available in the application.

Using the **`Blocked if diff.prot.active`** parameter, you establish whether the distance protection zone is blocked or not as long as the **Line differential protection** function is active.

Parameter Value	Description
no	If the zone is switched on (parameter **Mode** = ***on***) and the parameter **Blocked if diff.prot.active** = ***no*** is set, the zone will run regardless of the line differential protection. If the zone picks up, it will generate an operate indication after the time delay has elapsed.
yes	If the zone is switched on (parameter **Mode** = ***on***) and the **Blocked if diff.prot.active** = ***yes*** parameter is set, the zone is blocked as long as the line differential protection function is working. If the line differential protection is blocked, then the zone is **not** blocked.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:27) Blk. w. inrush curr. detect.** = ***no***

The **Blk. w. inrush curr. detect.** parameter is visible only when the **Inrush-current detection** function is available in the application. With the **Blk. w. inrush curr. detect.** parameter, you determine whether the distance protection zone is blocked or not during the detection of a transformer inrush current.

NOTE

With the parameter **Blk. w. inrush curr. detect.** = ***yes*** set, the minimum pickup and operate time for this distance protection zone is about 1.5 system cyles even if no transformer inrush current is detected. Set the parameter **Blk. w. inrush curr. detect.** = ***yes*** only if you really need blocking on the basis of **inrush-current detection**.

Parameter: Function mode

- Recommended setting value **(_:101) Function mode** = ***ph-gnd and ph-ph***

You can use the **Function mode** parameter to determine which measuring element the zone will work with. The possible alternatives are ***ph-gnd and ph-ph***, ***ph-gnd only*** and ***ph-ph only***.

Parameter Value	Description
ph-gnd and ph-ph	The zone works with phase-to-ground and phase-to-phase measuring elements. Siemens recommends using the default setting.
ph-gnd only	The zone works only with the phase-to-ground measuring element.
ph-ph only	The zone works only with the phase-to-phase measuring element.

Parameter: Directional mode

- Default setting **(_:109) Directional mode** = ***forward***

You can use the **Directional mode** parameter to define whether the zone operates ***forward***, ***reverse***, or ***non-directional***. Set the parameter **Directional mode** for the specific application.

Parameter: X reach

- Default setting **(_:102) X reach** = ***2.500 Ω***

You can use the **X reach** parameter to set the limit of the polygon in the X direction. Determine the setting value for the specific application.

First, create a time-grading schedule for the entire galvanically connected system. Enter the section lengths with their reactances X in Ω/km into the time-grading schedule. The reactances X then define the range of the distance zones.

Under *Notes on the R/X Ratio in the Zone Setting* at the end of the section, you will find notes on the R/X setting.

You can find additional setting notes in *Example application: High-voltage overhead line*.

Parameter: R (ph-g)

- Default setting **(_:103) R (ph-g)** = ***2.500 Ω***

You can use the **R (ph-g)** parameter to set the polygon limits in the R direction for phase-to-ground loops. The R radius for ground faults is calculated in a manner similar to that used for **R (ph-ph)** setting value for phase-to-phase faults. For phase-to-ground faults, the fault resistance is greater than that for phase-to-phase faults. For overhead lines, not only the arc resistance must be taken into consideration for a ground fault, but also the tower-grounding resistance.

Under *Notes on the R/X Ratio in the Zone Setting* at the end of the section, you will find notes on the R/X setting.

You can find additional setting notes in *Example application: High-voltage overhead line*.

Parameter: R (ph-ph)

- Default setting **(_:104) R (ph-ph)** = ***1.250 Ω***

You can use the **R (ph-ph)** parameter to set the polygon limits in the R direction for phase-to-phase loops. The **R (ph-ph)** setting value considers the fault resistance at the fault location. The fault resistance is added to the impedance of the fault loop as an additional effective resistance. This fault resistance is, for example, the arc resistance or the dissipation resistance of ground phases. Do not set the reserve resistance any larger than necessary. For long, heavily loaded lines, the setting value may enter the load range. A configurable load cutout prevents the activation of the zone in the event of overload (see *Load cutout* in chapter *6.15.5 Pickup Method: Impedance Pickup*.

For overhead lines, the setting value is determined primarily by the arc resistance. No significant arc is possible in cables. With very short cables, ensure that the arc flashover at the local cable box is included in the set resistance for Zone 1.

Under *Notes on the R/X Ratio in the Zone Setting* at the end of the section, you will find notes on the R/X setting.

You can find additional setting notes in *Example application: High-voltage overhead line*.

Parameter: Operate delay (1-phase)

- Default setting **(_:110) Operate delay (1-phase)** = ***0.00 s***

You can use the **Operate delay (1-phase)** parameter to set the grading time of the zone for 1-phase short circuits. The **Operate delay (1-phase)** must be set for the specific application.

Parameter: Operate delay (multi-ph.)

- Default setting **(_:112) Operate delay (multi-ph.)** = ***0.00 s***

You can use the **Operate delay (multi-ph.)** parameter to set the grading time of the zone for multi-phase short circuits. The **Operate delay (multi-ph.)** must be set for the specific application.

Parameter: Zone-inclination angle

- Default setting **(_:113) Zone-inclination angle** = ***0.0°***

The **Zone-inclination angle** parameter is used to set the angle by which the upper limit of the polygon is inclined in the first quadrant.

Under no circumstances may Zone 1 respond in the event of external faults, since this represents a loss of selectivity. To prevent the loss of selectivity, the limit of the X setting for Zone 1 is inclined downwards by the set angle. The default angle of 0° is typically retained for greater distance zones.

You can find additional setting notes in *Example application: High-voltage overhead line*.

Parameter: Zone-spec. residu. comp.

- Default setting **(_:114) Zone-spec. residu. comp.** = ***no***

You can use the **Zone-spec. residu. comp.** parameter to determine whether the zone operates with its own, specific residual compensation factors or not.

Parameter Value	Description
no	The zone works with the residual compensation factors set in the **Line** function group.
yes	The zone works with the specific residual compensation factors of the zone.

NOTE

Only if you set the parameter **Zone-spec. residu. comp.** = ***yes*** in the zone will the residual compensation factors set here be valid and visible. If you set the parameter **Zone-spec. residu. comp.** = ***no***, the residual compensation factors set for the device apply.

Parameter: Kr and Kx

- Default setting **(_:105) Kr** = ***1.00***
- Default setting **(_:106) Kx** = ***1.00***

You can use the **Kr** and **Kx** parameters to set the residual compensation with scalar factors.

NOTE

The parameters **Kr** and **Kx** are visible in the zone only if you have set the parameter **Zone-spec. residu. comp.** = ***yes*** in the zone and the parameter **Set. format residu. comp.** = ***Kr, Kx*** for the device. You can only change the setting value of the parameter **Set. format residu. comp.** in DIGSI 5 under **Device settings**.

Parameter: K0 and Angle (K0)

- Default setting **(_:3571:107) K0** = ***1.000***
- Default setting **(_:3571:108) Angle (K0)** = ***0.00°***

You can use the **K0** and **Angle (K0)** parameters to set the residual compensation with the complex residual compensation factor.

NOTE

The parameters **K0** and **Angle (K0)** are visible in the zone only if you have set the parameter **Zone-spec. residu. comp.** = ***yes*** in the zone and the parameter **Set. format residu. comp.** = ***K0*** for the device. You can only change the setting value of the parameter **Set. format residu. comp.** in DIGSI 5 under **Device settings**.

Notes on the R/X Ratio in the Zone Setting

In practice, the ratio of the resistance to the reactance setting lies in the following ranges:

Section Type	R/X Ratio in the Zone Setting
Short cable sections (about 0.5 km to 3 km)	3 to 5
Longer cable sections (> 3 km)	2 to 3
Short overhead-line sections < 10 km	2 to 5
Overhead lines < 100 km	1 to 2
Long overhead lines 100 km to 200 km	0,5 to 1
Long extra-high voltage lines > 200 km	≤ 0.5

NOTE

For short lines with large R/X ratios, note the following during zone setting: The angle errors of the current and voltage transformers cause a rotation of the impedance measured in the direction of the R axis. The risk that external faults will be shifted into the first zone increases if, because of the settings for the polygon, kr and kx, the loop range is large in the R direction in relation to the X direction for Zone 1. Use the grading factor of 85 % only up to an R/X ratio ≤ 1 (loop range).

For larger R/X settings, you can calculate a reduced grading factor for Zone 1 using the following formula:

STF	Grading factor = range of Zone 1 relative to the line length
R	Loop range in the direction R for Zone 1 = R1· (1 + kr)
X	Loop range in the direction X for Zone 1 = X1· (1 + kx)
δ_V	Angle error of the voltage transformer (typically 1°) 1°)
δ_I	Angle error of the current transformer (typically 1°) 1°)

$$STF \leq \left[1 - \frac{R}{X} \cdot \tan\left(\delta_V + \delta_I\right)\right] \cdot 88.5\ \%$$

[fofdustf-060709-01.tif, 1, en_US]

Alternatively or additionally, you can use the **Zone-inclination angle** parameter to incline the polygon of Zone 1 in the first quadrant. This also prevents overreach (see *Figure 6-297*).

6.15.7 Zone with Quadrilateral Characteristic Curve and Adaptive Pickup

6.15.7.1 Description

The **Zone with quadrilateral characteristic curve and adaptive pickup** is essentially the same as the **Zone with quadrilateral characteristic curve**.

The chapter describes only the extensions of the **Zone with quadrilateral characteristic curve and adaptive pickup**.

You can find the description for the **Zone with quadrilateral characteristic curve** beginning with chapter *6.15.6.1 Description*.

The **Zone with quadrilateral characteristic curve and adaptive pickup** has the following extensions:

- You set the load cutout directly in the zone. The load cutout applies for all the additional zones in the **Distance protection for grounded systems** function.
- The load cutout applies to both the phase-to-phase and the phase-to-ground loops.
- You can additionally limit the load cutout by user-specific minimum/maximum values.
  In that way, you can adapt the load cutout better to the load curve.
- The load-cutout settings are available as measured values *R load cutout* and *Angle load cutout*.

You can define multiple characteristic curves with different load cutouts and store them in different settings groups. If you switch the settings group, you can adapt the load cutout in the operate curve of the **Distance protection** quickly and flexibly to different load conditions. This increases the safety against erroneous pickups due to overloads.

For more detailed information regarding settings group switching, refer to *3.11.1 Settings-Group Switching*.

Measured Values of the Zone with Quadrilateral Characteristic Curve and Adaptive Pickup

The measured values are prerouted to the operational and fault log. This supports fault analysis if the function trips.

Measured Value	Description
(_:306) R load cutout	Resistance for defining the load cutout in the R-X plane
(_:307) Angle load cutout	Opening angle of the load cutout

6.15.7.2 Application and Setting Notes

NOTE

If you insert a **Zone with quadrilateral characteristic curve and adaptive pickup** into the **Distance protection** function, the load-cutout settings migrate from the impedance pickup into this zone.

If you delete this zone in the function, you must again set the load-cutout settings in the impedance pickup.

In the impedance pickup, you can again set the load cutout separately for phase-to-phase and phase-to-ground loops.

NOTE

If you set the load cutout in the **Quadrilateral zone with adaptive pickup**, the load cutout applies for all zones, both for phase-to-phase and for phase-to-ground loops.

Load Cutout

The load cutout can be set using the following parameters:

- Default setting **(_:122) R load cutout** = *25.000 Ω*
- Default setting **(_:123) Max. R load cutout** = *600.000 Ω*
- Default setting **(_:124) Min. R load cutout** = *0.050 Ω*
- Default setting **(_:125) Angle load cutout** = *45.0°*
- Default setting **(_:126) Max. Angle load cutout** = *60.0°*
- Default setting **(_:127) Min. Angle load cutout** = *20.0°*

The load cutout is set jointly for phase-to-ground loops (ph-gnd) and phase-to-phase loops (ph-ph).

You can find application and setting notes for the **R load cutout** and **Angle load cutout** parameters in the description of impedance pickups in chapter *6.15.5.2 Application and Setting Notes*.

Parameters: Max. R load cutout, Min. R load cutout

- Default setting **(_:123) Max. R load cutout** = *600.000 Ω*
- Default setting **(_:124) Min. R load cutout** = *0.050 Ω*

With the **Max. R load cutout** and **Min. R load cutout** parameters, you can define an upper and a lower limiting value for the **R load cutout** parameter. This allows you to additionally limit the setting range of the **R load cutout** parameter and adapt it to specific load conditions. If you set the **Max. R load**

cutout and **Min. R load cutout** parameters to the same value, the parameter **R load cutout** cannot take on a different value.

Parameters: Max. Angle load cutout, Min. R load cutout

- Default setting **(_:126) Max. Angle load cutout** = ***60.0°***
- Default setting **(_:127) Min. Angle load cutout** = ***20.0°***

With the **Max. Angle load cutout** and **Min. Angle load cutout** parameters, you can define an upper and a lower limiting value for the **Angle load cutout** parameter. This allows you to additionally limit the setting range of the **Angle load cutout** parameter and adapt it to specific load conditions. If you set the **Max. Angle load cutout** and **Min. Angle load cutout** parameters to the same value, the parameter **Angle load cutout** cannot take on a different value.

6.15.8 Zone with MHO Characteristic Curve

6.15.8.1 Description

Logic of a Zone

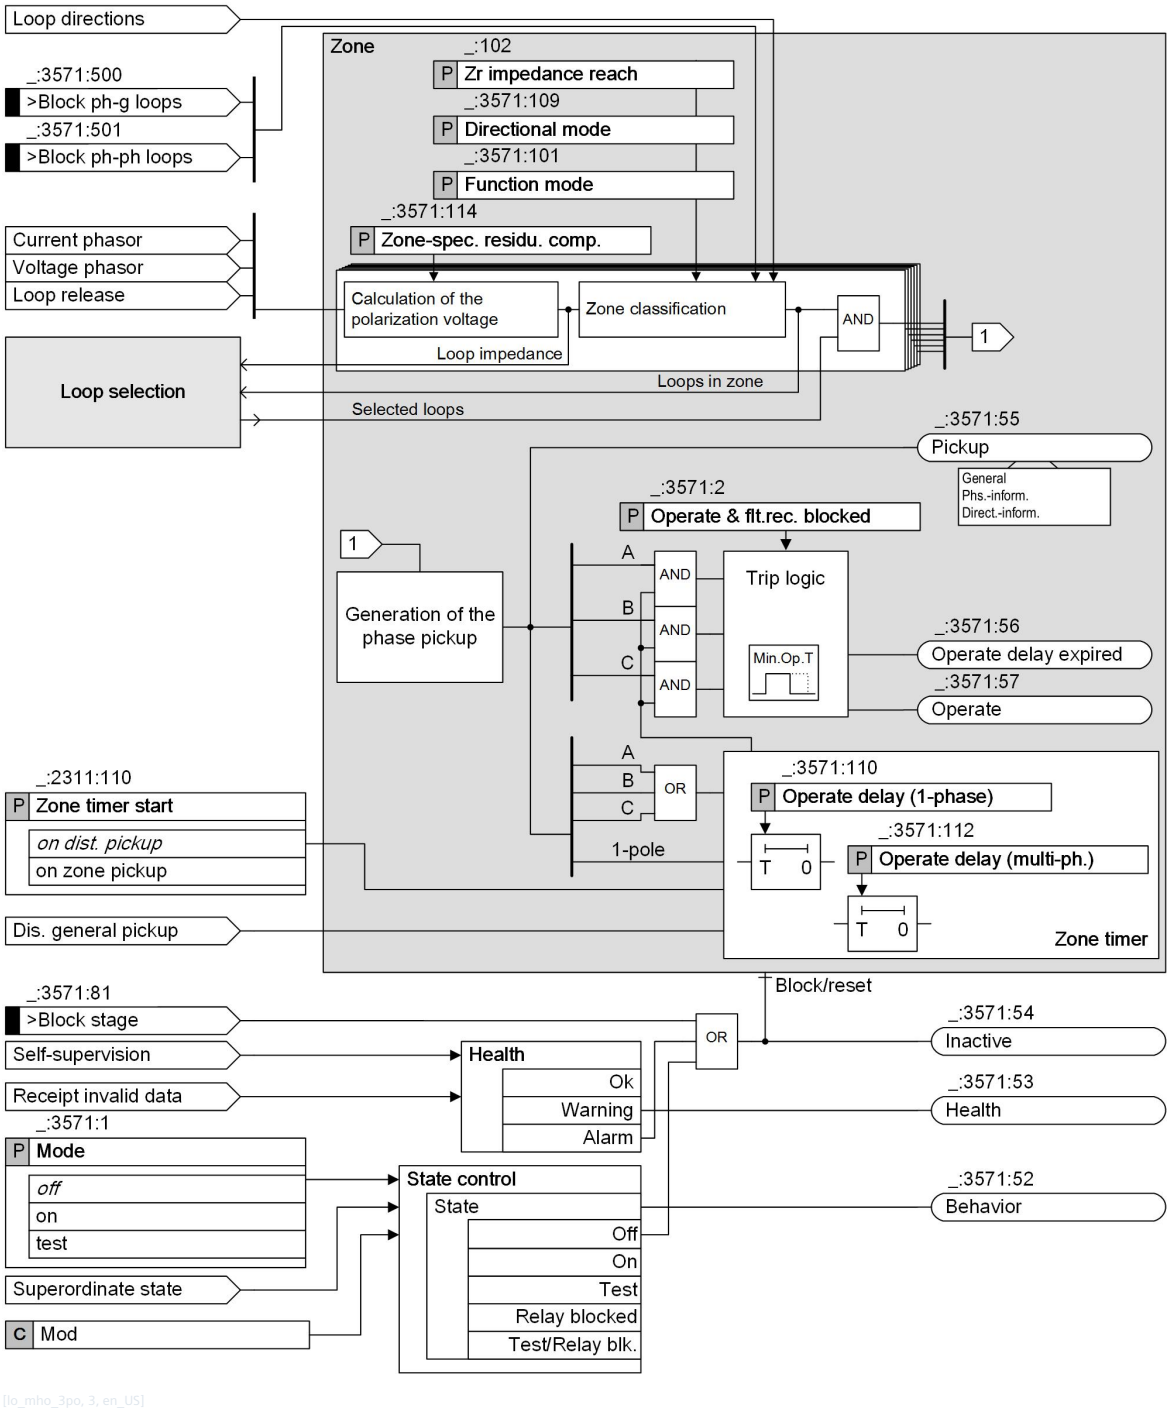

Figure 6-301 Logic Diagram of a Zone with MHO Characteristic Curve

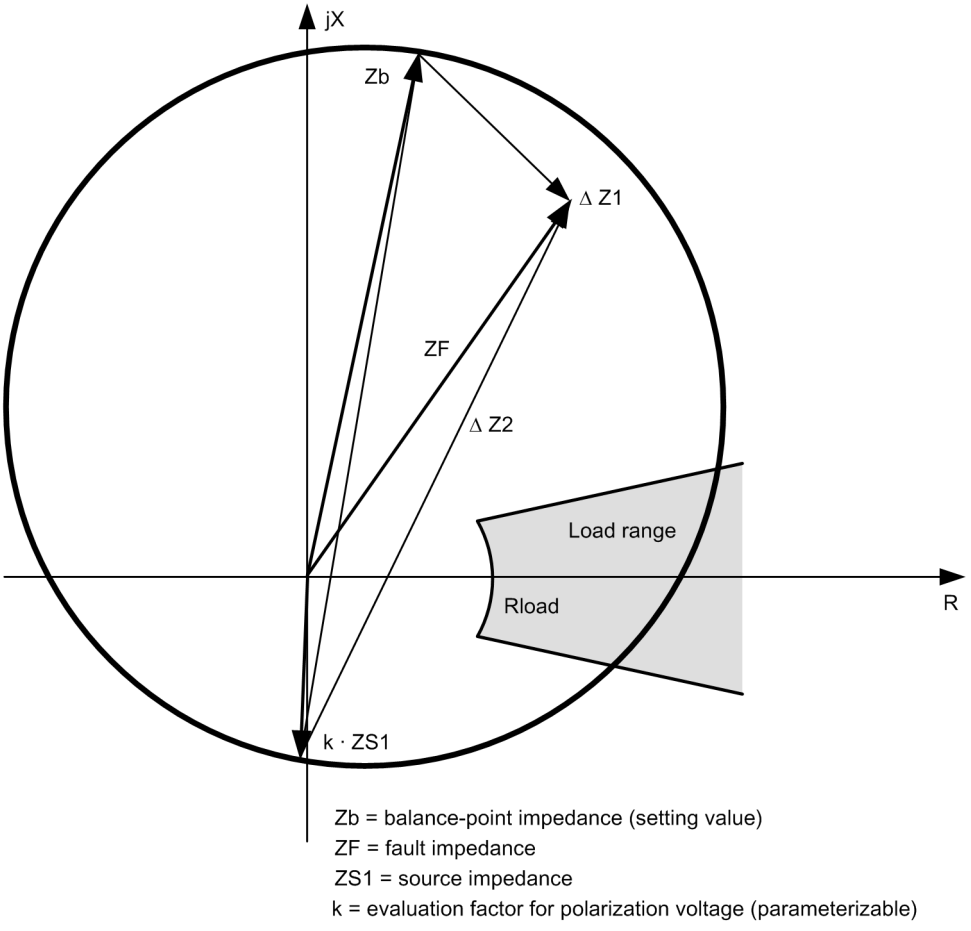
Mode of Operation

The zone handles the following tasks:



- Calculation of the polarization voltage from the measured current values
- Placement of the polarization and loop voltage into the zone
- Generation of pickup and tripping for the zone

To arrange the measurands in the tripping level of the MHO characteristic curve, the angle between 2 difference vectors ΔZ1 and ΔZ2 is determined (see *Figure 6-302*). These vectors are calculated from the difference between the 2 peaks of the circle diameter and the fault impedance. The peak Zr corresponds to the setting value of the zone (parameter **`Zr impedance reach`** and φ as in *Figure 6-303*); the peak k·ZV corresponds to the polarization value. The difference vectors are calculated as follows:

$$\Delta \underline{Z}_1 = \underline{Z}_F - \underline{Z}_r$$
$$\Delta \underline{Z}_2 = \underline{Z}_F - k \cdot \underline{Z}_V$$

[fofdltzr-130709-01.tif, 1, en_US]

In the boundary case, ZF is on the periphery of the circle. Then, the angle between the 2 difference vectors is 90° (Thales' theorem). Within the characteristic, the angle is greater than 90°; outside the characteristic, it is less than 90°.

[dwmhomes-140211-01.tif, 1, en_US]

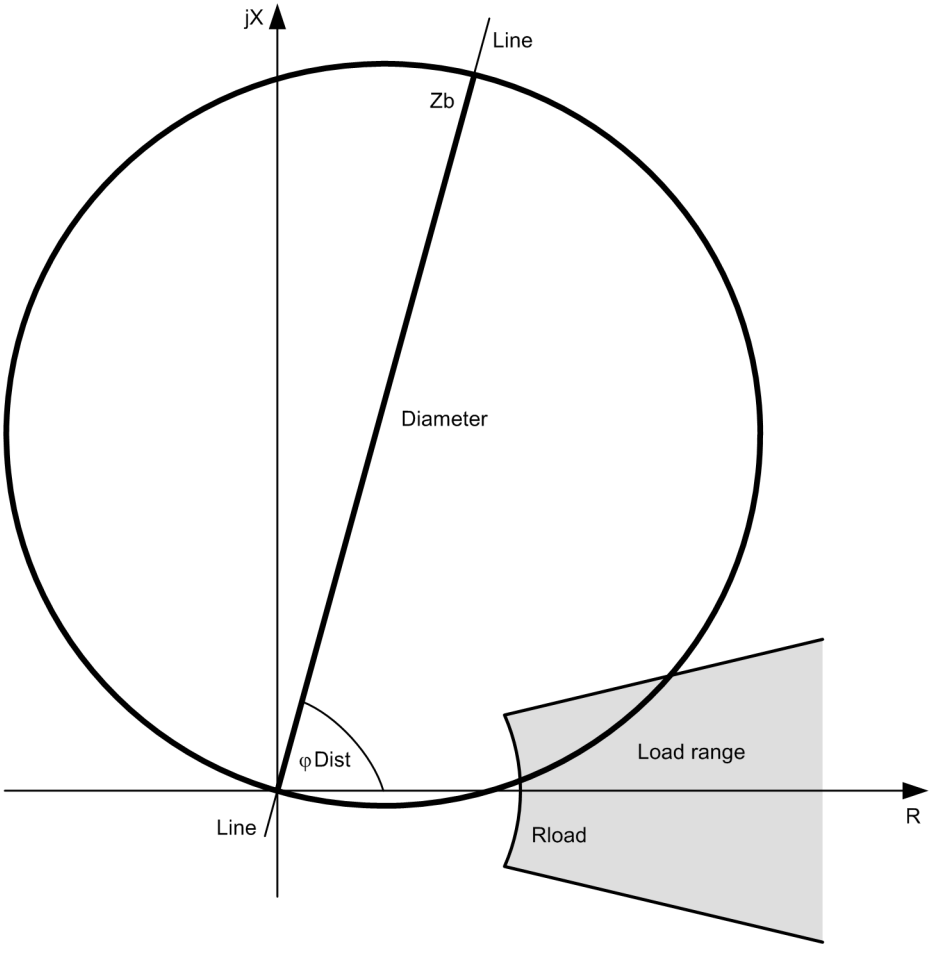


Figure 6-302 Vector Diagram of the Measurands for the MHO Characteristic Curve

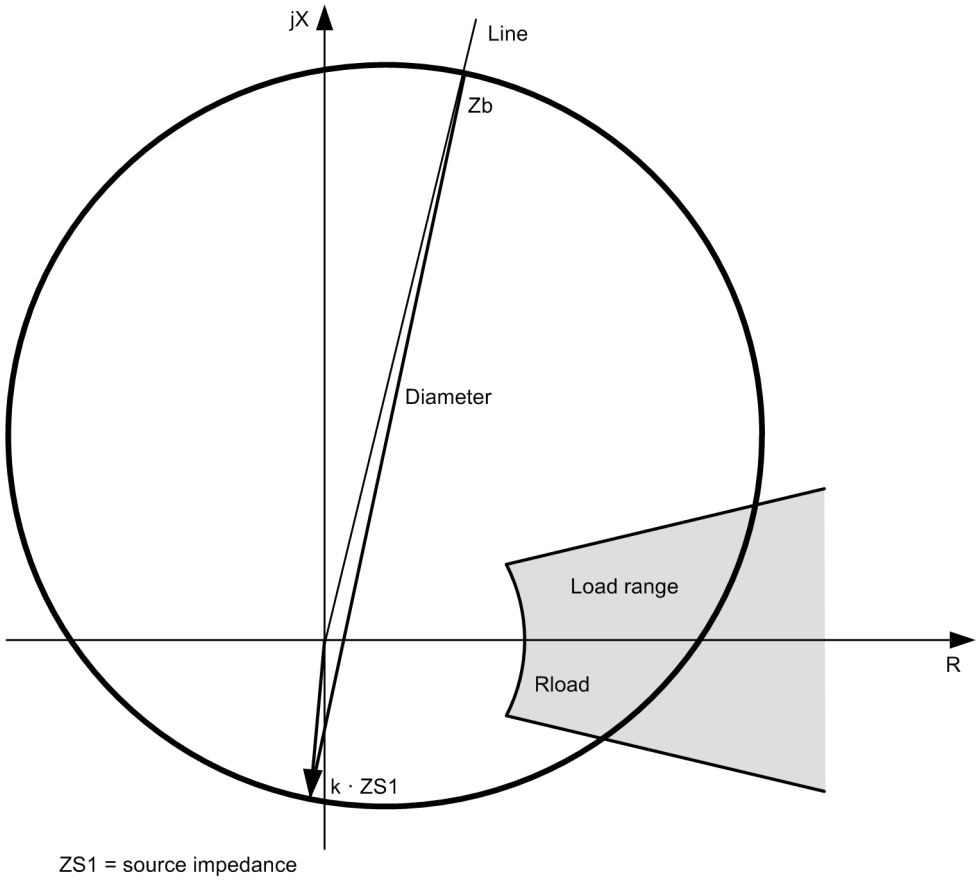
The **`Zr impedance reach`** parameter is used to define the zone. With the parameter **`Directional mode`**, you can specify whether the zone works ***`forward`*** or ***`reverse`*** directed. In the reverse direction, the MHO characteristic curve is reflected across the coordinate origin. Once the fault impedance of a loop lies well

within the MHO characteristic curve of a distance zone, the zone picks up. The loop information is converted into phase-selective pickup indications. The phase-selective pickup indications of the zones are processed further in the output logic of the distance protection and by external additional functions (for example, teleprotection scheme). The output logic of the distance protection is described in chapter *6.15.11 Output Logic of the Distance Protection*.

Basic Characteristic Curve of the MHO Circuit

The basic form of the MHO characteristic curve is shown in *Figure 6-303*. The MHO characteristic curve of the zone is a circle through the coordinate origin in the R-X plane. The diameter is defined by the parameter **`Zr impedance reach`**. The inclination is defined by the parameter **`Dist. characteristic angle`**.

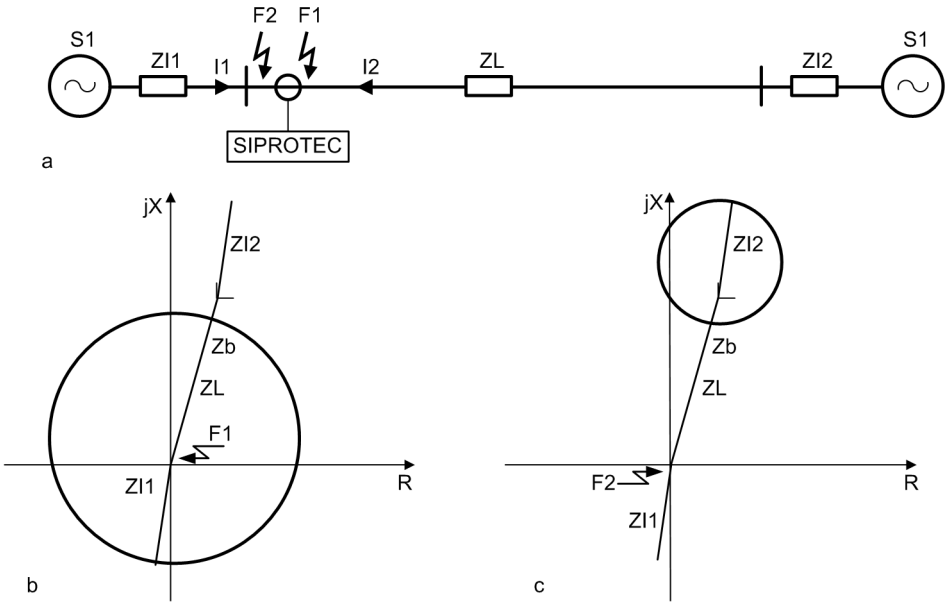


[dwmhogru-140211-01.tif, 1, en_US]

Figure 6-303 Basic Form of the MHO Characteristic Curve

Polarized MHO Characteristic Curve

The MHO characteristic curve passes through the coordinate origin. The boundary around the origin is undefined, since the measuring voltage there is too small for reliable analysis. The MHO characteristic curve is thus polarized. The polarization determines the lower peak of the circle, that is, the lower intersection of the diameter line on the circle circumference. The upper peak remains unchanged. It is defined by the parameter **`Zr impedance reach`**. Immediately after a fault occurs, the short-circuit voltage is influenced by the compensation procedure. Hence, the voltage buffered before the occurrence of the short circuit is used to perform the polarization. This shifts the lower peak by the impedance corresponding to the buffer voltage (see *Figure 6-304*). If the buffered short-circuit voltage is too small, a cross-polarized voltage is used. Theoretically, this is perpendicular to the actual short-circuit voltages for both the phase-to-ground loops and the phase-to-phase loops. This is taken into consideration with a 90° rotation during the calculation. The quadrature voltage also shifts the lower peak of the MHO characteristic curve.



[dwmhopol-140211-01.tif, 1, en_US]

Figure 6-304 Polarized MHO Characteristic Curve

Properties of the MHO Characteristic Curve

The cross-polarized or buffered voltage (without load transport) is equal to the corresponding generator voltage E. After the short circuit, it does not change (see also *Figure 6-305*). The lower peak of the circle diameter thus appears shifted in the impedance diagram by the polarization value k·ZV1 = k·E1/I1. The upper peak remains defined by the setting value **`Zr impedance reach`**. For fault location F1 (*Figure 6-305*a), the short circuit lies in the forward direction, and the source impedance is in the reverse direction. All fault locations up to directly where the device is installed (current transformer) are unambiguously within the MHO characteristic curve (*Figure 6-305*b). If the current reverses, the peak of the circle diameter changes suddenly (*Figure 6-305*c). A reversed current I2 now flows through the measuring point (current transformer). The source impedance ZV2 + ZL determines the current I2. The peak Zr remains unchanged. It is now the lower limit of the diameter of the circle. During load transport on the line, the peak phasor can also rotate by the load angle.

[dwksfrsp-140211-01.tif, 1, en_US]

Figure 6-305 Polarized MHO Characteristic Curve with Cross-Polarized or Buffered Voltages

Selecting the Polarization

For short lines, the range of the zone must be set as a small value. For small loop voltages, the phase angle comparison between the differential voltage and the loop voltage is not secure. This can lead to incorrect directional decisions (tripping or blocking despite reverse faults). If a polarization voltage is used for the phase angle comparison, these problems are avoided. The polarization voltage is proportionally composed of the loop voltage buffered before the fault occurred and the present loop voltage. The following equation shows the polarization voltage V_P for a phase-to-ground loop:

$$\underline{V}_P = (1 - k_{pre}) \cdot \underline{V}_{ph-gnd} + k_{pre} \cdot \underline{V}_{ph-gnd\ memory}$$

[fofuspch-090709-01.tif, 1, en_US]

A value (factor k_{pre}) for the prefault voltage can be set separately for phase-to-ground and phase-to-phase loops. Memory polarization is only carried out when the RMS value of the corresponding buffer voltage for phase-to-ground loops is greater than 40 % of the rated voltage (V_{rated}). For phase-to-phase loops, the RMS value of the buffer voltage must be greater than 70 % of V_{rated}.

For a subsequent fault or after switching onto a fault, the prefault voltage can be missing. In this case, the buffer voltage can only be used for a limited time, for reasons of accuracy. For 1-phase short circuits and 2-phase short circuits without ground contact, you can use a voltage not involved in the fault for polarization. This voltage is rotated by 90° in relation to the actual fault voltage (cross polarization). The polarization voltage V_P is a mixture of the present voltage and the corresponding external-fault voltage. The following equation shows the polarization voltage V_P for a phase-to-ground loop:

$$\underline{V}_P = (1 - k_{cross}) \cdot \underline{V}_{ph-gnd} + k_{cross} \cdot \underline{V}_{ph-gnd\ healthy}$$

[fofukrzp-090709-01.tif, 1, en_US]

If the buffer voltage is not available, then cross polarization can be used. An evaluation (factor k_{cross}) for the voltage can be set separately for phase-to-ground and phase-to-phase loops.

NOTE

The following parameters are available as evaluation factors for polarization:

- **Mem. polarization(ph-g)**
- **Mem. polarization(ph-ph)**
- **Cross polarization(ph-g)**
- **Cross polarization(ph-ph)**

Set the parameters for all zones in the general parameters of the Distance protection function.

6.15.8.2 Application and Setting Notes

Parameter: Blocked if diff.prot.active

- Recommended setting value **(_:121) Blocked if diff.prot.active** = ***no***

The **Blocked if diff.prot.active** parameter is visible only when the **Line differential protection** function is available in the application.
You can use the **Blocked if diff.prot.active** parameter to establish whether the distance protection zone is blocked or not as long as the **Line differential protection** function is active.

Parameter Value	Description
no	If the zone is switched on (parameter **Mode** = ***on***) and the parameter **Blocked if diff.prot.active** = ***no*** is set, the zone will run regardless of the line differential protection. If the zone picks up, it will generate an operate indication after the time delay has elapsed.
yes	If the zone is switched on (parameter **Mode** = ***on***) and the **Blocked if diff.prot.active** = ***yes*** parameter is set, the zone is blocked as long as the line differential protection function is working. If the line differential protection is blocked, then the zone is **not** blocked.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:27) Blk. w. inrush curr. detect.** = ***no***

The **Blk. w. inrush curr. detect.** parameter is visible only when the **Inrush-current detection** function is available in the application. You can use the **Blk. w. inrush curr. detect.** parameter to determine whether the distance protection zone is blocked or not during the detection of a transformer inrush current.

NOTE

With the parameter **Blk. w. inrush curr. detect.** = ***yes*** set, the minimum pickup and operate time for this distance protection zone is 1.5 power-system cyles even if the transformer inrush current is detected. Set the parameter **Blk. w. inrush curr. detect.** = ***yes*** only if you really need blocking on the basis of **inrush-current detection**.

Parameter: Function mode

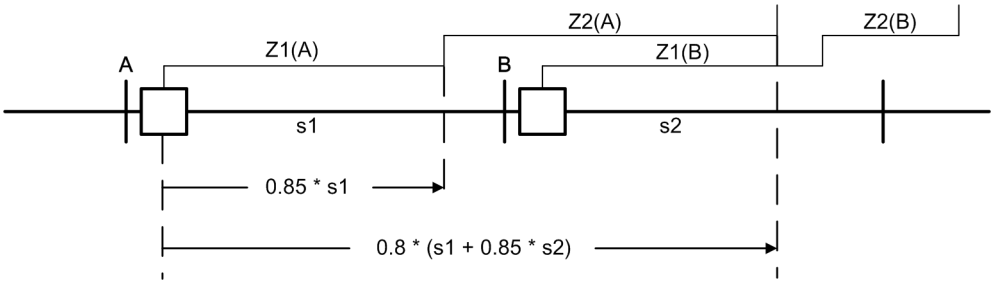
- Recommended setting value **(_:101) Function mode**= ***ph-gnd and ph-ph***

You can use the **Function mode** parameter to determine which measuring element the zone will work with. The possible alternatives are ***ph-gnd and ph-ph***, ***ph-gnd only*** and ***ph-ph only***.

Parameter Value	Description
ph-gnd and ph-ph	The zone works with phase-to-ground and phase-to-phase measuring elements. Siemens recommends using the default setting.
ph-gnd only	The zone works only with the phase-to-ground measuring element.
ph-ph only	The zone works only with the phase-to-phase measuring element.

Parameter: Directional mode

- Recommended setting value **(_:109) Directional mode**= ***forward***



You can use the **Directional mode** parameter to specify whether the zone works ***forward*** or ***reverse***. Set the parameter **Directional mode** for the specific application.

Parameter: Zr impedance reach

- Recommended setting value **(_:102) Zr impedance reach**= ***2.500 Ω***

You can use the **Zr impedance reach** parameter to define the reach of the zone. Determine the setting value for the specific application.

First, create a time-grading schedule for the entire galvanically connected system. Enter the section lengths with their primary reactances X in Ω/km into the time-grading schedule. The reactances X then define the range of the distance protection zones.

[dwstaffz-140211-01.tif, 1, en_US]

Figure 6-306 Setting of the Range – Example for Device A

Set the range of Zone Z1 to about 85 % of the line section to be protected. Zone Z1 should trip quickly. Set the time delay of Zone Z1 to 0.00 s. The protection then switches off faults at this distance with its operating time. For higher levels, increase the time delay by 1 grading time increment.

The grading time must take the following factors into consideration:

- Circuit-breaker opening time including variation
- Dropout time for protection systems
- Variation in time delays

The usual grading times are 0.2 s to 0.4 s. Set the range of Zone Z2 to a value that extends to about 80 % of the lower-level zone of the protection for the shortest subsequent line (see *Figure 6-306*).

When parameterizing using PC and DIGSI, you can select to enter the values in either primary or secondary variables. If you wish to enter secondary variables during parameterization, convert the primary values from the time-grading schedule into secondary values as follows:

$$Z_{secondary} = \frac{Ratio_I}{Ratio_V} \cdot Z_{primary}$$

[fofpmsek-140409-01.tif, 1, en_US]

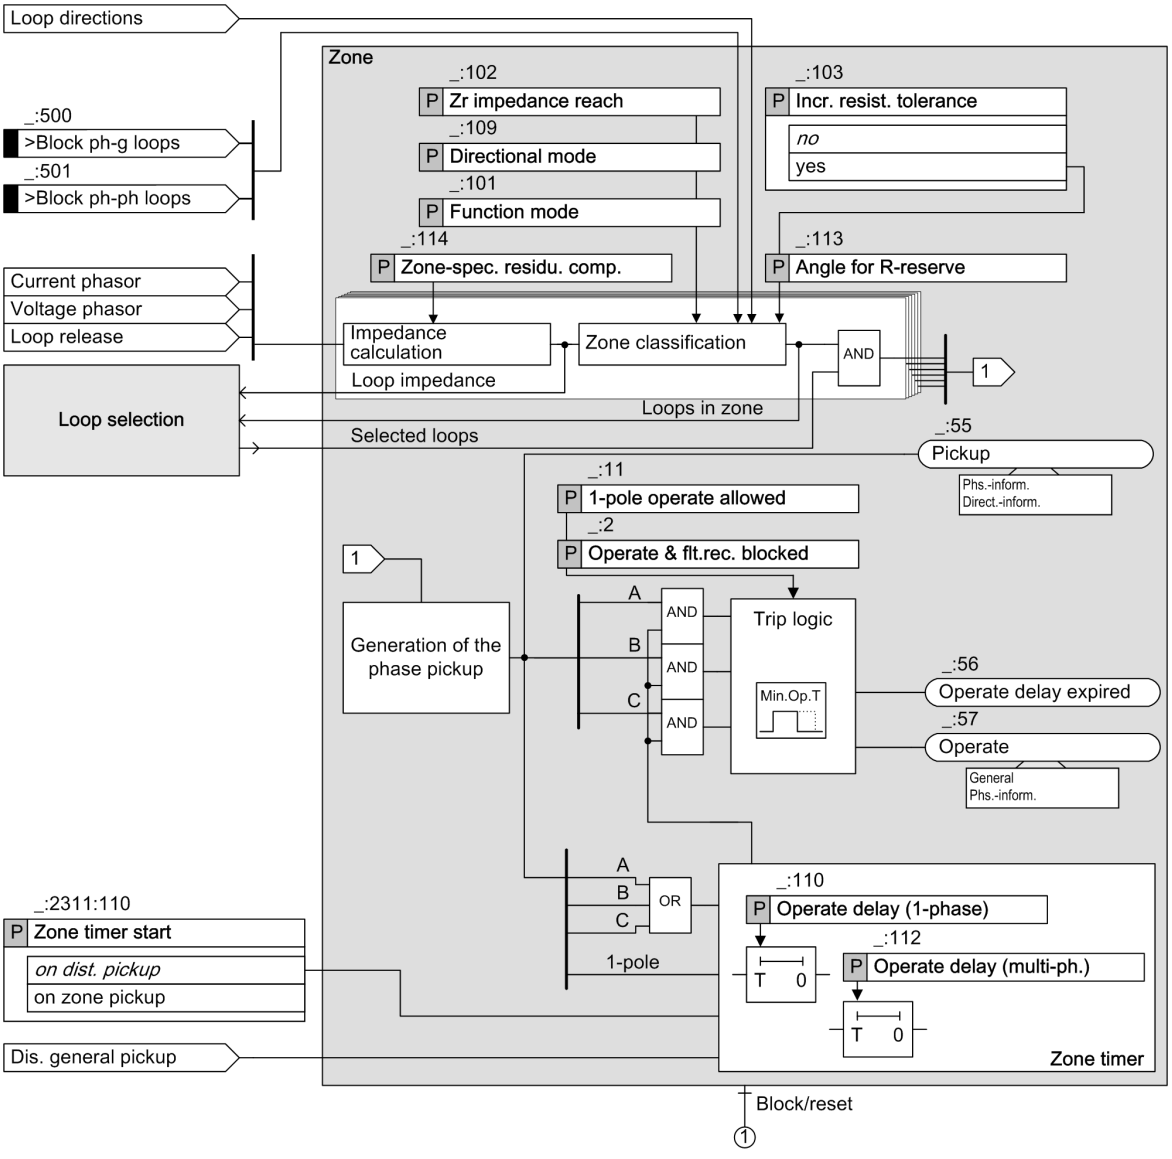
6.15.9 Zone with Circular Characteristic Curve

6.15.9.1 Description

Logic of a Zone



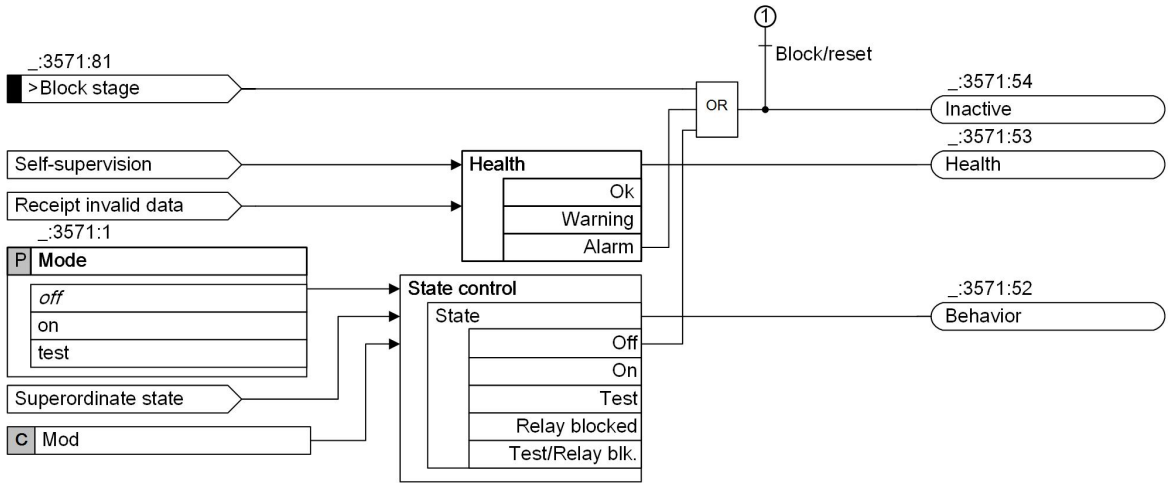


Figure 6-307 Logic Diagram of a Zone with Circular Characteristic Curve

[lo_block_i, 3, en_US]

Figure 6-308 Logic Diagram of a Zone with Circular Characteristic Curve (Continuation)

Mode of Operation

The zone handles the following tasks:

- Placement of the calculated impedance into the zone
- Generation of pickup and tripping for the zone

If the fault impedance of a loop lies well within the circular characteristic curve of a distance zone, and the direction of the impedance phasor matches the directionality of the zone, the zone picks up. The loop information is converted into phase-selective pickup indications. The phase-selective pickup indications of the zones are processed further in the output logic of the distance protection and by external additional functions (for example, teleprotection scheme). The output logic of the distance protection is described in chapter *6.15.11 Output Logic of the Distance Protection*.

Base Circle

The operate curve of the zone is a centered impedance circle around the origin of the R-X coordinate system. The base circle of the circular characteristic curve is defined by the parameter **`Zr impedance reach`**.

Since the circle cannot distinguish between positive impedance (forward direction) and negative impedance (reverse direction), direction-characteristic curves delimit the operating zones to the desired quadrant.

You can find more detailed information regarding the direction determination in chapter *6.15.4 Direction Determination*.

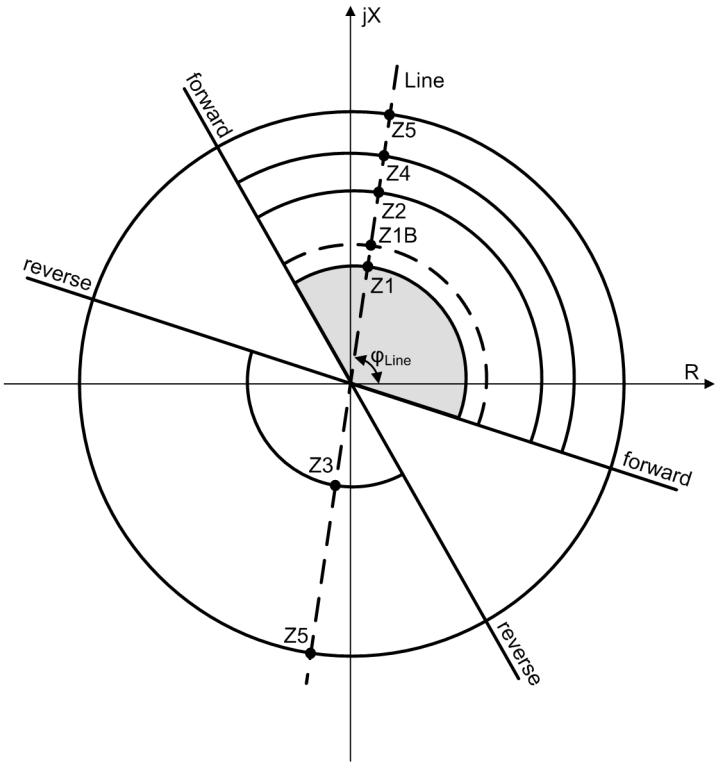

Figure 6-309 shows an example of the shape of the impedance circles. The circle for the first zone as a forward-directed zone is shaded. The third zone is shown as a reverse-directed zone. Zone Z5 is non-directional.

The impedance circle is defined by its radius and it forms the local curve of constant impedance.

$$Z = \sqrt{R^2 + X^2}$$

[fo_7sa6_fkt-beschr-Grundkreis, 1, en_US]

The radius thus determines the reach of a distance-protection zone in the R-X diagram and is independent of the short-circuit angle φ_{SC}.

[dw_kreis-charakteristik, 1, en_US]

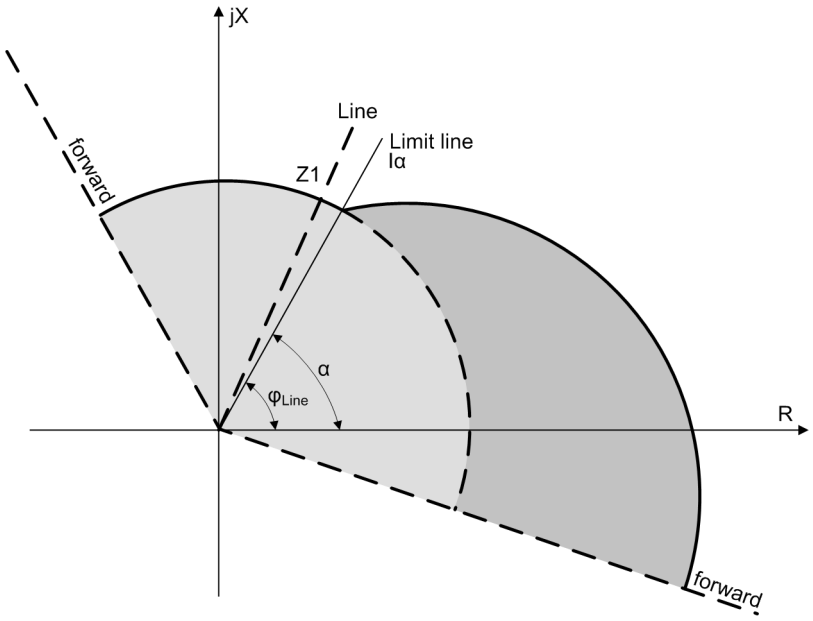

Figure 6-309 Example of Zones with Circular Characteristic Curve

Increased Resistance Reserve

Due to its centered symmetry, the circular characteristic curve includes only a limited resistance reserve for faults near the zone reach limit. This means that – for overhead lines – arc resistances can only be taken into consideration to a limited extent. For local faults (X ≈ 0), fault resistances R up to the magnitude of the set impedance Z (parameter: **(_:102) Zr impedance reach**) can be detected. For relatively long cables, this is sufficient if the arc resistance at the local sealing end is covered by the R-segment of the circle. In the cable itself, no significant arc resistance is possible.

In order to achieve a sufficient resistance reserve for overhead lines, even in the vicinity of the zone reach limit, an extension of the operate curve in the R-direction can be set. This also makes sense if an increased resistance reserve is necessary for short cables. This is the case if the resistance of an arc fault at the local sealing end of the cable is greater than the cable impedance at the zone reach limit of the first distance protection zone.

The increase of the resistance reserve takes effect below an adjustable limit angle α (parameter: **(_:113) Angle for R-reserve**), which should correspond approximately to the line angle. The following figure shows an example for the 1st zone and α = 60°. The somewhat more darkly shaded section is the increased resistance relative to the more lightly shaded impedance circle.

[dw_bsp-erhoehte-resistanzreserve, 1, en_US]

Figure 6-310 Example of Increased Resistance Reserve

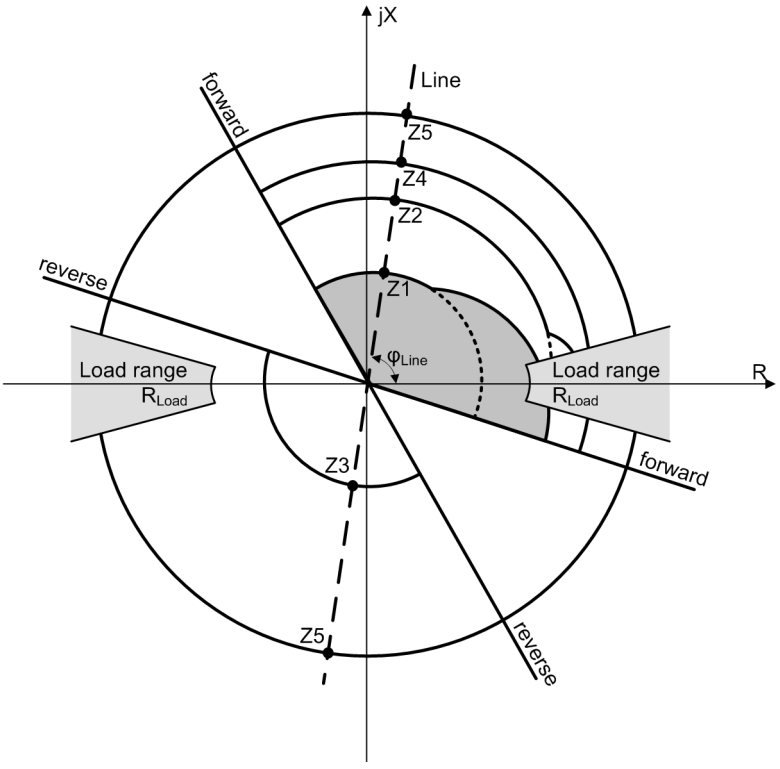
The limit angle α can be set separately for each zone. If a zone is set in the reverse direction, the section of the increased resistance reserve is mirrored at the coordinate origin.

The resistance reserve is increased according to the following equation

$$\frac{Z_{Break}}{Z_r} = 1 + \sin(\alpha - \varphi_{sc})$$

[fo_resist_up_circlezone, 1, en_US]

with



Z_{Break}	Balance-point impedance = actual limit of the zone
Z_r	Set impedance (parameter **`Zr impedance reach`**) = radius of the base circle
α	Set limit angle (parameter **`Angle for R-reserve`**) = angle below which the increased resistance reserve takes effect
φ_{sc}	Actual short-circuit angle = angle of the calculated short-circuit impedance

At the set limit angle α, the zone reach limit is therefore still on the impedance circle: because $\varphi_{sc} = \alpha$, $\sin(\alpha - \alpha) = 0$, and thus $Z_{Break} = Z_r$. If φ_{sc} is greater than the set limit angle α, then the impedance circle takes effect by definition and the increase of the resistance reserve makes no sense and is ineffective. For smaller angles up to -45°, the resistance reserve is increased by the expression $\sin(\alpha - \varphi_{sc})$, thus by $\sin(\alpha)$ at $\varphi_{sc} = 0°$.

Load Range

If the impedance circle is used as an implicit pickup method, there is a danger on long, heavily loaded lines that the load impedance may extend into the operate curves of the distance protection. In order to avoid faulty pickups of the distance protection in case of high power transmission, you can adjust a load cutout here. For operate curves with a high R-range, the load cutout excludes faulty pickups due to overload. For other pickup methods, this load cutout is unnecessary since the distance zones are only enabled after a pickup has taken place. In other words, the pickup in those cases distinguishes between load operation and short circuit.

The load cutout cuts the section of the load impedance from the circular characteristic curves (*Figure 6-311*). It also acts on the section of increased resistance reserve, as shown in the figure for the 1st zone. The shape of the load cutout is determined by the load section R_{load} and the load-range angle φ_{load}. These values apply to all zones.

[dw_kreis-charakteristik-mit-lastk, 1, en_US]

Figure 6-311 Circular Characteristic Curve with Load Cutout – Example

Direction Determination

Since each zone can be set to ***forward***, ***reverse***, or ***non-directional***, there are different (centrally mirrored) direction-characteristic curves for ***forward*** and ***reverse***. A non-directional zone has no direction-characteristic curve. For such a zone, the entire trip region applies.

6.15.9.2 Application and Setting Notes

Parameter: Blocked if diff.prot.active

- Recommended setting value **(_:121) Blocked if diff.prot.active** = ***no***

The **Blocked if diff.prot.active** parameter is visible only when the **Line differential protection** function is available in the application.

With the **Blocked if diff.prot.active** parameter, you determine whether the distance protection zone is blocked or not as long as the **Line differential protection** function is active.

Parameter Value	Description
no	If the zone is switched on (parameter **Mode** = ***on***) and the parameter **Blocked if diff.prot.active** = ***no*** the zone will run regardless of the line differential protection. If the zone picks up, it will generate an operate indication after the time delay has elapsed.
yes	If the zone is switched on (parameter **Mode** = ***on***) and the parameter **Blocked if diff.prot.active** = ***yes*** the zone is blocked as long as the line differential protection function is operating. If the line differential protection is blocked, then the zone is **not** blocked.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:27) Blk. w. inrush curr. detect.** = ***no***

The **Blk. w. inrush curr. detect.** parameter is visible only when the **Inrush-current detection** function is available in the application. With the **Blk. w. inrush curr. detect.** parameter, you determine whether the distance-protection zone is blocked or not during the detection of a transformer inrush current.

NOTE

If you have set the parameter **Blk. w. inrush curr. detect.** = ***yes***, the minimum pickup and operate time for this distance-protection zone is 1.5 power-system cycles even if no transformer inrush current is detected. Set the parameter **Blk. w. inrush curr. detect.** = ***yes*** only if you really need the blocking by **Inrush-current detection**.

Parameter: 1-pole operate allowed

- Default setting **(_:11) 1-pole operate allowed** = ***yes***

With the **1-pole operate allowed** parameter, you specify whether the zone may execute 1-pole tripping or not. If the circuit breaker can do 1-phase switching, then 1-pole tripping is allowed on overhead lines. For practical applications, only the 1st distance zone and the overreaching zone shall trip in a 1-pole way. Set the parameter **1-pole operate allowed** = ***yes*** for the 1st distance zone and the overreaching zone. For all higher zones, set the parameter **1-pole operate allowed** = ***no***.

Parameter: Function mode

- Recommended setting value **(_:101) Function mode**= ***ph-gnd and ph-ph***

With the **Function mode** parameter, you can determine which measuring element the zone will work with. Possible alternatives are ***ph-gnd and ph-ph***, ***ph-gnd only*** and ***ph-ph only***.

Parameter Value	Description
ph-gnd and ph-ph	The zone works with phase-to-ground and phase-to-phase measuring elements. Siemens recommends using the default setting.
ph-gnd only	The zone works only with the phase-to-ground measuring element.
ph-ph only	The zone works only with the phase-to-phase measuring element.

Parameter: Zone-spec. residu. comp.

- Default setting **(_:114) Zone-spec. residu. comp.** = ***no***

You can use the **Zone-spec. residu. comp.** parameter to determine whether the zone operates with its own, specific residual compensation factors or not.

Parameter Value	Description
no	The zone works with the residual compensation factors set in the **Line** function group.
yes	The zone works with the specific residual compensation factors of the zone.

NOTE

The residual compensation factors set here will be valid and visible only if you have set the parameter **Zone-spec. residu. comp.** = ***yes*** in the zone. If you have set the parameter **Zone-spec. residu. comp.** = ***no***, the residual compensation factors set for the device apply.

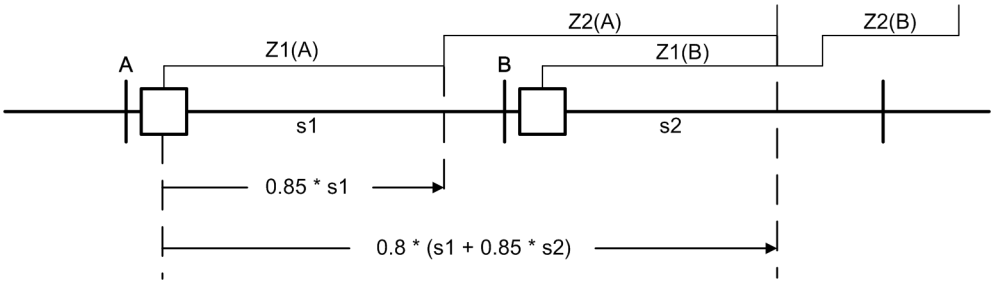
Parameter: Directional mode

- Recommended setting value **(_:109) Directional mode**= ***forward***

You can use the **Directional mode** parameter to define whether the zone operates ***forward***, ***reverse*** or ***non-directional***. Set the parameter **Directional mode** for the specific application.

Parameter: Incr. resist. tolerance

- Default setting **(_:103) Incr. resist. tolerance** = ***no***



With the **Incr. resist. tolerance** parameter, you can set whether the zone is to have an increased resistance reserve (= ***yes***) or not (= ***no***).

Parameter: Zr impedance reach

- Default setting **(_:102) Zr impedance reach**= ***2.500 Ω***

You can use the **Zr impedance reach** parameter to define the reach of the zone. Determine the setting value for the specific application.

First, create a time-grading schedule for the entire galvanically connected system. Enter the section lengths with their primary reactances X in Ω/km into the time-grading schedule. The reactances X then define the range of the distance-protection zones.

[dwstaffz-140211-01.tif, 1, en_US]

Figure 6-312 Setting of the Range – Example for Device A

Set the reach of Zone Z1 to about 85 % of the line section to be protected. Zone Z1 should trip without delay. Set the time delay of Zone Z1 to 0.00 s. The protection then switches off faults at this distance with its operating time. For higher levels, increase the time delay by 1 grading time increment.

The grading time must take the following factors into consideration:

- Circuit-breaker opening time including variation
- Dropout time for protection systems
- Variation in time delays

The usual grading times are 0.2 s to 0.4 s. Set the reach of Zone Z2 to a value that extends to about 80 % of the lower-level zone of the protection for the shortest subsequent line (see *Figure 6-312*).

When parameterizing using PC and DIGSI, you can select to enter the values in either primary or secondary variables. If you wish to enter secondary variables during parameterization, convert the primary values from the time-grading schedule into secondary values as follows:

$$Z_{secondary} = \frac{Ratio_I}{Ratio_V} \cdot Z_{primary}$$

[fofpmsek-140409-01.tif, 1, en_US]

EXAMPLE:

Belted cable 10 kV with Al jacket 3 x 120 mm² and the data:

s (length)	8.5 km
R_1/s	0.15 Ω/km
X_1/s	0.10 Ω/km
R_0/s	0.83 Ω/km
X_0/s	0.31 Ω/km

Current transformer	500 A/5 A
Voltage transformer	10 kV/0.1 kV

Use the data to calculate the line impedance as follows

$$Z_L = \sqrt{0.15^2 + 0.10^2} \cdot \frac{\Omega}{\text{km}} \cdot 8.5\ \text{km} = 0.18 \frac{\Omega}{\text{km}} \cdot 8.5\ \text{km} = 1.53\ \Omega$$

[fo_zl_circlezone, 1, en_US]

If you set the first zone to 85 % of the line length, the following setting values result:

Primary:

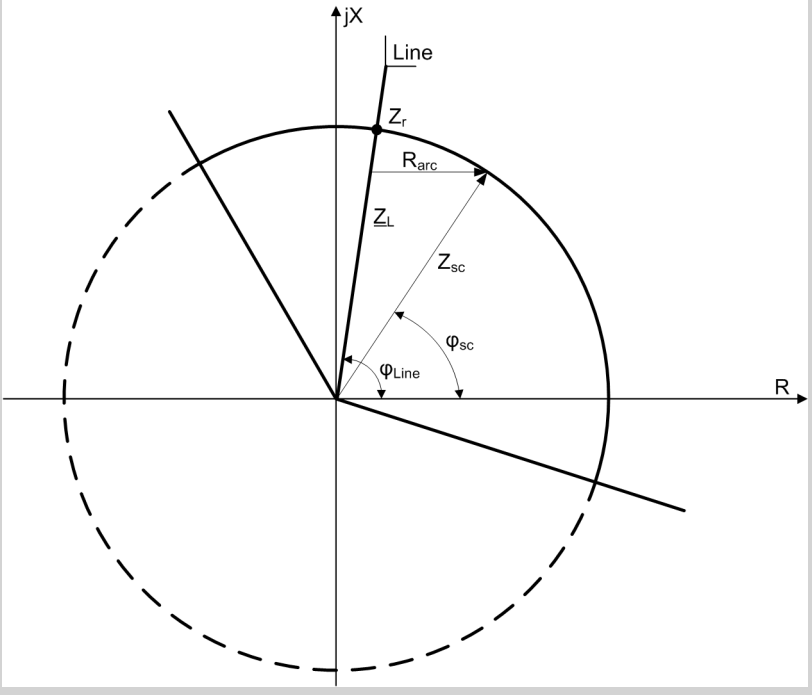
$$Z1_{prim} = 0.85 \cdot Z_L = 0.85 \cdot 1.53\ \Omega = 1.30\ \Omega$$

Secondary:

$$Z1_{sec} = \frac{Ratio_I}{Ratio_V} \cdot Z1_{prim} = \frac{500\ \text{A}/5\ \text{A}}{10\ \text{kV}/0.1\ \text{kV}} \cdot 1.30\ \Omega = 1.30\ \Omega$$

Parameter: Angle for R-reserve

- Default setting **(_:113) Angle for R-reserve** = ***60.0°***



With the **Angle for R-reserve** parameter, you define the transition from the impedance circle to the curve of the increased resistance reserve (see *Figure 6-316*).

The natural resistance reserve of the impedance circle consists in the horizontal distance between the line and the periphery of the circle.

EXAMPLE:

Resistance reserve for overhead lines

For overhead lines, the presence of a fault resistance (arc) causes underreaching of the distance zones because the resistance reserve at the breakdown point is 0, but then increases sharply in the direction of the coordinate origin (see the following figure).

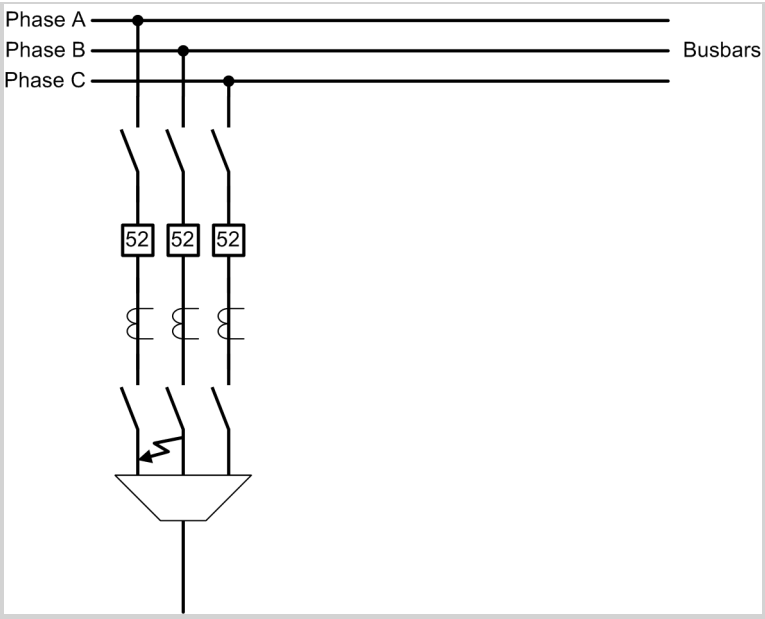
[dw_resistanzreserve-impedanzkreis-bei-freiltg, 1, en_US]

Figure 6-313 Resistance Reserve of the Impedance Circle for Overhead Lines

Z_r	Set reach
$\underline{Z}_L$	Line impedance
φ_{line}	Line angle
R_{arc}	Arc resistance
Z_{sc}	Short-circuit impedance
φ_{sc}	Short-circuit angle

The resistance reserve R_{arc} in this case depends on the line angle and on the underreaching of the distance zone that is to be tolerated. For a line angle of $\varphi_{line} = 80°$ and 10 % underreaching, for example, the resistance reserve is 30 % of the balance-point impedance.

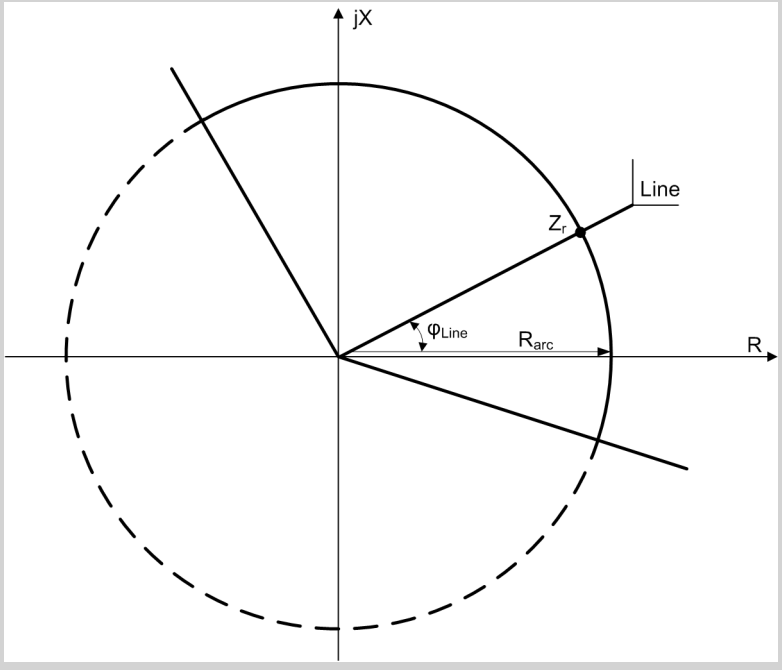
The following table shows additional values for the resistance reserve at the impedance circle:



Line Angle φ_{line}	Resistance Reserve R_{arc} for Tolerable Underreaching of		
	10 %	**15 %**	**20 %**
85°	36 %	45 %	53 %
80°	30 %	40 %	47 %
75°	26 %	35 %	42 %
70°	22 %	31 %	38 %
65°	19 %	27 %	35 %
60°	17 %	25 %	32 %
All percentage values relate to the balance-point impedance (= circle radius)			

EXAMPLE:

Resistance reserve for cables

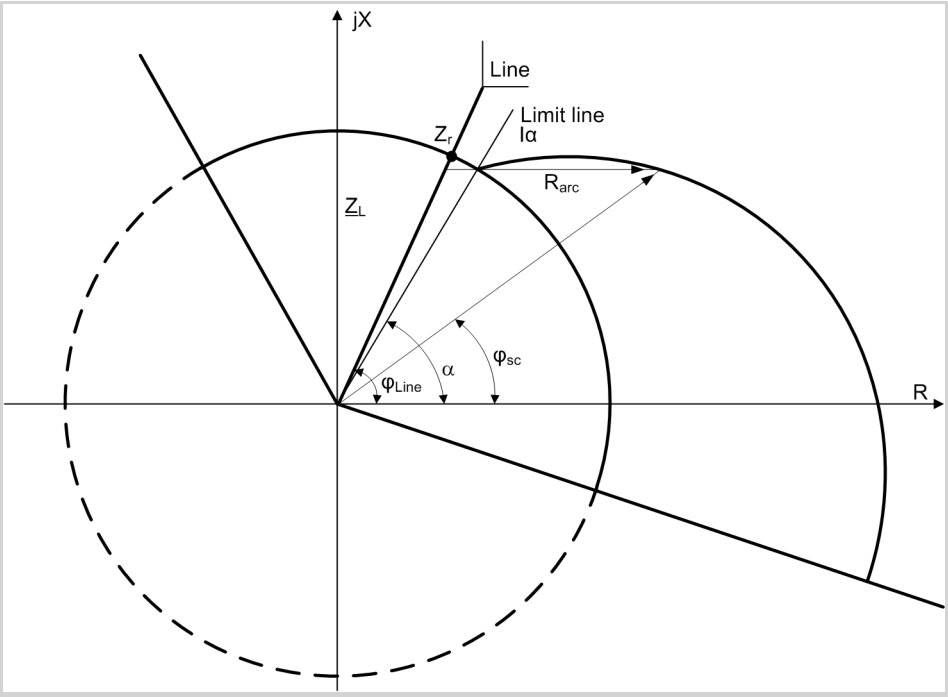


For cables, the resistance reserve in the vicinity of the breakdown point is not relevant, but rather the local resistance reserve. Since an arc is practically impossible in the cable itself, the resistance reserve only has to take account of the arc faults in the vicinity of the local sealing end (*Figure 6-314*).

The impedance circle here covers fault resistances up to the absolute value of the balance-point impedance (*Figure 6-315*).

[dw_kabelabg-mit-lichtbogenfehler-am-oertl-endverschluss, 1, en_US]

Figure 6-314 Outgoing Cable with Arc Fault at Local Sealing End



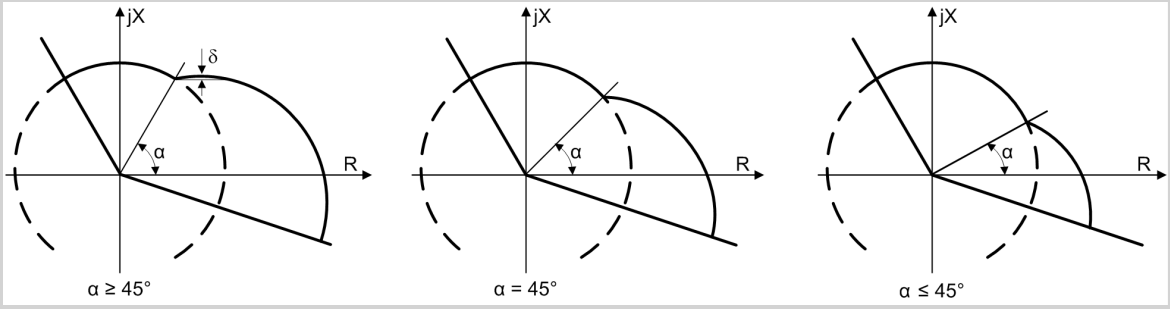
[dw_oertl-resistanzreserve-impedanzkreis-bei-kabel, 1, en_US]

Figure 6-315 Local Resistance Reserve of the Impedance Circle for Cables

EXAMPLE:

Increased resistance reserve

If you wish to increase the reserve for fault resistances, you must set the parameter **`Incr. resist. tolerance`** = ***`yes`***. In this case, the impedance circle is increased by an extension in the R direction (*Figure 6-316*). The angle α in this case determines the transition from the impedance circle to the curve of the increased resistance reserve.



[dw_bsp-eine-erhoehte-resistanzreserve-mit-erweiterung, 1, en_US]

Figure 6-316 Example of Increased Resistance Reserve

This extension leads to an increased resistance reserve both in the vicinity of the breakdown limit and in the vicinity of the installation location. The curvature of the extension curve in the X direction can determine an overreaching. This overreaching can be tolerated within certain limits, however, because the breakdown limit in any case normally has a 15 % reserve distance from the next station, that is from the end of the line.

There is no extension-induced overreaching for limit angles α (for example, parameter **(_:113) Angle for R-reserve** for the 1st zone) of 45° or less. The greater the set value of α, the greater the possible overreaching. The following figure qualitatively shows the shape of the operate curve for different angles α.

[dw_quali-verlauf-ausloesekennl-erhoeht-resistanzreserve, 1, en_US]

Figure 6-317 Qualitative Plot of the Operate Curve for Increased Resistance Reserve

Since the overreaching and the resistance reserve both depend on the line angle φ_{line} and on the set limit angle α, a few reference values are listed in the following sections.

The resistance reserve for short-circuits through an arc near of the breakdown point is primarily relevant for overhead lines. Select the limit angle α (for example, parameter **(_:113) Angle for R-reserve** for the 1st zone) so that a high resistance reserve goes into effect without impermissibly high overreaching.

Note the following:

- Do not set the parameter **Angle for R-reserve** to a value greater than the line angle.
- Do not set the parameter **Angle for R-reserve** above 75°.

Otherwise, increased overreaching may occur in the event of arc faults. The following table shows the conditions for some examples of the approximate overreaching caused by setting an increased resistance reserve.

α	Possible Overreaching Values Due to Arc Faults for a Line Angle of								
	90°	**85°**	**80°**	**75°**	**70°**	**65°**	**60°**	**55°**	**50°**
75°	10 %	11 %	12 %	14 %	-[47]	-[47]	-[47]	-[47]	-[47]
70°	3 %	4 %	5 %	7 %	10 %	-[47]	-[47]	-[47]	-[47]
65°	0 %	0 %	0 %	0 %	3 %	7 %	-[47]	-[47]	-[47]
60°	0 %	0 %	0 %	0 %	0 %	0 %	4 %	-[47]	-[47]
55°	0 %	0 %	0 %	0 %	0 %	0 %	0 %	2 %	-[47]
50°	0 %	0 %	0 %	0 %	0 %	0 %	0 %	0 %	1 %

As with the base circle, the level of the resistance reserve R_{arc} depends on the line angle and on the tolerable underreaching of the distance zone (also see *Figure 6-316*). The following table shows the approximate resistance reserve for tolerable underreaching of 15 %.

α	Resistance Reserve R_{arc} for Tolerable Underreaching of 15 % at a Line Angle of								
	90°	**85°**	**80°**	**75°**	**70°**	**65°**	**60°**	**55°**	**50°**
75°	148 %	141 %	135 %	129 %	-[47]	-[47]	-[47]	-[47]	-[47]
70°	137 %	131 %	125 %	120 %	116 %	-[47]	-[47]	-[47]	-[47]
65°	125 %	118 %	112 %	108 %	105 %	102 %	-[47]	-[47]	-[47]
60°	107 %	100 %	96 %	93 %	91 %	90 %	89 %	-[47]	-[47]
55°	-[48]	-[48]	59 %	86 %	71 %	73 %	75 %	77 %	-[47]
50°	-[48]	-[48]	-[48]	-[48]	-[48]	36 %	55 %	61 %	65 %

The resistance reserve in the near the breakdown point is not relevant for cables but rather the local resistance reserve, that is for $\varphi_{sc} = 0°$. To avoid overreaching, do not set the parameter **`Angle for R-reserve`** to a value greater than the line angle here either. The resistance reserve is derived from the R axis segment (X = 0) of the expanded operate curve. The following table shows some values for various setting values of the parameter **`Angle for R-reserve`**:

α	Resistance Reserve R_{arc} for X = 0
65°	190 %
60°	186 %
55°	181 %
50°	176 %
45°	170 %
40°	164 %
35°	157 %
30°	150 %
25°	142 %
20°	134 %
15°	125 %
10°	117 %
All percentage values relate to the balance-point impedance (= circle radius)	

For the higher zones, a resistance reserve lower than that for the 1st zone makes sense (relative to the impedance reach in each case). To do this, adjust the parameter **`Angle for R-reserve`** to a lower value.

47 The condition $\alpha \leq \varphi_{line}$ is not fulfilled here.

48 Underreaching greater than 15 %

Parameter: Operate delay (1-phase)

- Default setting **(_:110) Operate delay (1-phase)** = ***0.00 s***

With the **Operate delay (1-phase)** parameter, you set the grading time of the zone for 1-pole short circuits. Set the **Operate delay (1-phase)** for the specific application.

Parameter: Operate delay (multi-ph.)

- Default setting **(_:112) Operate delay (multi-ph.)** = ***0.00 s***

With the **Operate delay (multi-ph.)** parameter, you set the grading time of the zone for multi-phase faults. Set the **Operate delay (multi-ph.)** for the specific application.

Parameter: Kr and Kx

- Default setting **(_:105) Kr** = ***1,00***
- Default setting **(_:106) Kx** = ***1,00***

With the **Kr** and **Kx** parameters, you set the residual compensation with scalar factors.

NOTE

The parameters **Kr** and **Kx** are visible in the zone only if you have set the parameter**Zone-spec. residu. comp.** = ***yes*** in the zone and the parameter **Set. format residu. comp.** = ***Kr, Kx*** for the device. You can only change the setting value of the parameter **Set. format residu. comp.** in DIGSI 5 under **Device settings**.

Parameter: K0 and Angle (K0)

- Default setting **K0** = ***1.000***
- Default setting **Angle (K0)** = ***0.00°***

You can use the **K0** and **Angle (K0)** parameters to set the residual compensation with the complex residual compensation factor.

NOTE

The parameters **K0** and **Angle (K0)** are visible in the zone only if you have set the parameter **Zone-spec. residu. comp.** = ***yes*** in the zone and the parameter **Set. format residu. comp.** = ***K0*** for the device. You can only change the setting value of the parameter **Set. format residu. comp.** in DIGSI 5 under **Device settings**.

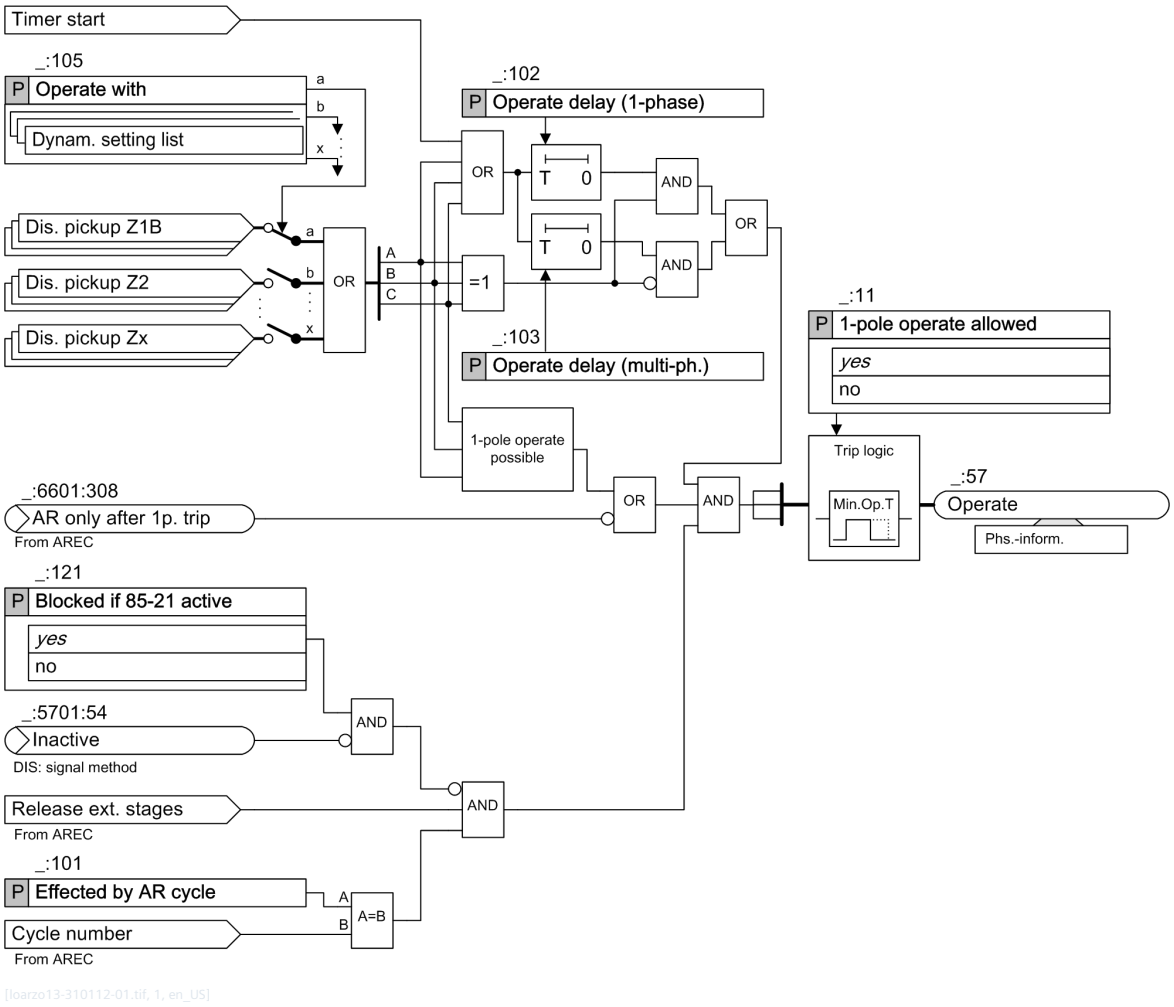
6.15.10 Release of Tripping through AREC Zone

6.15.10.1 Description

The AREC zone works together with the **Automatic reclosing** function. In order for automatic reclosing to be successful, short circuits on the entire transmission route to all line ends must be switched off at the same time and with as little delay as possible. In addition, with distance protection, the AREC zone may be functioning as an overreaching distance zone, or example, Zone Z1B, prior to automatic reclosing. After automatic reclosing, the AREC zone is typically no longer in effect. For the relevant AREC cycle, short circuits up to the breakdown point of the AREC zone can be switched off quickly (see following figure). Before automatic reclosing, limited non-selectivity in favor of fast simultaneous disconnection is acceptable. Automatic reclosing will be performed in any case. The normal stages of the distance protection (Z1, Z2, etc.) are typically operated independently of the automatic reclosing function.



[dw_reichweite_ar_zone, 1, en_US]

Figure 6-318 Reach Control Before 1st Reclosure for Distance Protection

The automatic reclosing zone is available in the function library in DIGSI (in **Line function group** → **Distance protection** → **Zone types**). If necessary you can insert the automatic reclosing zone into the **Distance protection** function. The automatic reclosing zone can be controlled from the internal automatic reclosing function and also externally via the automatic reclosing function type **Operation with external automatic reclosing function**.

Logic

[loarzo13-310112-01.tif, 1, en_US]

Figure 6-319 Logic of the Automatic Reclosing Zone

Mode of Operation

The automatic reclosing zone is an instance of controlled trip logic. You use the parameter **Operate with** to select which distance zones will deliver the pickup information. If the selected distance zones have picked up and a release from the automatic reclosing function is present, the automatic reclosing zone generates an operate indication.

You use the parameter **Effected by AR cycle** to select the automatic reclosing cycle for the release of tripping. If you wish to have a zone release in several automatic reclosing cycles, you must instantiate several automatic reclosing zones and select a different automatic reclosing cycle for each zone. If the selected automatic reclosing cycle is only parameterized for 1-pole tripping (indication *(_:6601:308) AR only after 1p. trip*), the automatic reclosing zone only trips if this operate indication leads to a 1-pole trip command in the trip logic of the Circuit breakers function group.

The, both the 3-pole coupling via pickup or trip command and the handling of 2-pole phase-to-phase short circuits are considered.

If the selected automatic reclosing cycle is parameterized for 1-pole operation and the parameter **1-pole operate allowed** is set to ***no*** , the automatic reclosing zone indicates *Inactive* .

If the function **teleprotection with distance protection** is present and in effect, you can block the automatic reclosing zone with the parameter **Blocked if 85-21 active** . The AREC zone is active only if the teleprotection with distance protection is not in effect, for example, with a communication failure. If the teleprotection with distance protection is in effect, you achieve 100% selectivity through the teleprotection method as distance protection only if the comprehensive AR zone is blocked.

6.15.10.2 Application and Setting Notes

Parameter: Operate with

- Recommended setting value **(_:105) Operate with** = ***Z1B***

You use the parameter **Operate with** to specify which distance zones will generate an operate indication when pickup occurs while an automatic reclosing release is present. Typically, you use an overreaching distance zone. This is called Z1B in the application templates.

The selection texts for the parameter **Operate with** are identical to the texts you assign during zone configuration in the **Distance protection** function.

Parameter: Operate delay (1-phase)

- Recommended setting value **(_:102) Operate delay (1-phase)** = ***0.00 s***

The **Operate delay (1-phase)** parameter is used to set the tripping delay of the automatic reclosing zone for 1-phase short circuits. Set the parameter **Operate delay (1-phase)** for the specific application. If the distance zone selected with the parameter **Operate with** picks up and all release conditions are met, the distance zone trips with the **Operate delay (1-phase)** set here.

Parameter: Operate delay (multi-ph.)

- Recommended setting value **(_:103) Operate delay (multi-ph.)** = ***0.00 s***

You can use the **Operate delay (multi-ph.)** parameter to set the tripping delay for multi-phase short circuits. Set the parameter **Operate delay (multi-ph.)** for the specific application. If the distance zone selected with the parameter **Operate with** picks up and all release conditions are met, the distance zone trips with the **Operate delay (multi-ph.)** set here.

Parameter: Effected by AR cycle

- Recommended setting value **(_:101) Effected by AR cycle** = ***1***

You use the parameter **Effected by AR cycle** to select the automatic reclosing cycle for the release of tripping. If you wish to have a zone release in several automatic reclosing cycles, you must instantiate several automatic reclosing zones and select a different automatic reclosing cycle for each zone. If you use the **automatic reclosing** function with the **operation with external reclosing system** or **automatic reclosing with adaptive dead time (ADT)** function type, you must retain the default setting ***1***.

If the selected automatic reclosing cycle is only parameterized for 1-pole tripping (indication *(_:6601:308) AR only after 1p. trip*), the automatic reclosing zone only trips if this operate indication leads to a 1-pole trip command in the trip logic of the Circuit breakers function group. If you do not use the **Automatic reclosing** function, you must delete the automatic reclosing zone in the **Distance protection** function in order to ensure consistent parameterization in DIGSI.

Parameter: Blocked if 85-21 active

- Recommended setting value **(_:121) Blocked if 85-21 active** = ***yes***

The **Blocked if 85-21 active** parameter is used to block the automatic reclosing zone with the teleprotection method in effect. If the function **teleprotection with distance protection** is present and in effect, Siemens recommends blocking the automatic reclosing zone. To do this, set the parameter **Blocked if 85-21 active** = ***yes***. If the parameter **Blocked if 85-21 active** = ***yes*** is set, the AR zone is active only if the teleprotection with distance protection is no in effect (for example, in the case of a communication failure).

6.15.10.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
AR zone #				
_:1	AR zone #:Mode		• off • on • test	on

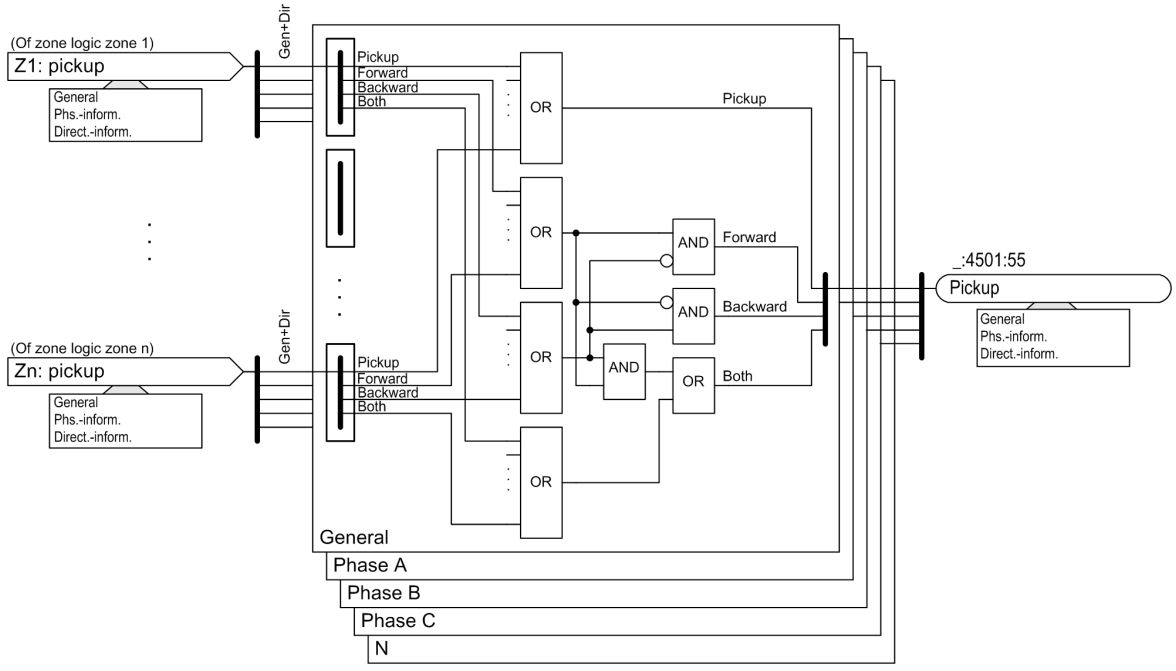
6.15.11 Output Logic of the Distance Protection

Mode of Operation

The output logic treats the pickup and trip signals of the distance zones separately, in one pickup logic and one trip logic each. The pickup and trip logic generate the superordinate indications of the distance protection.



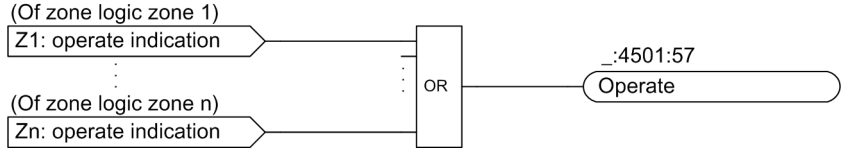
General Pickup

In impedance pickup, the signal *General* is generated once a fault is reliably detected in the working area of a zone. In the pickup methods I>, V, and V/Phi, the signal *General* is generated when a pickup condition is met.

The signal *General* is indicated and can be further processed by internal and external additional functions, for example, teleprotection scheme or automatic reclosing.

Pickup Logic

The distance zone pickups are combined phase-selectively and output as indications.



[loanrdis-140211-01.tif, 2, en_US]

Figure 6-320 Pickup Logic

Trip Logic

The trip signals of the distance zones always lead to a 3-phase operate indication of the distance protection.

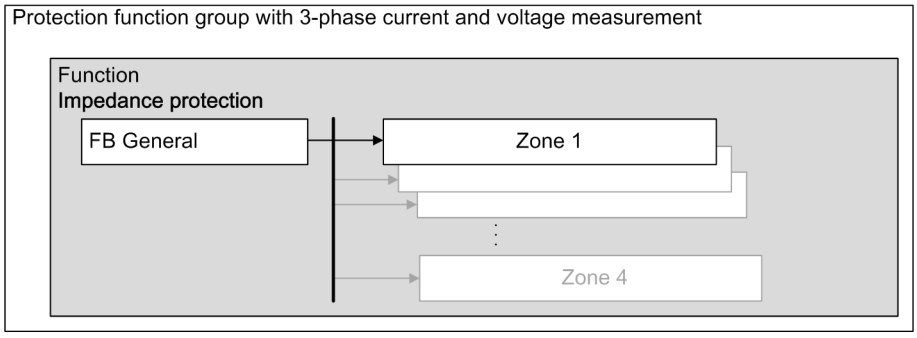
[loaus3po-140211-01.tif, 1, en_US]

Figure 6-321 3-Phase Trip Logic

6.16 Impedance Protection

6.16.1 Overview of Functions

The **Impedance protection** function (ANSI 21):



- Protects transformers as backup protection for transformer differential protection
- Is used as a backup protection for the transformer and the generator in the block units of power stations
- Functions as backup protection in the event of energy recovery to faults in the upstream electrical power system beyond a transformer

6.16.2 Structure of the Function

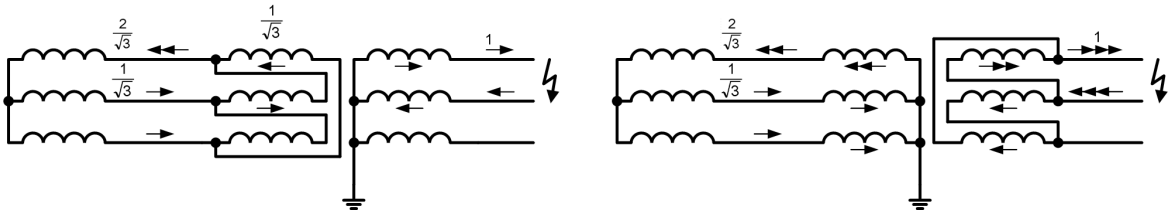
The **Impedance protection** function is used in protection function groups which provide current and voltage measurement values.

The **Impedance protection** function is preconfigured at the factory with the function block (FB) **General** and **one** zone. A maximum of **4** zones can be operated simultaneously in the function. The zones are structured identically.

The protection function is structured in that way that the settings in the FB **General** are valid for all zones.

[dw_strimpedanceprot, 3, en_US]

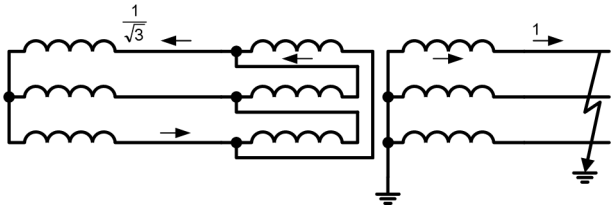
Figure 6-322 Structure/Embedding of the Function



6.16.3 Description

Impedance Measurement via the Transformer

Pay attention to the following features when measuring impedance in or via transformers:



- Impedance is transferred to the side to be measured using the quadrant of the transformer ratio.
- For star-delta transformers, an opposite phase rotation occurs in the positive-sequence and negative-sequence system, depending on the vector group. This changes the fault situation on the other side. A 2-phase short circuit on the star side appears as a 3-phase short circuit with different current distribution on the delta side (see *Figure 6-323*).

  Since star-delta transformers do not permit the zero-sequence system to be transferred, a 1-phase ground fault on the star side appears as a 2-phase short circuit on the delta side (see *Figure 6-324*).
- In the case of auto transformers and transformers grounded on both sides in the star-star connection, measurement through the transformer is possible. Here, distance protection for lines can be used without any problems.

[dw_ratio-2pol-ifault, 2, en_US]

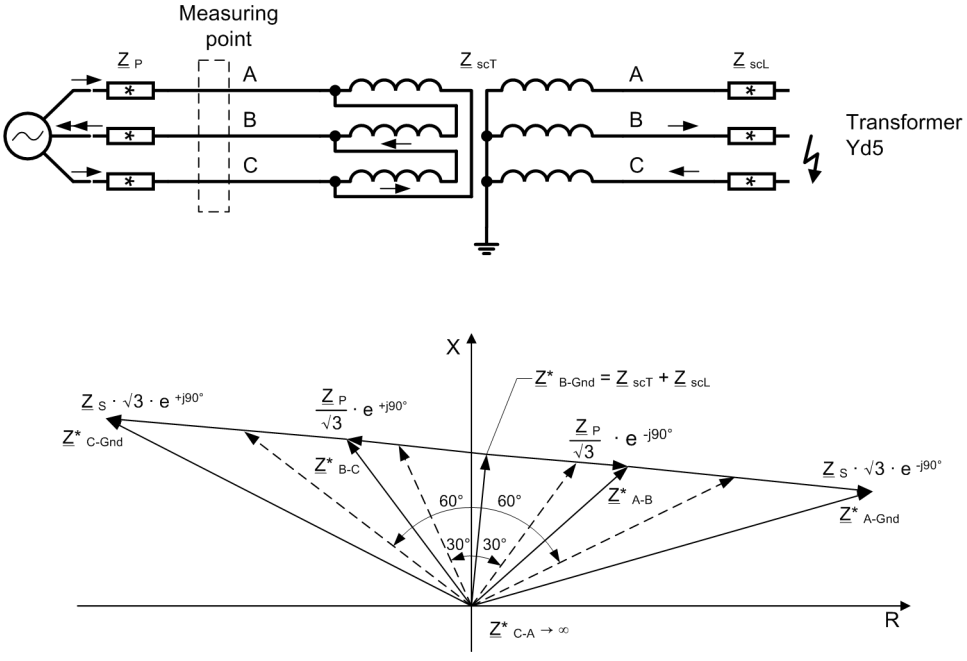


Figure 6-323 Transformation of a 2-Phase Short-Circuit Current

[dw_ratio-1pol-fault, 2, en_US]

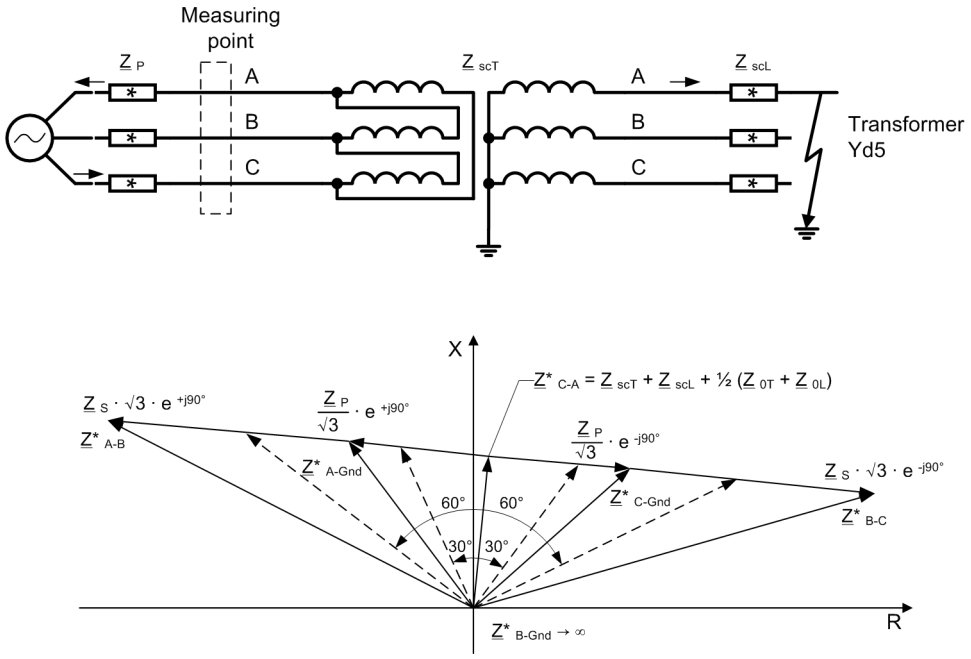

Figure 6-324 Transformation of a 1-Phase Short-Circuit Current

The changed measurand mapping also leads to a different impedance mapping. *Figure 6-325* and *Figure 6-326* show, for example, for a 2-phase or 1-phase short circuit on the star side, the resulting phasors on the delta side. To simplify it, the transformer ratio was assumed to be **1**.

[dw_imp-2pol-short-ciruit, 2, en_US]

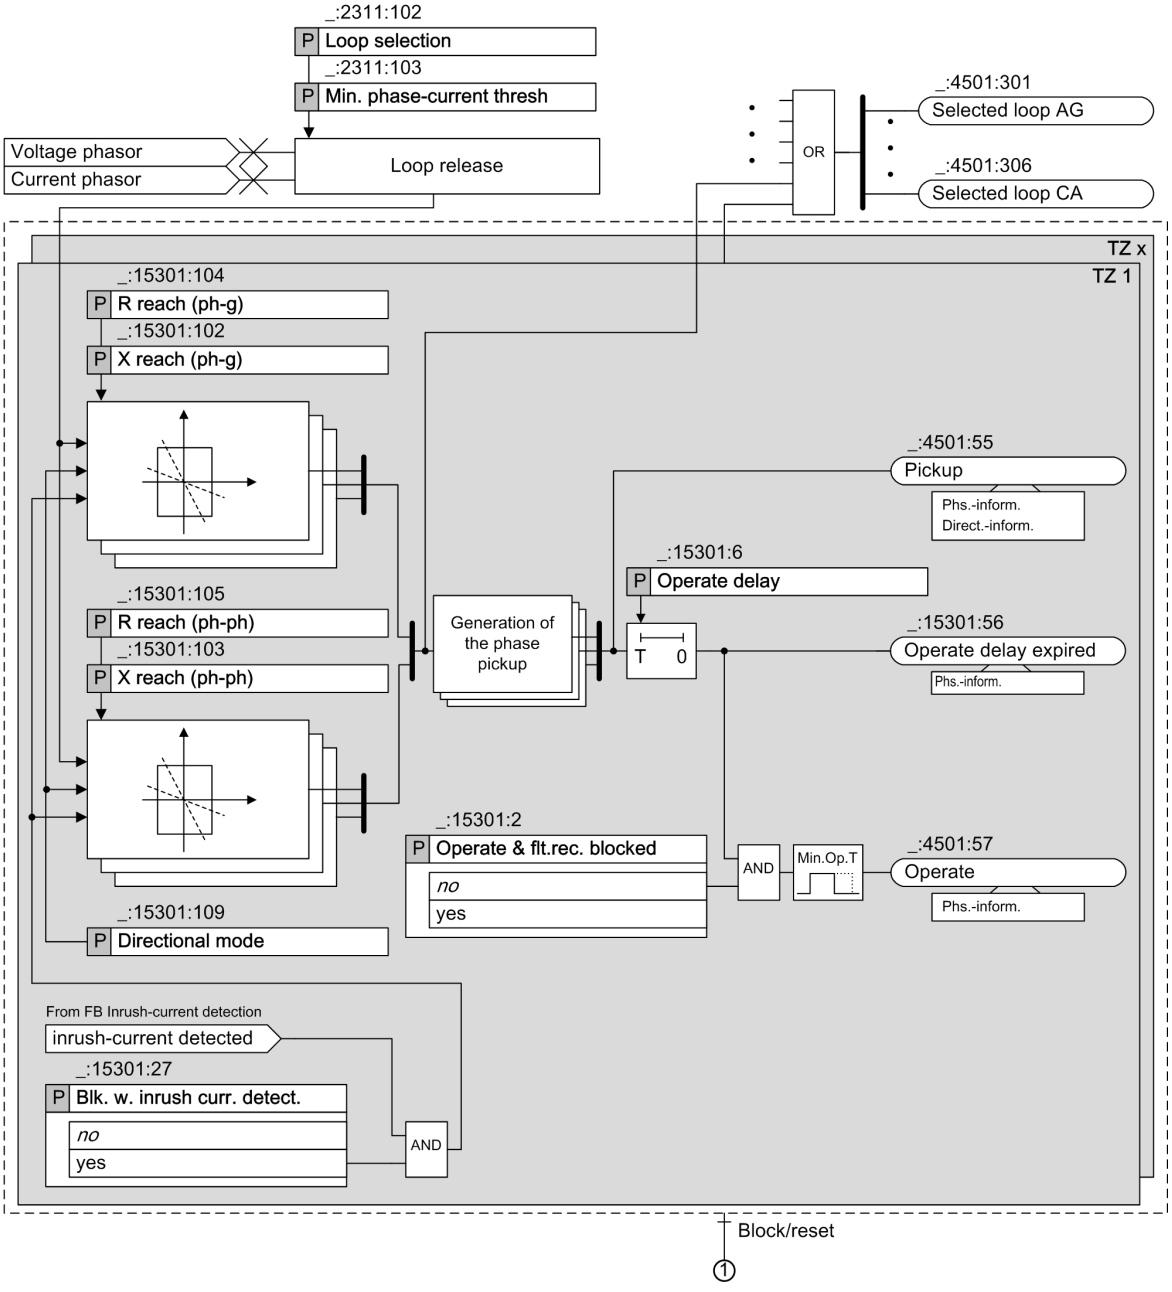
Figure 6-325 Impedance Measurement with a 2-Phase Short Circuit

[dw_imp-1pol-short-ciruit, 2, en_US]

Figure 6-326 Impedance Measurement with a 1-Phase Short Circuit

With a 2-phase short circuit, the phase-to-ground impedance of the phase corresponds to the double phase current of the actual fault impedance via the transformer. The impedance is correctly measured. All other impedances are measured as considerably larger. Subtracting the currents results in an infinite impedance measured value for the C-A loop.

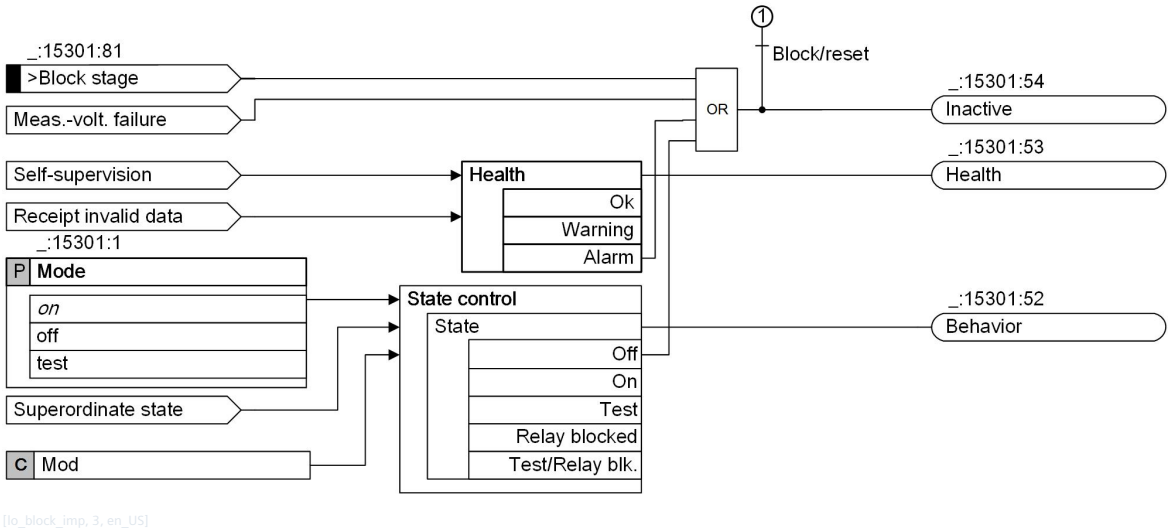
A 1-phase ground fault results in the smallest impedance value based on the calculation with phase-to-phase voltages (in the example, C-A). Because the zero-sequence system cannot be transferred via a star-delta transformer, an impedance is measured that is too large by the amount of the zero-sequence impedances (transformer, line). The actual fault location is seen as being farther away.



With a 3-phase short circuit, the impedance measurement for all measuring loops is correct.

The following table summarizes the results of the impedance measurement for a star-delta transformer:

Table 6-7 Fault Mapping and Measuring Errors during the Impedance Measurement of a Star-Delta Transformer

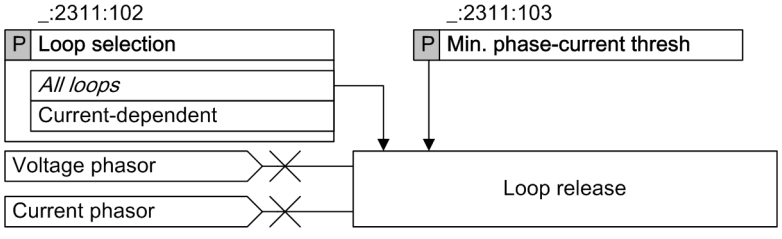


Power-System Incident on the Star Side	Fault Mapping on the Delta Side	Correct Impedance Loop	Measuring Error
3-phase short circuit	3-phase short circuit	Phase-to-ground and phase-to-phase loop	Correct measurement
2-phase short circuit	3-phase short circuit, different fault-current distribution	Phase-to-ground loop with largest fault current	Correct measurement
1-phase ground fault	2-phase short circuit	Phase-to-phase loop, but with measuring error	Impedance measured too large by the amount of the zero-sequence impedance (0.5 Z0)

Logic of the Function

[lo_dis-impedance-protection, 3, en_US]

Figure 6-327 Logic Diagram for Impedance Protection



[lo_block_imp, 3, en_US]

Figure 6-328 Logic Diagram for Impedance Protection (Continued)

Loop Selection

The function **Impedance protection** can be used in electrical power systems and plants with different neutral points. With the **`Loop selection`** parameter, you control which parameters influence the loop release.

In power systems with effective neutral point grounding – solidly or low-impedance grounded neutral point – all impedance loops (phase-to-ground and phase-to-phase loops) can work parallel to each other. When all loops are working in parallel, the loop release is controlled by the parameter **`Min. phase-current thresh`** (see following figure).

[lo_loopselect1 impprot, 3, en_US]

Figure 6-329 Effective Parameter for Loop Release for All Loops

In power systems with a non-effective neutral point grounding – isolated, grounded, or high-impedance grounded neutral point – the control for the loop selection is necessary to avoid an overfunction, for example, a ground fault. The loop selection is controlled by the ***`Current-dependent`*** parameter. The following figure shows which parameter controls the loop selection.

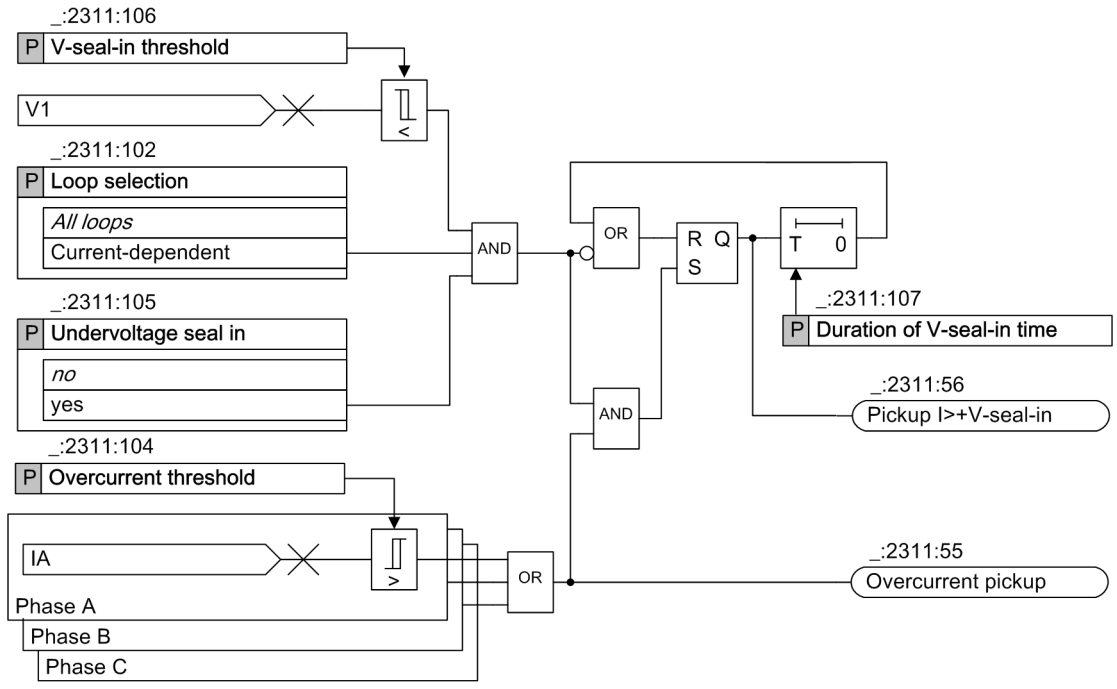


Figure 6-330 Effective Parameter in Current-Dependent Loop Release

In case of a ground fault, the voltage collapsed – ideally to 0 – and the phase-to-ground loop measures either a small impedance or 0 Ω. The phase-selective overcurrent detection releases the loops (parameter **Overcurrent threshold**). The undervoltage seal-in (parameter **Undervoltage seal in**) keeps the overcurrent erect. The undervoltage seal-in is necessary for use in power plants when an exciting transformer is connected to the generator bus. During a near short circuit, the excitation voltage collapses and results in a decreased synchronous generated voltage. Thereby the fault current sinks below the rated current and thereby the current threshold value (parameter **Overcurrent threshold**). The parameter **V-seal-in threshold** monitors the positive-sequence voltage. The undervoltage seal-in drops out when the threshold value **V-seal-in threshold** is topped or the undervoltage seal-in time (parameter **Duration of V-seal-in time**) runs out.

The following rules apply for loop selection:

- In the event of 1-phase pickup, an associated phase-to-ground loop is used.
- In the event of 2-phase pickup, an associated phase-to-phase loop with the applicable phase-to-phase voltage is used for the impedance calculation.
- In the event of a 3-phase pickup, the loop selection is dependent on the ratio of the current amplitudes of the phases to one another.

The following table shows the measuring-loop selection:

Pickup		Measuring Loops	
1-phase	A B C	Phase-to-ground	A-gnd B-gnd C-gnd
2-phase	A, B B, C C, A	Phase-to-phase	A-B B-C C-A

Pickup		Measuring Loops	
3-phase with unequal phase current amplitudes	A, 2· B, C B, 2· C, A C, 2· A, B	When the current in 1 phase is double the size, the phase-to-ground loops are measured.	B-gnd C-gnd A-gnd
	(A, B) ≈ 2 · C (B, C) ≈ 2 · A (C, A) ≈ 2 · B	When the current in 2 phases is double the size, the phase-to-phase loops are measured.	A-B B-C C-A
3-phase with equal amplitudes	A, B, C	When all voltages are almost equal, the phase-to-phase loops are measured. All 3 loops are released.	A-B B-C C-A

Impedance Measurement

From the sampled values of the phase currents and the phase-to-ground voltages, the fundamental phasors are determined per period using an FIR filter (FIR = Finite Impulse Response). The impedances are calculated from the fundamental phasors. By using the frequency-tracking sampled values, the impedance is measured using another frequency range. This is advantageous for island networks or block-unit power plants, for example, for start-up processes.

There is an impedance measuring element available for each of the 6 possible phase loops A-gnd, B-gnd, C-gnd, A-B, B-C, C-A. If another fault occurs during analysis, the impedances are calculated using the current cyclical measurands. The analysis thus always works with the measurands of the current fault condition.

The impedance for phase-to-phase loops is calculated as follows:

$$\underline{Z}_{ph-ph} = \frac{\underline{V}_{phx\ phy}}{\underline{I}_{phx} - \underline{I}_{phy}}$$

[fo_loop_ZLL, 2, en_US]

The impedance of phase-to-ground loops is calculated as follows:

$$\underline{Z}_{Ph-gnd} = \frac{\underline{V}_{Phx}}{\underline{I}_{Phx}}$$

[fo_loop_ZLE, 2, en_US]

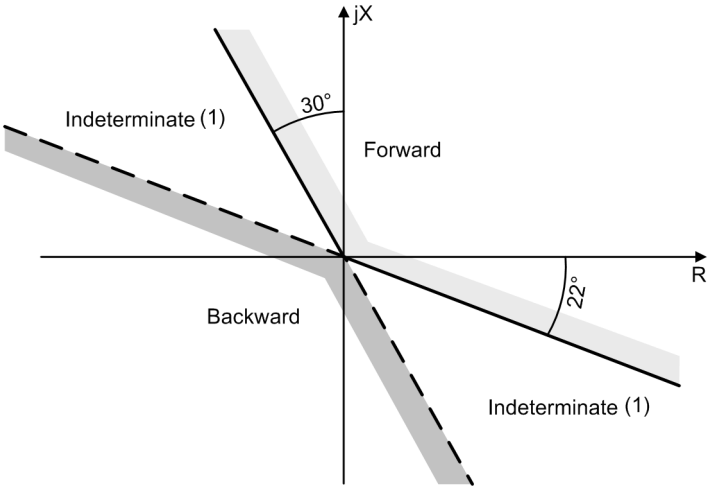
Mode of Operation

If the phase currents exceed the set **`Min. phase-current thresh`**. All released impedance loops are calculated.

To release phase-to-ground loops, it is sufficient if the corresponding phase current exceeds the **`Min. phase-current thresh`**. For phase-to-phase loops, both phase currents and the loop current must exceed the **`Min. phase-current thresh`**.

There is no special ground-fault detection, such as distance protection for lines.

If the released impedance loop(s) lie in one zone, the **Impedance protection** function generates a pickup indication with loop information. At the same time, a pickup indication in the picked up zone occurs with specification of the relevant phase and direction. The direction is subsequently determined for all picked up impedance loops and the associated time delay started. The output logic processes the pickup and trip signals of the zones and forms the pickup and trip signals of the function.



Direction Determination

The direction is determined either using a stored prefault voltage or negative-sequence system variables. If the measured negative-sequence voltage or the negative-sequence current exceed 10 % of the rated values of the device, the variables of the negative-sequence system are used exclusively. For the direction decision, the angle between the negative-sequence current I_2 and the negative-sequence voltage V_2 is evaluated.

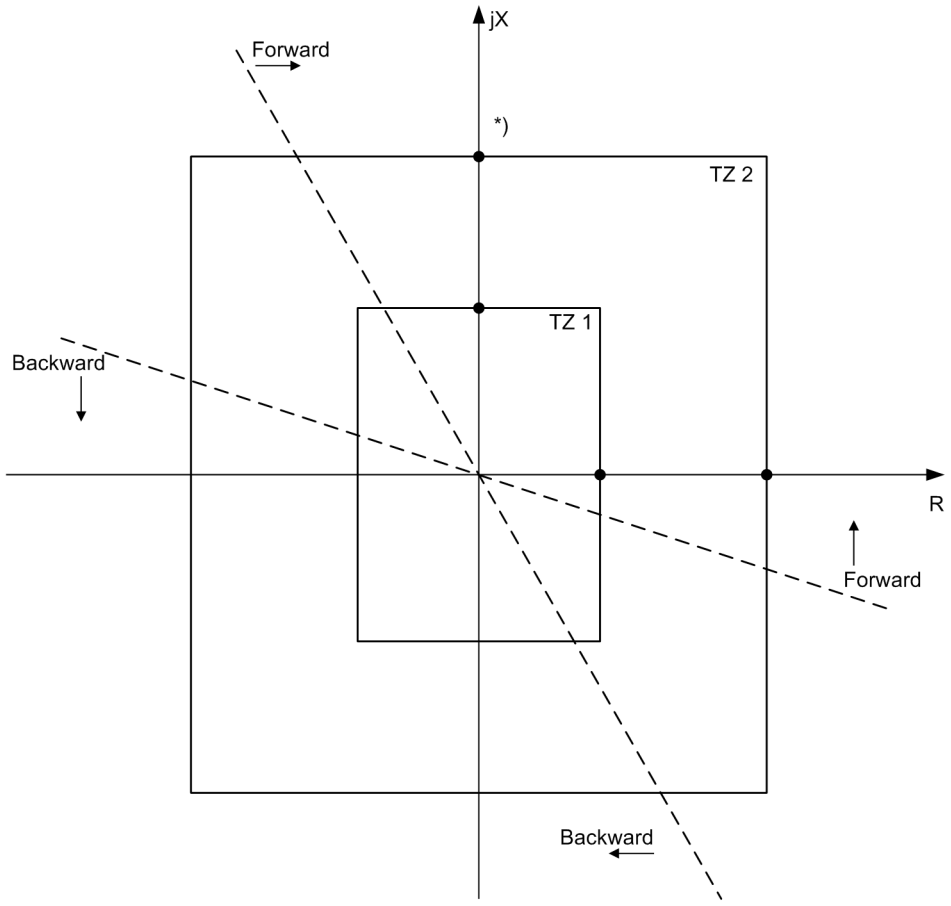
Figure 6-331 shows the defined directional areas on impedance level.

For 3-phase symmetrical short circuits, there is no negative-sequence system. In this case, the memory voltage is used. If the memory voltage is not available either, for example when switching onto a fault, all zones – regardless of their parameterized direction – pick up and generate an operate indication after the time delay has expired.

Optionally, you can link the **Impedance protection** function with the **Instantaneous tripping at switch onto fault** function (see chapter *6.16.4 Application and Setting Notes*). This enables the selected **Impedance-protection** zones to trip without delay.

[dw_ritgkl, 2, en_US]

Figure 6-331 Direction-Characteristic Curve in the R-X Diagram



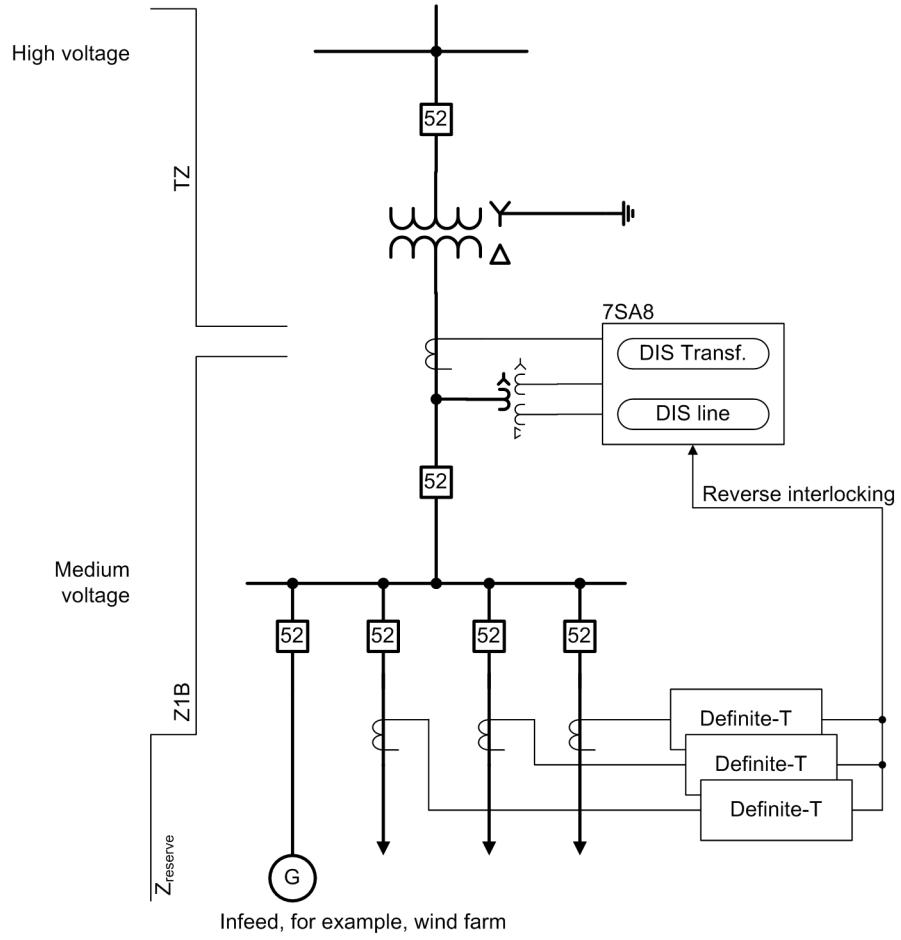
Inrush-Current Detection

If the device is equipped with the **Inrush-current detection** function, you can stabilize the zones against tripping due to transformer inrush currents.

Impedance Polygon

The quadrilateral operate curve (impedance polygon) in the zone is a rectangle in the R-X plane. The polygon is defined by the parameters **`X reach (ph-g)`**, **`X reach (ph-ph)`**, **`R reach (ph-g)`**, and **`R reach (ph-ph)`** and the **`Directional mode`**. This means that, in special situations, a different setting is possible for phase-to-phase and phase-to-ground loops.

To stabilize the quadrilateral limits, the characteristics have a hysteresis of 5 %. If the fault impedance lies within a polygon, the limits are increased by 5 % in all directions. The following figure shows an example with 2 non-directional zones:



[dw_klpoly-impedanceprot, 2, en_US]

Figure 6-332 Operate Curve with Quadrilateral Characteristic

6.16.4 Application and Setting Notes

Sample Configuration

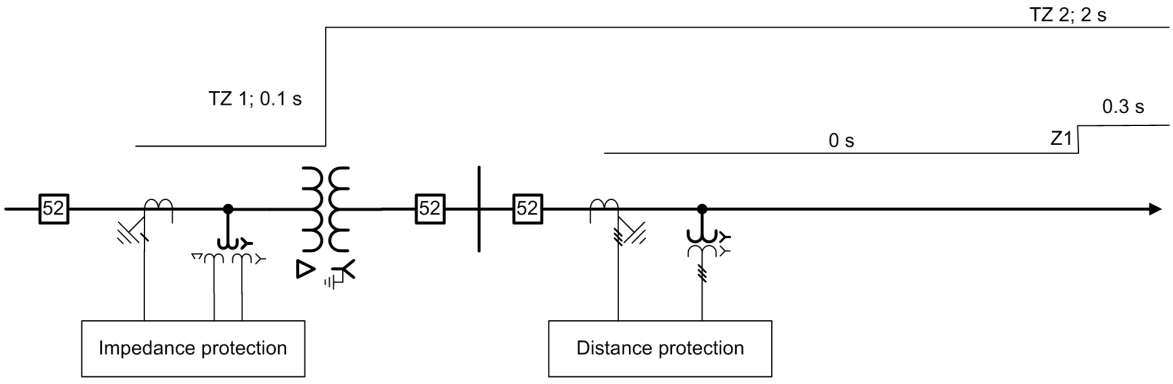
The following figure is an example of how the **Impedance protection** function is used at a feeder point in a medium-voltage power system.

[dw_example-protection, 1, en_US]

Figure 6-333 Example of a Network Protection Application

The medium-voltage power system is fed on the high-voltage side with a YNd5 transformer. In addition, there is an infeed that enables energy recovery to faults occurring on the high-voltage side.

The protection device installed on the delta side of the transformer functions as **distance protection**, which is the backup protection for the medium-voltage power system.



In addition to distance protection, the protection device on the delta side functions as **impedance protection**, which looks in the transformer direction. The power system on the high-voltage side is a meshed system and also contains distance protection devices.

In the following, you can find recommendations for the protection setting values and a view of the setting problems. *Figure 6-334* shows a possible setting approach.

Zone **TZ 1** should be coordinated with the protection system and delayed by approx. 100 ms. The delay makes preferred tripping possible due to the differential protection and a dropout of the zone.

Zone **TZ 2** is intended as a directional reserve stage, whose time must, without fail, be coordinated with the protection system. At the same time, this stage can be used if, when switching the transformer on, it switches onto a fault.

In exchange, the function **Instantaneous tripping at switch onto fault** must be present and set accordingly (see function description in chapter *6.56 Instantaneous Tripping at Switch onto Fault*).

[dw_config-staffel, 1, en_US]

Figure 6-334 System Configuration and Possible Time Grading

For this example, the following data apply:

Table 6-8 Data for Sample Calculations

Transformer	Vector group		YNd5
	Rated voltages	Upper-voltage side	$V_{rated, UV}$ = 230 kV
		Undervoltage side	$V_{rated, LV}$ = 20 kV
	Rated power		S_{rated} = 50 MVA
	Short-circuit voltage		V_{sc} = 12 %
Overhead line	Reactance per unit length		X´ = 0.3 Ω/km
	Length up to $Z_{1, Dis}$		L = 50 km
Transducer	Voltage transformer		20 kV/√3 /100 V/√3 / 100V/3
	Current transformer, Undervoltage side		1500 A/1 A

The primary side reactances are calculated as follows:

Transformer:

$$X_{Tr} = \frac{V_{sc} \cdot V_{rated}^2}{100\ \% \cdot S_{rated}} = \frac{12\ \% \cdot 20^2 kV^2}{100\ \% \cdot 50\ MVA} = 0.96\ \Omega$$

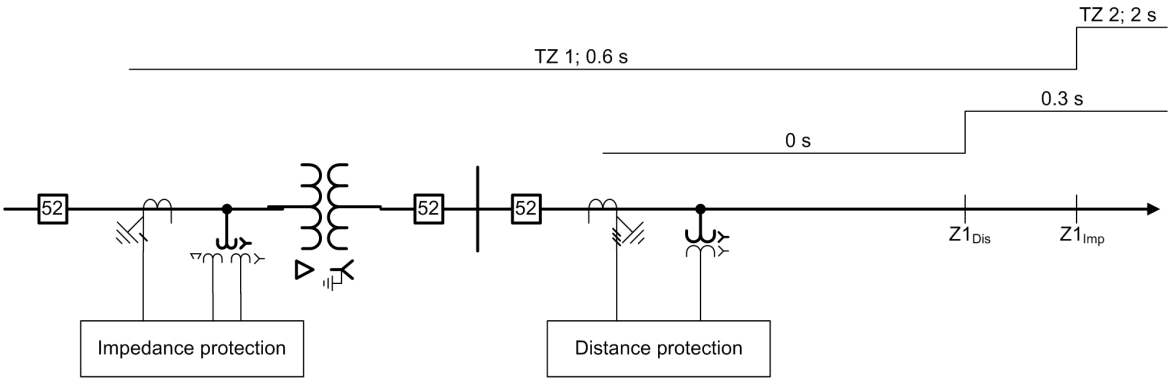
Line (transformed to 20 kV):

$$X_{Ph} = l \cdot X' \cdot \left(\frac{V_{rated\ ,\ UV}}{V_{rated\ ,\ LV}}\right)^2 = 50\ km \cdot 0.3 \frac{\Omega}{km} \cdot \left(\frac{20\ kV}{230\ kV}\right)^2 = 1.5\ \Omega \cdot 0.0756 = 0.011\ \Omega$$

The sample calculation clearly shows that the line reactance can be disregarded compared to transformer reactance due to the quadratic transformation.

To avoid overfunction, select the following setting values for the 1st zone (**TZ 1)**

$X_1 = 0.9 \cdot X_{Tr} = 0.9 \cdot 0.96\ \Omega = 0.864\ \Omega$



For the 2nd zone, select the double transformer impedance and set the time delay correspondingly high.

$X_2 = 2 \cdot X_{Tr} = 2 \cdot 0.96\ \Omega = 1.92\ \Omega$.

With the selected setting, Zone **TZ 1** does not protect the transformer completely, especially if you take into account the incorrect measurement for a 1-phase short circuit.

If you want to achieve a reliable tripping for all fault situations (see *Table 6-7*), the setting value must extend far beyond the transformer. One possible strategy for the time grading is a setting value of approx. 1.5 X_{Tr}.

You must guarantee the selectivity using the **Time** criterion. The following figure shows the time-grading chart:

[dw_grading-x1-xtr, 3, en_US]

Figure 6-335 System Configuration and Possible Time Grading

The zone range in the R direction must take into account the fault resistance on the fault location. The fault resistance is added to the impedance of the fault loop as an additional effective resistance. This fault resistance is, for example, the arc resistance or the dissipation resistance of ground phases. For the zone range in the R direction, you do not have to take the fault resistance on the upper-voltage side and the line resistance into account. These are also divided by the transformer-ratio quadrant and can be mostly disregarded. However, fault resistances on the upper-voltage side during high-current feed on the upper-voltage side also impact the reactance and resistance measurement on the undervoltage side. This impact is unavoidable and can result in a short circuit with fault resistance on the upper-voltage side not being detected by the undervoltage side until the high-current feed on the upper-voltage side is cleared. Do not set the reserve resistance any larger than necessary. The setting can be adjusted to the maximum load in the direction of the line section to be protected, in other words, in the transformer direction. The setting value for the R range must be lower than the resistance under maximum load conditions ($R_{L\,max}$). For a sufficient distance to the load range, Siemens recommends a value of about 20 % to 50 % $R_{L\,max}$. This means an incorrect measurement is avoided by the apparent impedances (see*Figure 6-325* and *Figure 6-326*).

Parameter: Loop selection

- Default setting **(_:2311:102) Loop selection** = ***All loops***

With the parameter **Loop selection**, you control the measuring-loop selection.

Parameter Value	Description
All loops	The function evaluates all 6 impedance loops. Siemens recommends using this setting value for electrical power systems or plants with an effective neutral-point grounding. For effective neutral-point grounding the neutral point is either fixed or low-impedance grounded.
Current-dependent	Use this setting value for electrical power systems or plants with a non-effective neutral-point grounding. For non-effective neutral-point grounding the neutral point is isolated, grounded or high-impedance grounded. Siemens recommends this setting value for generator-protection applications.

Parameter: Min. phase-current thresh

- Default setting **(_:2311:103) Min. phase-current thresh** = ***0.100 A***

With the parameter **Min. phase-current thresh**, you set the lower pickup threshold for the current.

Set the **Min. phase-current thresh** parameter under the load current. A practical setting value is approximately 10 % to 20 % of the rated current of the protected object.

NOTE

The parameter **(_:2311:102) Loop selection** = ***All loops*** is visible only if you set the parameter **Min. phase-current thresh**.

Parameter: Overcurrent threshold

- Default setting **(_:2311:104) Overcurrent threshold** = ***1.300 A***

With the parameter **Overcurrent threshold**, you set the lower pickup threshold for the overcurrent.
Set the **Overcurrent threshold** parameter above the maximum possible load current. A practical setting value is approximately 1.2 to 1.4 times the generator rated current.

EXAMPLE:

The rated generator current is calculated as:

$$I_{\text{rated, Gen prim}} = \frac{S_{\text{rated}}}{V_{\text{rated}}} = \frac{100\ \text{MVA}}{15.75\ \text{kV} \cdot \sqrt{3}} = 3666\ \text{A}$$

[fo_1 irated gen, 2, en_US]

The primary setting value is calculated as follows:

$$I_{\text{Threshold value ,prim}} = 1.4 \cdot I_{\text{rated ,Gen .prim}} = 1.4 \cdot 3666\ \text{A} = 5132.4\ \text{A}$$

[fo_2 irated gen, 3, en_US]

Taking into account the transformer ratios, the secondary setting value is calculated as follows:

$$I_{\text{Threshold value , sec}} = \frac{I_{\text{Threshold value , prim}}}{\text{Ratio}_I} = \frac{5132.4\ \text{A}}{4000\ \text{A}/1\ \text{A}} = 1.283\ \text{A}$$

[fo_3 irated gen, 3, en_US]

Parameter: Undervoltage seal in

- Default setting **(_:2311:105) Undervoltage seal in** = ***no***

With the parameter **Undervoltage seal in**, you specify whether you would like to maintain pickup from undervoltage.

Parameter Value	Description
no	If the fault current is above the setting value of the parameter **Overcurrent threshold** during the entire error Fault duration, then keep the default setting.
yes	Siemens recommends using this setting value for generator-protection applications, if during static excitation the exciting transformer is connected to the generator bus. In this situation, the excitation voltage dips in case of a near short circuit. Thereby reducing the synchronous generated voltage, the fault current can sink after an extended period of time after the fault occurred below the generator rated current. If a fault occurs the fault current is noticeably greater than the rated current. The undervoltage seal-in maintains the pickup. When selecting this setting value, the following parameters are visible: • **(_:2311:106) V-seal-in threshold** • **(_:2311:107) Duration of V-seal-in time**

Parameter: V-seal-in threshold

- Default setting **(_:2311:106) V-seal-in threshold** = ***46.200 V***

With the parameter **V-seal-in threshold**, you set the lower pickup threshold for the undervoltage seal-in.

80 % of the generator rated voltage is a typical setting value. As the voltage transformers are precisely adapted to the object rated voltage, you can set 80 % of the secondary rated voltage. The parameter **V-seal-in threshold** evaluates the positive-sequence voltage. With a secondary rated voltage $V_{rated, sec}$ = 100 V, the setting value is determined as follows:

$$0.8 \cdot \frac{V_{rated\ ,sec}}{\sqrt{3}} = 0.8 \cdot \frac{100\ V}{\sqrt{3}} = 46.2\ V$$

[fo_undervolt pickup, 2, en_US]

Parameter: Duration of V-seal-in time

- Default setting **(_:2311:107) Duration of V-seal-in time** = ***4.00 s***

With the **Duration of V-seal-in time** parameter, you set how long the pickup must persist. If the **Duration of V-seal-in time** is exceeded, the pickup drops off. If the fault is cleared before the end of the **Duration of V-seal-in time**, the **Undervoltage seal in** drops off. If the voltage exceeds setting **V-seal-in threshold** again before the end of the **Duration of V-seal-in time**, the **Undervoltage seal in** also drops.

Set the **Duration of V-seal-in time** above the maximum **Operate delay**. The default setting 4 s is a practicable value.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:15301:27) Blk. w. inrush curr. detect.** = ***no***

The parameter is only visible when the **Inrush-current detection** function is present in the application. Use the parameter to define whether the zone is blocked or not during transformer inrush-current detection.

Parameter: X reach (ph-g)

- Default setting **(_:15301:102) X reach (ph-g)** = ***2.500 Ω***

With the parameter **X reach (ph-g)**, you set the polygon limit in the X direction for phase-to-ground impedance loops. Determine the setting value for the specific application.

If the impedance protection has to be measured well beyond the transformer into the upstream power system, Siemens recommends, as a setting value for the **X reach (ph-g)**, approx. 1.5 times the transformer reactance. Adjust the associated delay time high enough so that short circuits downstream from the transformer can be initially cleared selectively.

EXAMPLE:

For the calculation, the data from *Table 6-8* apply.

X range = 150 %

The primary setting value is calculated as follows:

X_{prim} = 150 %/100 % · Z_{KT} = 1.5 · 0.96 Ω = 1.44 Ω (primary)

Taking into account the transformer ratios, the secondary setting value is calculated as follows:

$$X_{sec} = \frac{I_{prim}/I_{sec}}{V_{prim}/V_{sec}} \cdot X_{prim} = \frac{1500\ A/1\ A}{20\ kV/100\ V} \cdot 1.44\ \Omega = 7.5 \cdot 1.44\ \Omega = 10.8\ \Omega$$

[fo_Xrange_sec, 2, en_US]

Parameter: X reach (ph-ph)

- Default setting **(_:15301:103) X reach (ph-ph)** = ***2.500 Ω***

With the parameter **X reach (ph-ph)**, you set the polygon limit in the X direction for phase-to-phase impedance loops. Determine the setting value for the specific application.

If the impedance protection has to be measured well beyond the transformer into the upstream power system, Siemens recommends, as a setting value for the **X reach (ph-ph)**, approx. 1.5 times the transformer reactance. Adjust the associated delay time high enough so that short circuits downstream from the transformer can be initially cleared selectively.

Because the phase-to-phase loop applies both to a 3-phase short circuit as well as a 1-phase short circuit, the 3-phase short circuit is taken as the basis.

You can estimate the range for 1-phase short circuits by taking into account the zero-sequence impedance (reactance). The following applies:

$Z_{SC} = (Z_{KT} + 0.5 \cdot Z_{0T})$

For star-delta transformers, the zero-sequence impedance amounts to approx. $0.8 \cdot Z_{KT}$. This results in the following impedance measured value:

$Z_{SC} = (Z_{KT} + 0.5 \cdot Z_{0T}) = (Z_{KT} + 0.5 \cdot 0.8 \cdot Z_{KT}) = 1.4\ Z_{KT}$

With a time grading of $1.5\ Z_{KT}$, measure the entire transformer winding for a 1-phase ground fault.

In the example, the same setting values apply for the phase-to-phase loops as for the phase-to-ground loops.

Parameter: R reach (ph-g)

- Default setting **(_:15301:104) R reach (ph-g)** = ***2.500 Ω***

With the parameter **R reach (ph-g)**, you set the polygon limit in the R direction for phase-to-ground loops. For phase-to-ground faults, the fault resistance can be greater than that of phase-to-phase faults.

EXAMPLE:

For the calculation, the data from *Table 6-8* apply.

The rated transformer current is assumed as the rated load current. The current is 1443 A on the 20 kV side.

The smallest impedance measured under maximum load conditions (Z_{max}) is calculated as follows assuming 10 % undervoltage and 10 % overcurrent:

$$Z_{max} = \frac{0.9 \cdot V_{rated}}{1.1 \cdot \sqrt{3} \cdot I_{rated\ load}} = \frac{0.9 \cdot 20\ kV}{1.1 \cdot \sqrt{3} \cdot 1443\ A} = 6.55\ \Omega$$

[fo_Zmax_trafo_RLE_2_en_US]

For the R reach, $20\ \% \cdot Z_{max}$ is specified. This means the primary setting value of the **R reach (ph-g)** parameter is calculated as follows:

R reach (ph-g) = $0.2 \cdot 6.55\ \Omega = 1.31\ \Omega$

This value corresponds to approx. the X value so that you can select, as a practical setting, R range = X range.

Taking into account the transformer ratios, the secondary setting value is calculated as follows:

$$R_{sec} = \frac{I_{prim}/I_{sec}}{V_{prim}/V_{sec}} \cdot R_{reach\ (ph-g)} = \frac{1500\ A/1\ A}{20\ kV/100\ V} \cdot 1.31\ \Omega = 7.5 \cdot 1.31\ \Omega = 9.82\ \Omega$$

[fo_r_range_sek_2_en_US]

Parameter: R reach (ph-ph)

- Default setting **(_:15301:105) R reach (ph-ph)** = ***1.250 Ω***

With the parameter **R reach (ph-ph)**, you set the polygon limits in the R direction for phase-to-phase loops.

EXAMPLE:

For the calculation, the data from *Table 6-8* apply.

Set the range for phase-to-phase loops just like for phase-to-ground loops. This results in the following setting values:

R reach (ph-ph) = **R reach (ph-g)** = 1.45 Ω (primary)

R reach (ph-ph) = **R reach (ph-g)** = 10.9 Ω (secondary)

Parameter: Directional mode

- Default setting **(_:15301:109) Directional mode** = ***reverse***

With the parameter **Directional mode**, you can specify whether the zone operates ***forward***, ***reverse***, or ***non-directional***. Set the parameter **Directional mode** for the specific application.

If the **Impedance protection** function is present in a power-system protection device, the directional mode is in the direction of the line ***forward***. If you want to use the impedance zone as backup protection for a transformer, you have to set the parameter **Directional mode** = ***reverse***.

Parameter: Operate delay

- Default setting **(_:15301:6) Operate delay** = ***0.30 s***

With the parameter **Operate delay**, your set the grading time of the zone. Set the parameter **Operate delay** for the specific application.

Select the associated time stage for Zone TZ so that it staggers the power-system protection devices of the following lines. Therefore, check the grading times in the superposed power system as well as the range in the power system if 1.5 Z_{KT} is set.

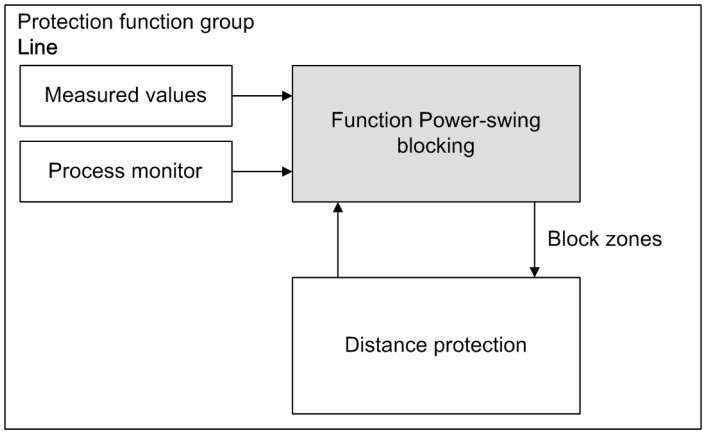
6.17 Power-Swing Blocking

6.17.1 Overview of Functions



Power-swing blocking

- Detects power swings
- Evaluates the impedances per phase accordingly
- Checks the impedance trajectory on a continual basis
- Reports the power-swing detection per phase
- Blocks the selected zones of the distance protection in case of power swings
- Detects 1-phase, 2-phase, and 3-phase short circuits during a power swing and then cancels the blocking for the specific phase
- Works during a 1-pole dead time
- Activates only when the distance-protection function is active
- Does not generate tripping of the out-of-step condition; a separate out-of-step protection function is available for this purpose

6.17.2 Structure of the Function

The Power-swing blocking function is a supplementary function to the distance protection. It only works if the distance-protection function is activated. If a power swing is detected, power-swing blocking blocks the pickup and tripping through the distance protection. Each distance-protection zone can be blocked separately.

The Power-swing blocking function is included in a function group with at least 3 voltage inputs and current inputs. The process monitor delivers status information to the function regarding the protected object (open poles in particular).

[dwpsdstr-010612-01.tif, 1, en_US]

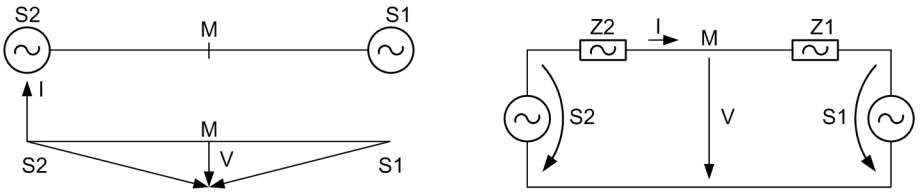


Figure 6-336 Power-Swing Blocking Works Together with the Distance-Protection Function

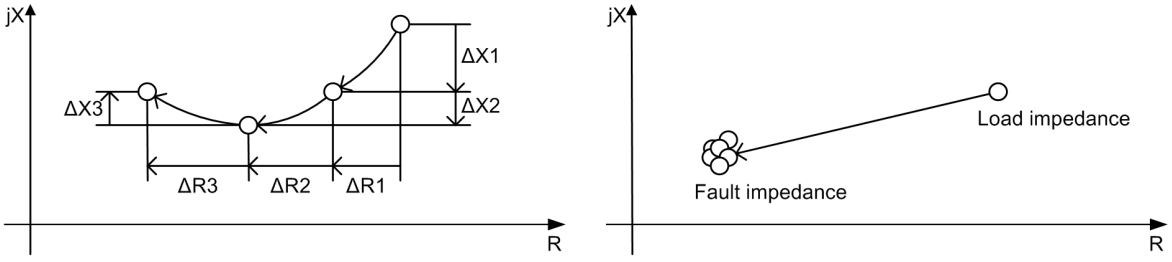
6.17.3 Function Description

Power-Swing Event

After dynamic events such as load jumps, short circuits, automatic reclosing functions, or switching operations, the generators exposed to the oscillations may have to respond to the new power balance of the system. In case of power swings, the distance-protection function is fed with high compensating currents and – especially at the electrical center – low voltages (*Figure 6-337*). Low voltages combined with high currents

represent apparently small impedances that can lead to tripping by the distance protection. Power-swing blocking prevents tripping by the distance protection in case of power swings.



[dwpendel-160211-01.tif, 1, en_US]

Figure 6-337 Power Swings

Power swings are 3-phase symmetrical events. As a rule, a certain symmetry of the measurands can be assumed. Power swings may also occur during unsymmetrical events, such as short circuits or during a 1-pole dead time. For this reason, power-swing detection is structured to use 3 measuring systems. One measuring system is available for each phase, which warrants phase-selective power-swing detection. If short circuits occur, the power swing detected in the respective phase will be discarded, which enables the distance-protection function to initiate selective tripping.

Functionality

In order to detect the power swing, the rate of change will be adjusted to the impedance phasor.

[dwzvekto-220311-01.tif, 1, en_US]

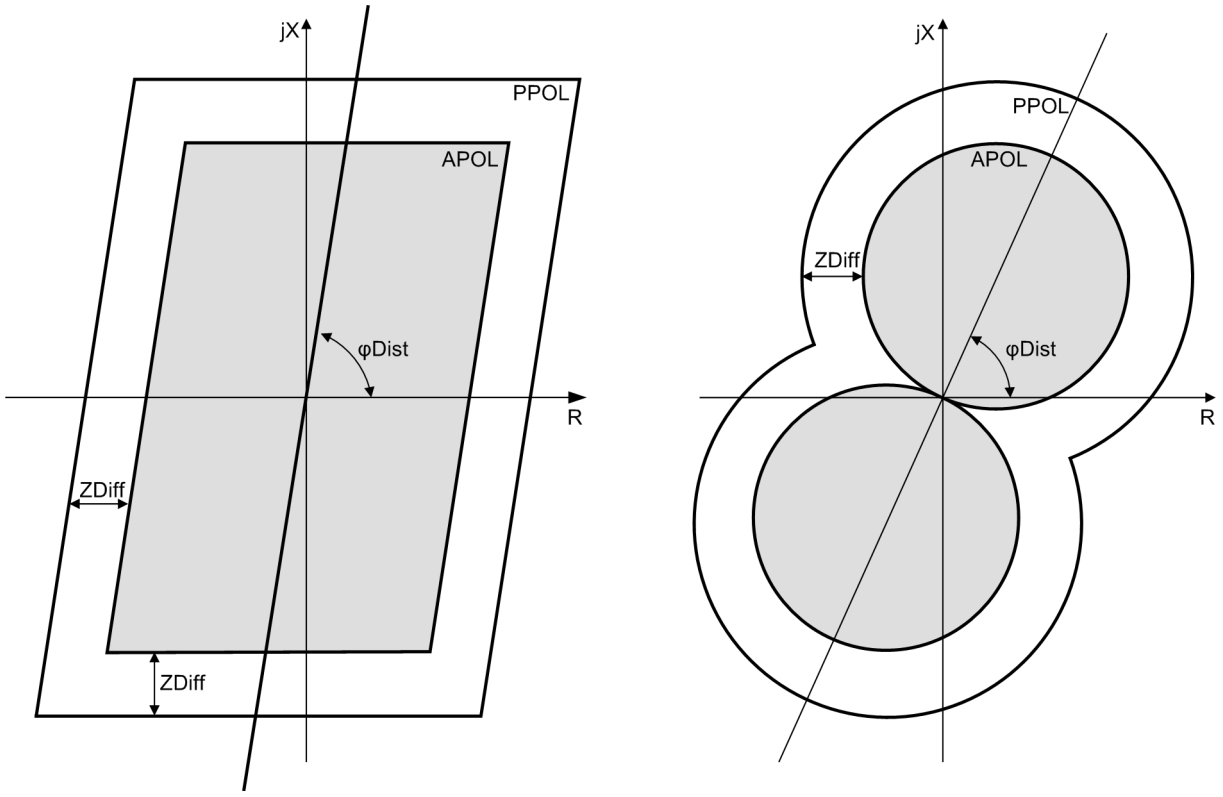


Figure 6-338 Impedance Vectors During a Power Swing and During a Short Circuit

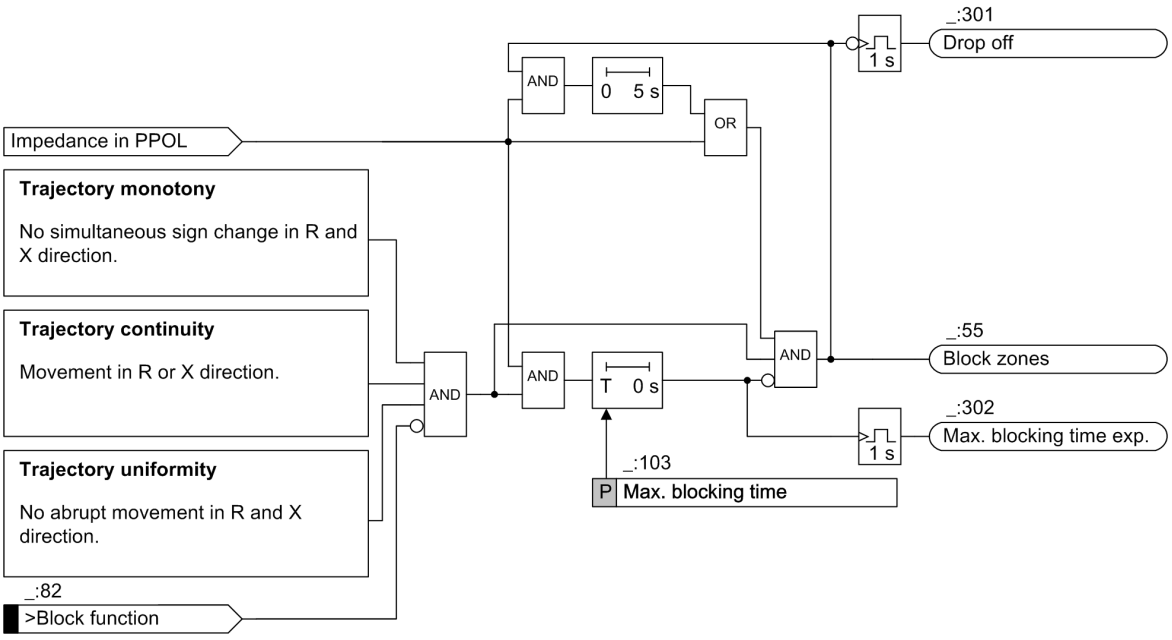
In order to warrant all functions of the power-swing detection are stable and secure, without the risk of overfunction during a short circuit, the following measurement criteria are used:

- **Trajectory monotony:**
  During a power swing, the measured impedance indicates a directional path of movement. This path occurs precisely if within the measurement window one of the components ΔR and ΔX at the most indicates a change of directions. As a rule, if a short circuit occurs, it causes a directional change in ΔR as well as in ΔX within the measured value window.
- **Trajectory continuity:**
  The spacing of 2 consecutive impedance values will clearly indicate a change of ΔR or ΔX during a power swing. If a short circuit occurs, the impedance vector skips to the short-circuit impedance and remains motionless.
- **Trajectory uniformity**:
  During a power swing the ratio between 2 consecutive changes of ΔR or ΔX do not overshoot a threshold. As a rule, if a short circuit occurs, it will cause an erratic movement since the impedance phasor abruptly skips from load impedance to short-circuit impedance.

The indication of a power swing is triggered when the impedance vector enters the PPOL power swing measuring range (see the following figure) and the criteria for power-swing detection are met. With the quadrilateral characteristic, the APOL pickup range is composed of the largest quantitative values set for R and X of all active zones. The power swing measuring range has a minimum distance $Z_{Diff}$of 5 Ω (at I_N = 1 A) or 1 Ω (at I_N = 5 A) in all directions from the pickup range. The same applies to the MHO characteristic. The power

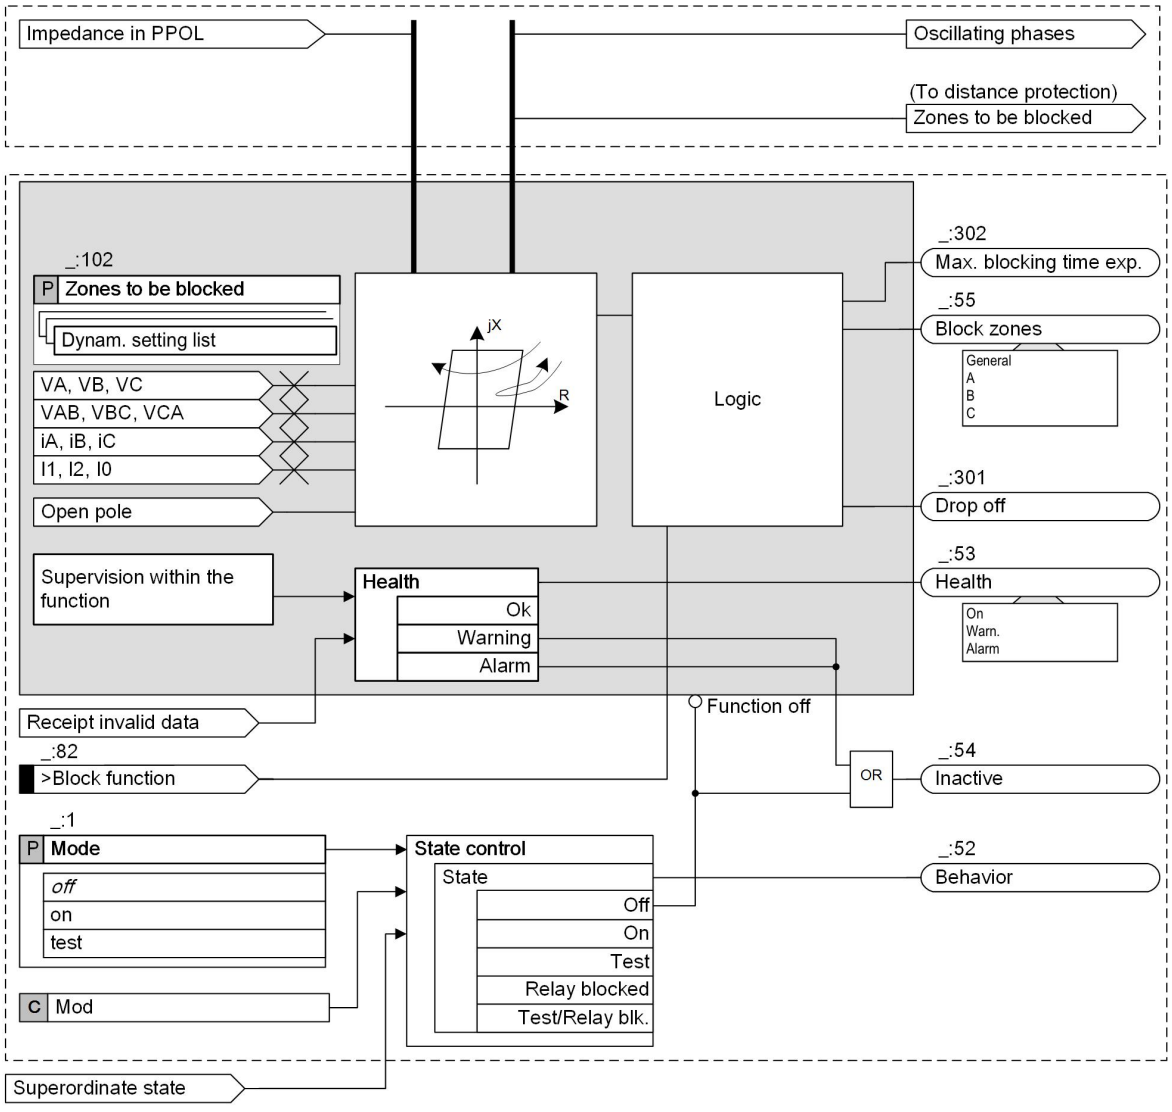


swing measuring range also has a distance of 5 Ω (at II_N = 1 A) or 1 Ω (at II_N = 5 A) from the largest pickup circuit. The power swing measuring range has no load trapezoid cut-out.

[arbeitsbereich-21062010, 1, en_US]

Figure 6-339 Operating Range for the Power-Swing Detection for Polygonal and MHO Characteristic

Figure 6-340 shows a simplified logic diagram of the power-swing detection function. The measurement is executed per phase. A power swing signal (*(_:55) Block zones*) will be generated if the measured impedance is inside the power swing measuring range (PPOL). If a power-swing detection signal is initiated, it remains active until a short circuit occurs or the power swing has decayed. The power-swing detection can be blocked via the binary input *>Block function*.



[lopendel-190413-01.tif, 3, en_US]

Figure 6-340 Power-Swing Blocking Logic

With the **`Max. blocking time`** parameter, you can place a time limit on the blocking effect of the power-swing blocking. In this way, for instance, the power-swing blocking can be eliminated when using systems that are slowly drifting apart.

When the impedance enters the power swing measuring range PPOL, the maximum blocking time will be started. When the impedance exits the power swing measuring range PPOL while the maximum blocking time is running, the maximum blocking time will be reset.

Logic

[lo_psd_log_3_en_US]

Figure 6-341 Functionality of Power-Swing Blocking

The distance protection delivers information about the loops contained in its zones to the power-swing blocking. If the power-swing blocking detects power swings in the activated loops, it delivers phase-selective information about the zones to be blocked to the distance protection. The actual blocking is carried out in the distance protection.

6.17.4 Application and Setting Notes

Selection of the Distance Zones to be Blocked

- Recommended setting value **(_:102) Zones to be blocked** = ***Zone x***

Parameter Value	Description
Zones to be blocked	Via a parameter, the user can individually select each zone present in the distance-protection function that is to be blocked during a power swing.

Maximum Blocking Time

- Default setting **(_:103) Max. blocking time** = ∞

When using the **Max. blocking time** parameter, you can limit the maximum blocking time of the distance protection during the power swing. In this way, for instance, the power-swing blockage can be eliminated when using networks that are slowly drifting apart.

For tripping during an asynchronous long-lasting power swings, **Max. blocking time** is not relevant. For this application, use the function **Out-of-step protection**.

If there is no operational requirement with regards to a time limit of the power-swing blocking, Siemens recommends the default setting ∞ (= not in effect).

Further Application Notes

The following table provides application notes for the interaction with other internal or external functions.

Interaction with Other Functions:	Note
Distance Protection	Distance protection delivers information about which impedance loops picked up. If power swings occur, pickup and tripping of the distance protection are blocked for the specific phases and zones. Power-swing blocking only works if the distance-protection function is activated.

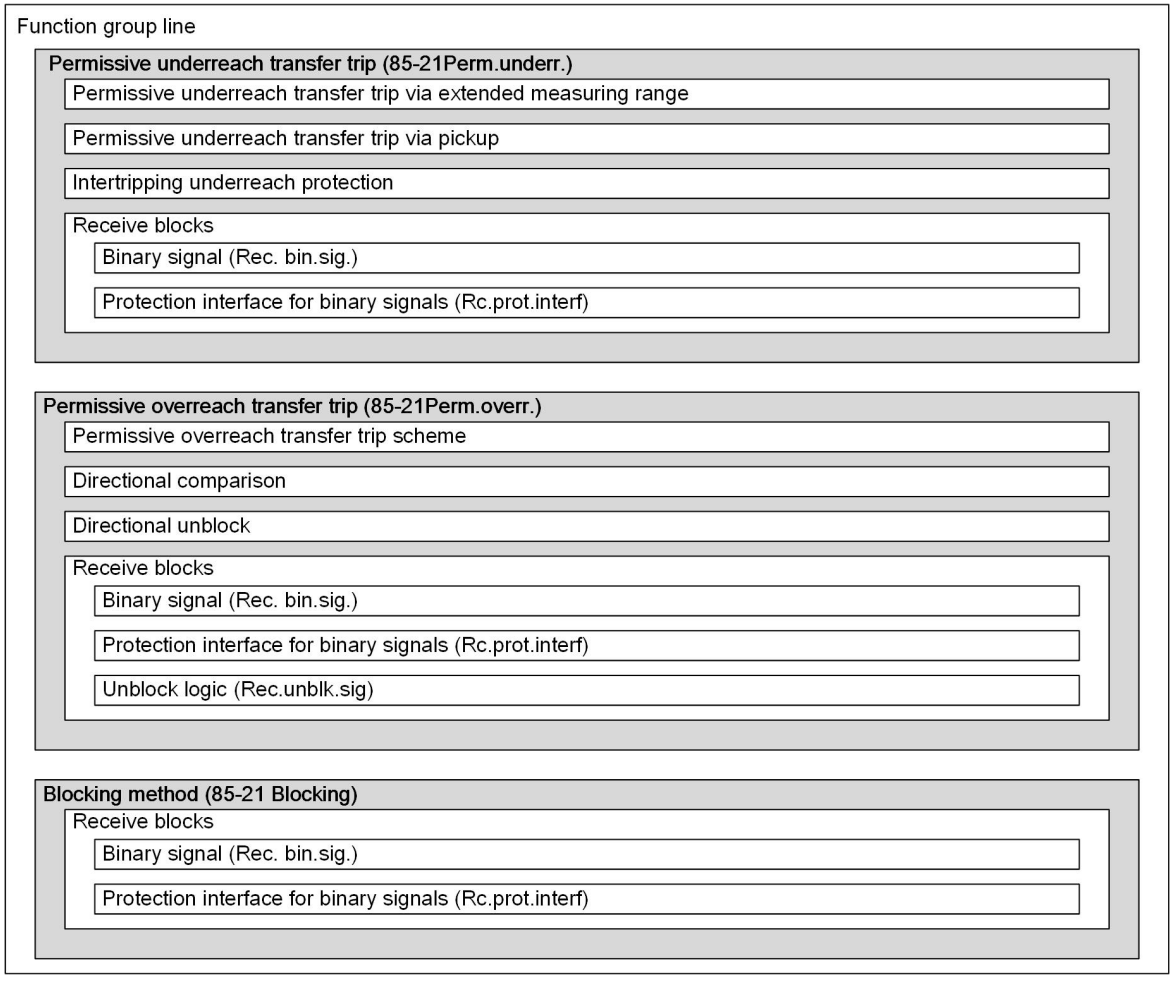
6.18 Teleprotection with Distance Protection



6.18.1 Overview of Functions

To enable selective and non-delayed fault clearance of all faults, on the entire line length, information exchange with the remote line end is applied. You can implement teleprotection using binary inputs and outputs (transmission and reception contacts) or using a digital communication connection.

6.18.2 Structure of the Function

The **Teleprotection schemes** is used in the protection function group **Line** in combination with the function Distance protection.

The functions shown in the following figure are available:

[dw_fkt-line_DIS_Mitnahme-Freigabe-Blockierverfahren, 1, en_US]

Figure 6-342 Structure/Embedding of the Function

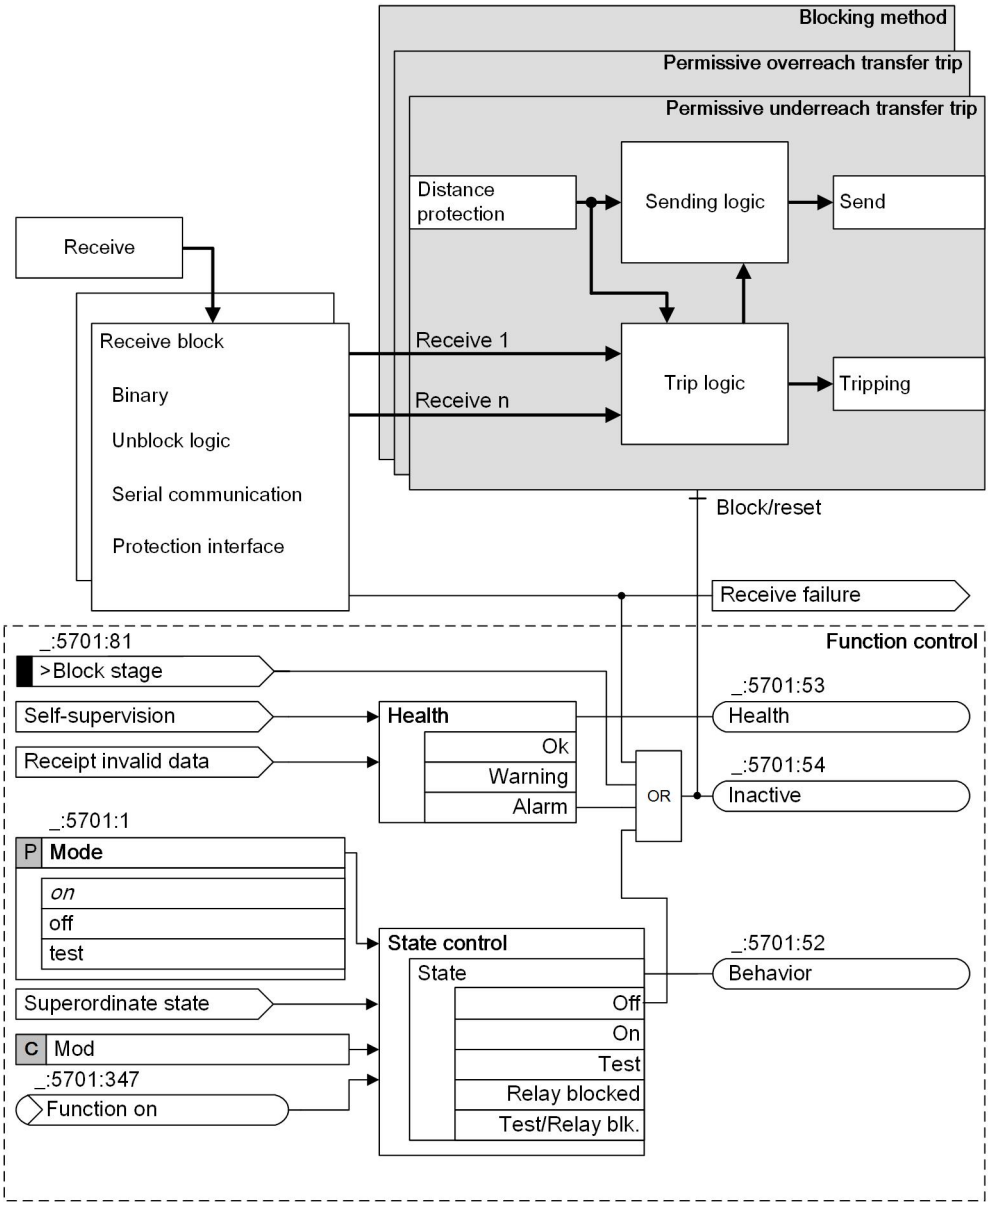


Figure 6-343 shows the function control and the function blocks.

The transmission logic analyzes the pickup signals of the distance protection and generates the associated transmission signal for transmission to the other line end.

The receive signal from the other line end is optionally coupled via a binary input, via the unblock logic or via the communication. For protection of the ends of multi-terminal lines, the function blocks **`Rec. bin.sig.`** and **`Rec.unblk.sig`** are available multiple times, once for each removed line end.

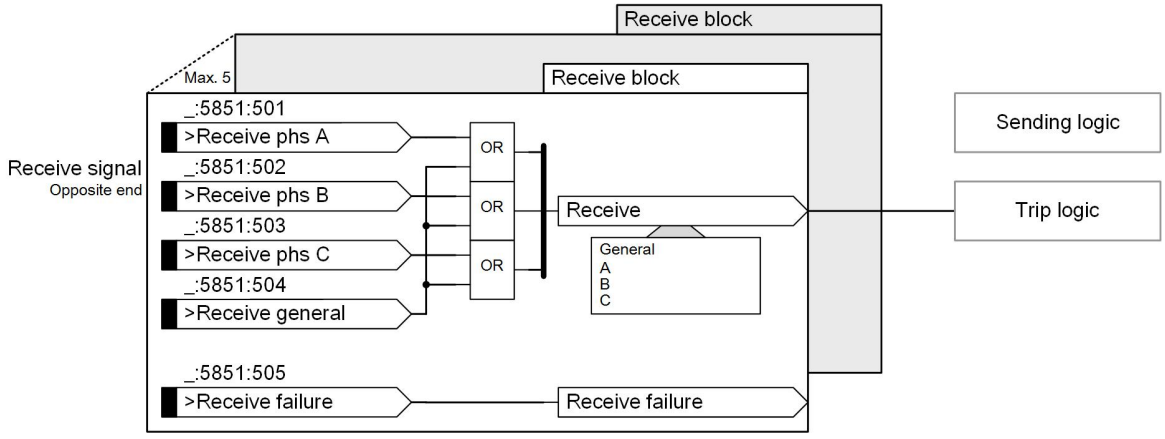
The distance zone parameterized for the teleprotection scheme provides the pickup information. This pickup information is combined with the reception information for the trip condition. If the trip condition is fulfilled, the teleprotection scheme creates the operate indication.

A trip signal results from the simultaneous presence of a pickup and a release signal.

[lo_struct_teleprot-wth_des-protec, 4, en_US]

Figure 6-343 Function Blocks and Function Control

In the following, the individual function blocks for the teleprotection scheme are described.



For more information, see *2.3 Function Control*.

6.18.3 Receive Blocks

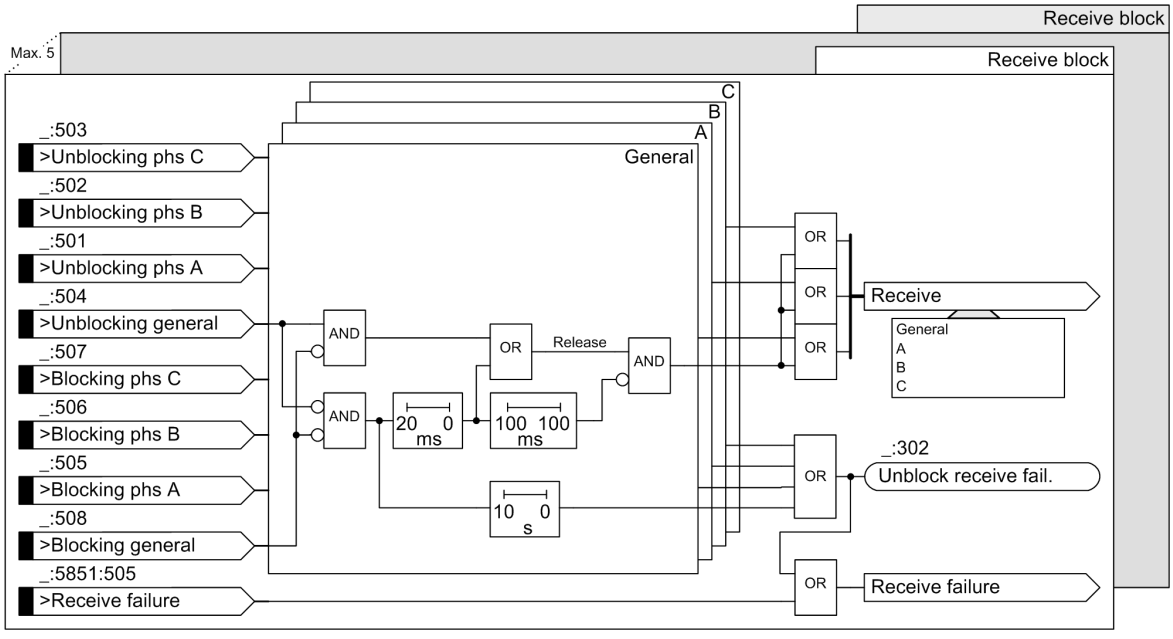
For the coupling of receive signals from the opposite end, the receive block types **`Rec. bin.sig.`**, **`Rec.unblk.sig`** and **`Rec. PI`** are available. The teleprotection scheme described below can be operated with the suitable receive blocks if required.

A mixture between a line end connected through a protection interface and a binary connected line end is not possible.

Receive Block, Binary (in DIGSI 5: `Rec. bin.sig.`)

[lotprxbi-100611-01.tif, 2, en_US]

Figure 6-344 Logic Diagram of the Receive Block: `Rec. bin.sig.`



This receipt logic is used if the communication takes place via binary signals. If a teleprotection scheme is configured with a total of 3 ends, for example, 2 function blocks `Rec. bin.sig.` are required.

For applications with 1-pole tripping, the selectivity of the permissive underreach transfer trip for double ground faults on parallel lines can be improved, if 3 phase-selective send signals are transmitted per communication direction. The receipt signals can thus be used phase-specifically for A, B, and C or in general as individual signals.

For common-phase teleprotection, the signal **`>Receive general`** is used, for phase-selective teleprotection the 3 signals **`>Receive phs A`**, **`>Receive phs B`** and **`>Receive phs C`**.

The binary input **`>Receive failure`** affects the status indications of the function control, see *Figure 6-343*.

Receive Block, Unblock (in DIGSI 5: `Rec.unblk.sig`)

[lotpsunb-140611-01.tif, 1, en_US]

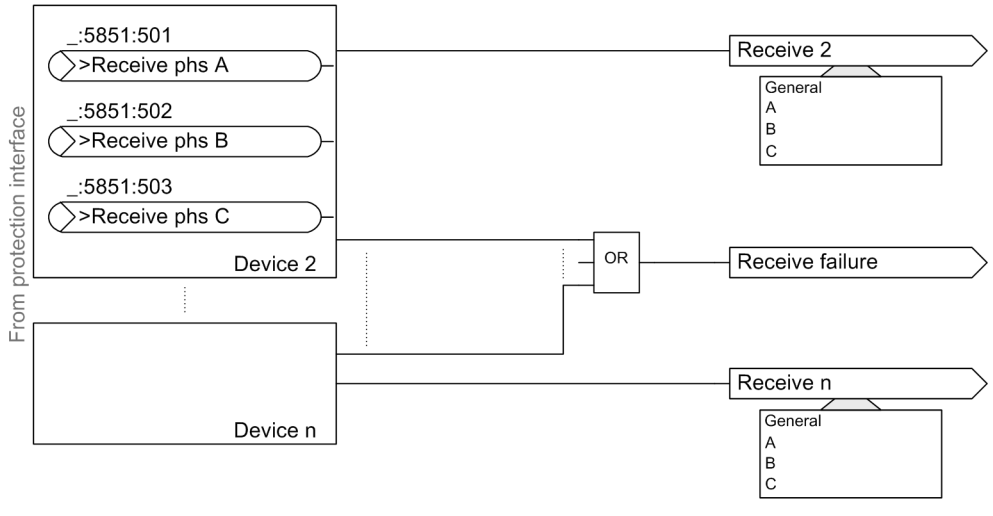
Figure 6-345 Logic Diagram of the Receive Block: `Rec.unblk.sig`

The teleprotection scheme can optionally be used with the unblock method. The difference to the conventional binary receipt is that a trip is also then possible if a release signal arrives from the opposite end.

The unblocking method is preferred under the following conditions:

- With long lines
- If the signal is transmitted via PLC (power-line carrier transmission) through the line that is to be protected
- If the attenuation of the transmission signal at the fault location can be so great that reception by the other line end is not ensured.

For transmission of the signal, 2 signal frequencies are required, which are sent from the transmission signal of the protection device. If the transmission device has channel monitoring, a monitoring frequency (blocking frequency) can be switched to a working frequency (unblocking frequency). During the idle state or during an external error, the monitoring frequency is transmitted, which signalizes the binary input *>Blocking general* (or during phase-selective teleprotection to the binary inputs *>Blocking phs A*, *>Blocking phs B*, and *>Blocking phs C*) of the unblock logic.



If in the event of a fault due to the transmission signal from the opposite line end the working frequency is received healthy, the receipt signal *>Unblocking general* will appear at the binary input of the unblock logic. During phase-selective teleprotection, instead of *>Unblocking general* the 3 receipt signals *>Unblocking phs A*, *>Unblocking phs B*, and *>Unblocking phs C* are used. Subsequently, the blocking signal *>Blocking general* disappears. During the phase-selective teleprotection, the 3 blocking signals *>Blocking phs A*, *>Blocking phs B* and *>Blocking phs C* are used. With this, the signal *>Unblocking general* (or the respective signals *>Unblocking phs A*, *>Unblocking phs B*, and *>Unblocking phs C*) are transmitted and the receipt of the trip logic of the teleprotection scheme is approved.

A short circuit on the line can cause an attenuation or reflection of the signal and the signal to be transmitted no longer reaches the other line end. In this state, both binary inputs *>Unblocking general* and *>Blocking general* are not active. After a time delay of 20 ms, the release is still created and forwarded to the receipt logic. The release is then retracted over the time stage after a further 100 ms.

If the signals continue to receive without disruptions, the release is possible again after a dropout delay of 100 ms.

If the device does not receive any of the signals for 10 s, the indication *Unblock receive fail.* is generated. This indication affects the status indications of the function control, see *Figure 6-343*.

Receive Block, Protection Interface (in DIGSI 5: `Rec. PI`)

[lotprxws-310511-01.tif, 1, en_US]

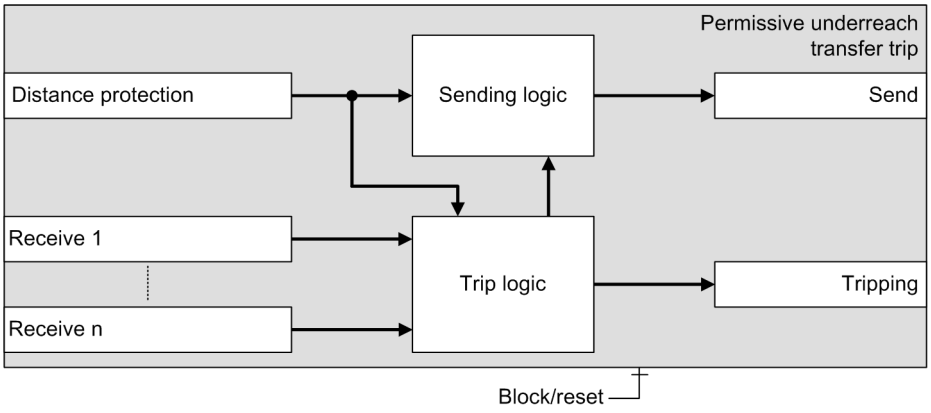


Figure 6-346 Logic Diagram of the Receive Block: **`Rec. PI`**

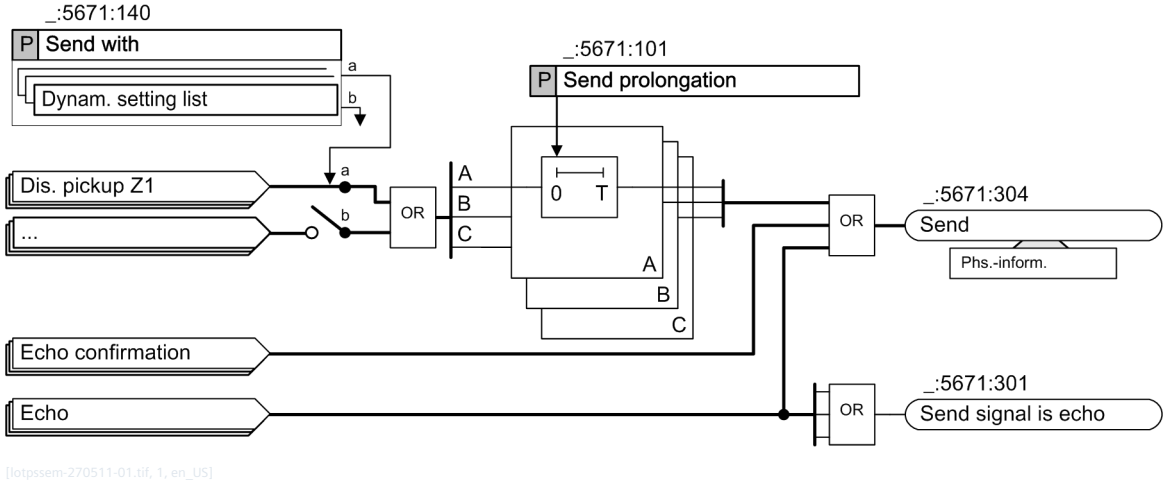
This receipt logic is used if the communication takes place via a protection interface (digital). Independent of the number of configured devices, only one function block **`Rec. PI`** is required at a time. The number and

the identity of devices participating in the teleprotection scheme for the protection of the line configuration are set by using the configuration of the protection interface, see *3.6.5.4 Configuration of the Protection Interface in DIGSI 5*.

6.18.4 Permissive Underreach Transfer Trip

6.18.4.1 Description



[dwtpsmit-100611-01.tif, 1, en_US]

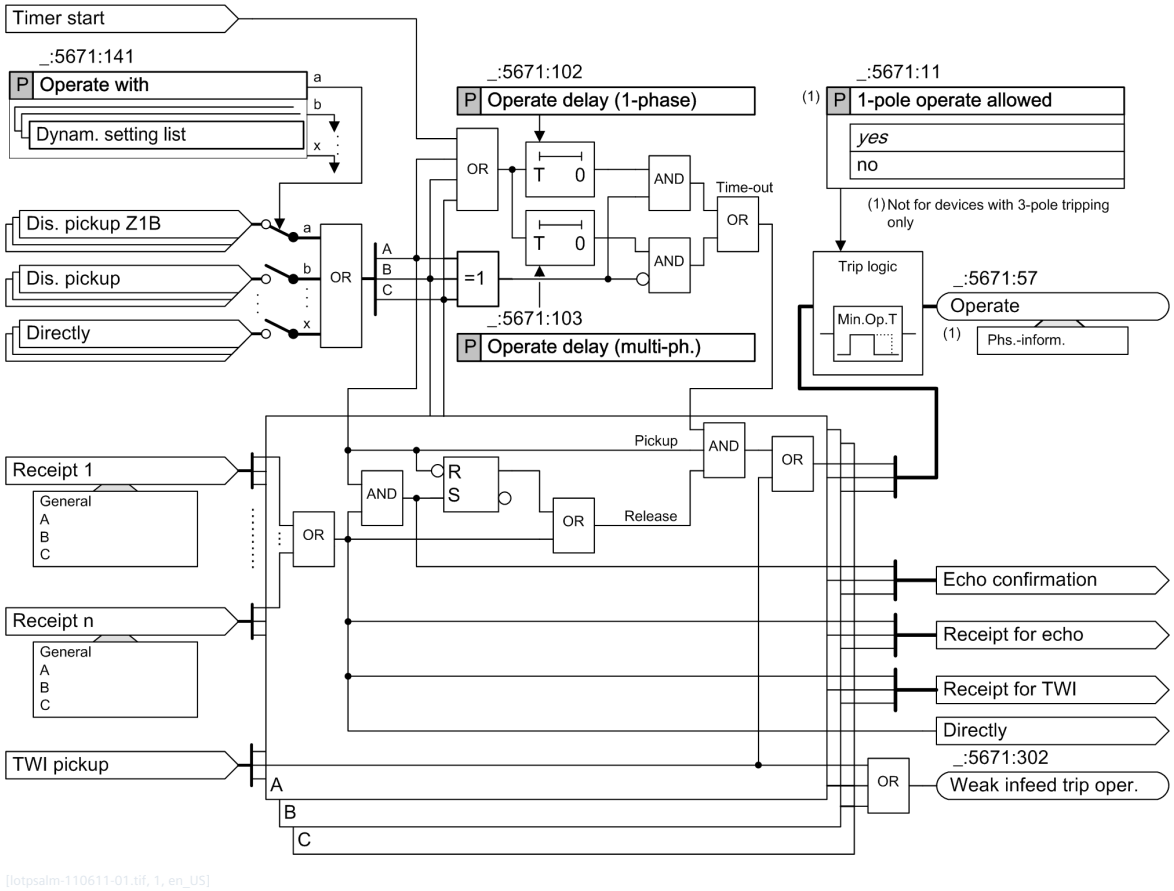
Figure 6-347 Function Block: Permissive Underreach Transfer Trip (85-21 Perm. underr.)

If a fault occurs within the underreaching zone - this is usually zone Z1 for the distance protection - a transfer-trip signal is sent to the remote end. The receive signal leads to accelerated tripping in the device at the remote end.

Sending Logic Permissive Underreach Transfer Trip

[lotpssem-270511-01.tif, 1, en_US]

Figure 6-348 Sending Logic for Permissive Underreach Transfer Trip



Sending takes place upon pickup in the distance zone selected as a send condition. You can use the **(_:5671:101) Send prolongation** parameter to compensate the differences in the pickup times at both line ends.

For applications with 1-pole tripping, the selectivity of the permissive underreach transfer trip for double ground faults on parallel lines can be improved, if 3 phase-selective send signals are transmitted per communication direction. Transmission and reception signals can thus be used phase-specifically for L1, L2 and L3 or phase-jointly as individual signals (general).

If the internal indication *Echo confirmation* from the trip logic is present, the sending logic also generates the *Send* signal. If, with a present receive signal, an **Operate with** parameterized zone has picked up, the

Echo Confirmation raises. Even if the **Send zone** is set below the **operate zone**, a definite tripping is possible for all line ends.

Trip Logic Permissive Underreach Transfer Trip

[lotpsalm-110611-01.tif, 1, en_US]

Figure 6-349 Trip Logic for Permissive Underreach Transfer Trip

The distance protection provides the pickup information to the teleprotection scheme. The tripping for the relevant zone is undertaken by that teleprotection scheme with which the distance protection works together.

If a receive signal is present, the zone set through the parameter **`Operate with`** will be released for tripping. The trip can be delayed. For 1-phase faults, set the time delay under **`(_:5671:102) Operate delay (1-phase)`**; for multi-phase faults, use the parameter **`(_:5671:103) Operate delay (multi-ph.)`**.

If the permissive underreach transfer trip is used to protect a line configuration with more than 2 ends, the receive signals from all line ends are linked with OR.

A trip signal results from a simultaneous presence of the distance zone pickup, the release signal, and the time sequence. The **`(_:5671:11) 1-pole operate allowed`** parameter can be used by the trip logic to allow 1-pole tripping in 1-pole/3-pole tripping devices. This parameter does not apply to devices that only have 3-pole trip.

For applications with time-delayed tripping, a receive signal once received is retained until the distance zone pickup drops out. This ensures that the release signal is still present if the expiration of the corresponding time delay releases the tripping, and the transmission signal of the protection from the remote end is no longer present.

Measures in the Event of Weak Infeed

If no or only a weak infeed is available at a line end, the protection does not pick up the phase information or it does so incorrectly. No trip command can therefore be issued there. In SIPROTEC 5 devices tripping can also be used together with the permissive underreach transfer trip in the event of weak infeed.

With the permissive underreach transfer trip, the protection trips parallel to the send signal with the underreaching distance zone at the line end with strong infeed. An echo from the line end with weak infeed is therefore unnecessary as a release signal. However, the echo is advisable for manually testing the signal connection between the protection devices.

The functions are described in more detail in *6.14.4 Tripping on Weak Infeed (TWI Function)*.

6.18.4.2 Application and Setting Notes for Permissive Underreach Transfer Trip, General

Setting the Process

The various permissive underreach transfer trip methods can be implemented by using both parameters **Send with** and **Operate with** (see *Figure 6-348* and *Figure 6-349*). In addition, the selection of the reception block must be observed.

The following methods can be ordered:

Methods	Parameter: Send with	Parameter: Operate with
DIS permissive underreach transfer trip via pickup, non-directional	Underreaching zone, type Z1	Pickup, general
DIS intertrip process via extended range	Underreaching zone, type Z1	Overreaching zone, type Z1B
DIS intertrip process direct	Underreaching zone, type Z1	Permissive underreach transfer trip, reception (direct tripping)

The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the underreaching distance zone can therefore also be different from Z1.

Parameter: Send prolongation

- Recommended setting value **(_:5671:101) Send prolongation** = ***0.05 s***

With the parameter **Send prolongation** in the transmission logic, you can compare the differences in the pickup times for both line ends. If SIPROTEC distance protection devices are used at all line ends, Siemens recommends the setting value ***0.05 s***.

Parameter: Operate delay (1-phase)

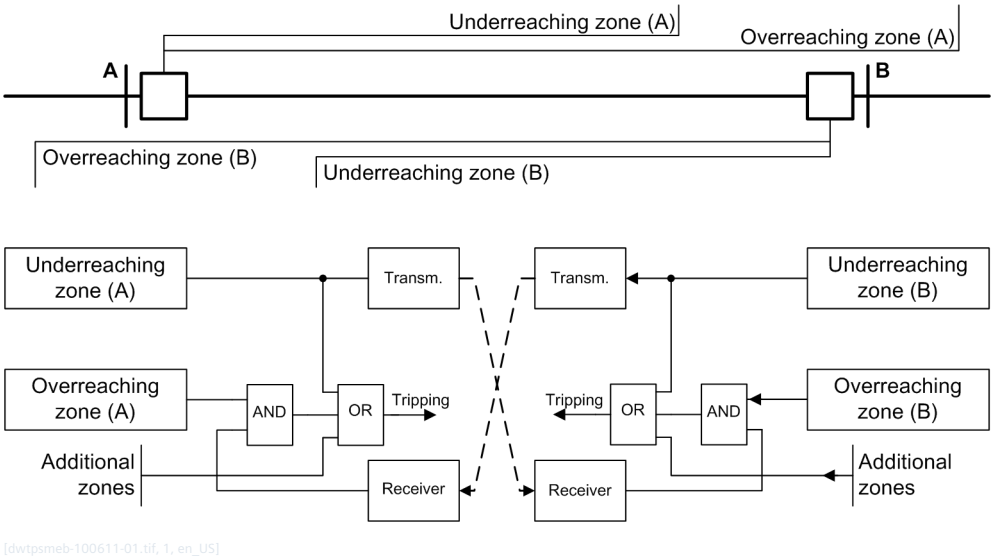
- Recommended setting value **(_:5671:102) Operate delay (1-phase)** = ***0.00 s***

With the parameter **Operate delay (1-phase)**, you set the operate delay for 1-phase ground faults. Since the teleprotection scheme should lead to a fast and selective operate, Siemens recommends the setting value ***0.00 s***.

Parameter: Operate delay (multi-ph.)

- Recommended setting value **(_:5671:103) Operate delay (multi-ph.)** = ***0.00 s***

With the parameter **Operate delay (multi-ph.)**, you set the operate delay for multi-phase faults. Since the teleprotection scheme should lead to a fast and selective operate, Siemens recommends the setting value ***0.00 s***.



Parameter: 1-pole operate allowed

- Recommended setting value **(_:5671:11) 1-pole operate allowed** = ***Yes***

This parameter allows 1-pole tripping of the teleprotection scheme in the event of 1-phase short circuits or multiphase short circuits and 1-phase reception. In devices with 1-pole tripping, Siemens recommends the setting ***Yes***. In devices with 3-pole trip, this parameter does not apply.

6.18.4.3 Application and Setting Notes for the Permissive Underreach Transfer Trip via an Extended Measuring Range (Distance Protection with Underreaching and Grading-Time Shortening)

A transfer-trip signal is transmitted to the remote end in the event of a fault within the underreaching zone. If the fault is detected there within the overreaching zone, the receive signal leads to tripping.

[dwtpsmeb-100611-01.tif, 1, en_US]

Figure 6-350 Function Diagram of the Permissive Underreach Transfer Trip via Extended Measuring Range

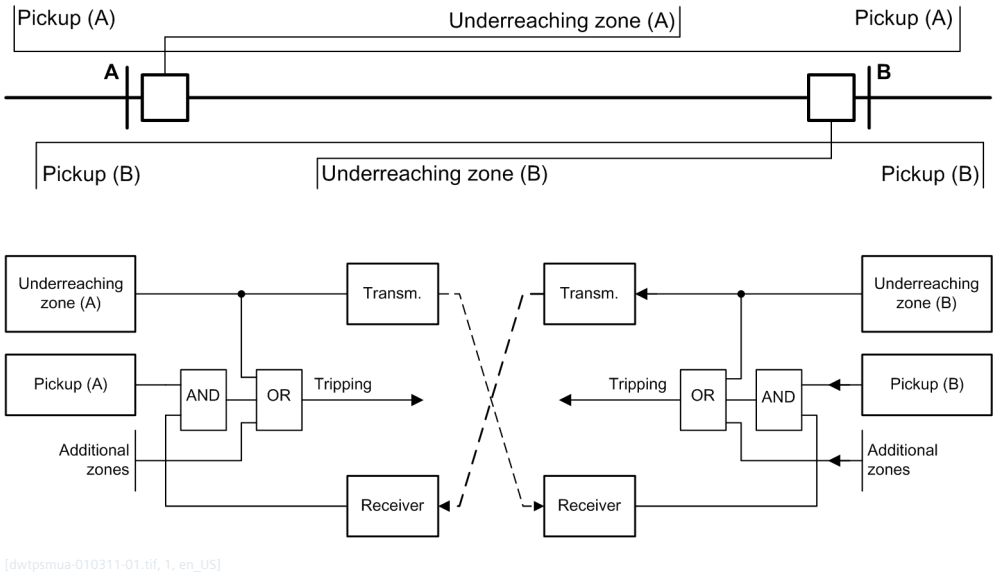
You can configure the Permissive Underreach Transfer Trip via an extended measuring range with the following settings:

Transmit with

- Recommended setting value **(_:5671:140) Send with** = ***Z1***

With the parameter **Send with**, you select the underreaching distance zone. The underreaching distance zone is typically designated with Z1. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the underreaching distance zone can therefore also be different from Z1.

Operate with



- Recommended setting value **(_:5671:141) Operate with** = ***Dis Z1B***

With the parameter **Operate with**, you select the overreaching distance zone Z1B. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

For applications in which the ranges for phase and ground faults are to be set differently, there are 2 underreaching or 2 overreaching distance zones. For example Z1(Ph-gnd) then takes effect for ground faults and Z1(Ph-Ph) for phase faults. In this case, you must select both zones as send or tripping zones in the teleprotection scheme. This applies to parameters **Send with** and **Operate with**.

6.18.4.4 Application and Setting Notes for the Permissive Underreach Transfer Trip via Pickup (Distance Protection with Underreaching and Remote Tripping with Release)

A transfer-trip signal is transmitted to the remote end in the event of a fault in the underreaching zone. If the distance-protection function picks up at the remote end, the signal received there leads to tripping.

[dwtpsmua-010311-01.tif, 1, en_US]

Figure 6-351 Function Diagram of the Permissive Underreach Transfer Trip via Pickup

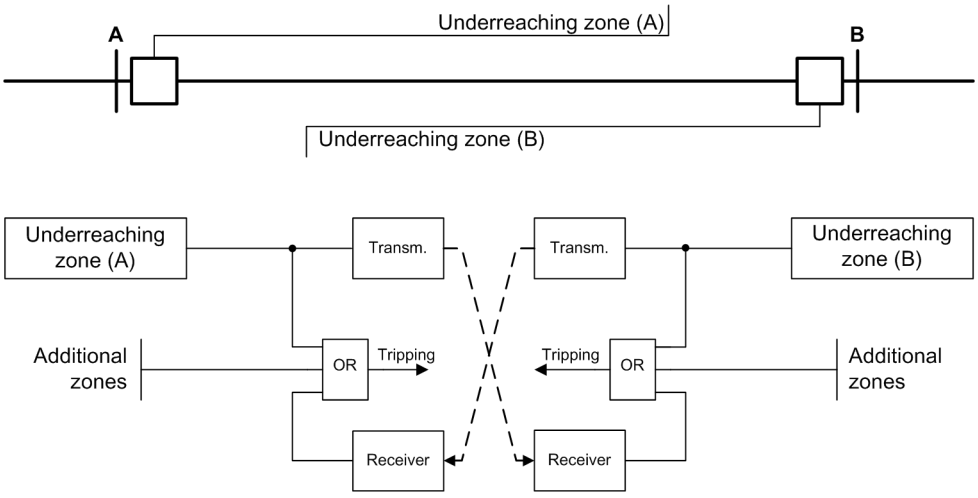
You can configure the permissive underreach transfer trip via pickup with the following settings:

Parameter: Send with

- Recommended setting value **(_:5671:140) Send with** = ***Z1***

With the parameter **Send with**, you select the underreaching distance zone. The underreaching distance zone is typically designated with Z1. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the underreaching distance zone can therefore also be different from Z1.

Parameter: Operate with



- Default setting **(_:5671:141) Operate with** = ***Pickup, general***

With the parameter **Operate with**, you set the pickup for the accelerated tripping.

Parameter Value	Description
Pickup, general	Select this setting value for the non-directional permissive underreach transfer trip via pickup.
Reception (direct tripping)	Select this setting value for direct tripping with the received signal.

6.18.4.5 Application and Setting Notes for the Direct Permissive Underreach Transfer trip

A transfer-trip signal is transmitted to the remote end in the event of a fault in the underreaching zone. The signal received there leads directly to the tripping.

[dwtpsdim-100611-01.tif, 1, en_US]

Figure 6-352 Function Diagram for the Direct Permissive Underreach Transfer Trip

Parameter: Send with

- Recommended setting value **(_:5671:140) Send with** = ***Z1***

With the parameter **Send with**, you can select the underreaching distance zone. The underreaching distance zone is typically designated with Z1. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the underreaching distance zone can therefore also be different from Z1.

Parameter: Operate with

- Recommended setting value **(_:5671:141) Operate with** = ***direct***

For the direct permissive underreach transfer trip, set the parameter to ***direct***.

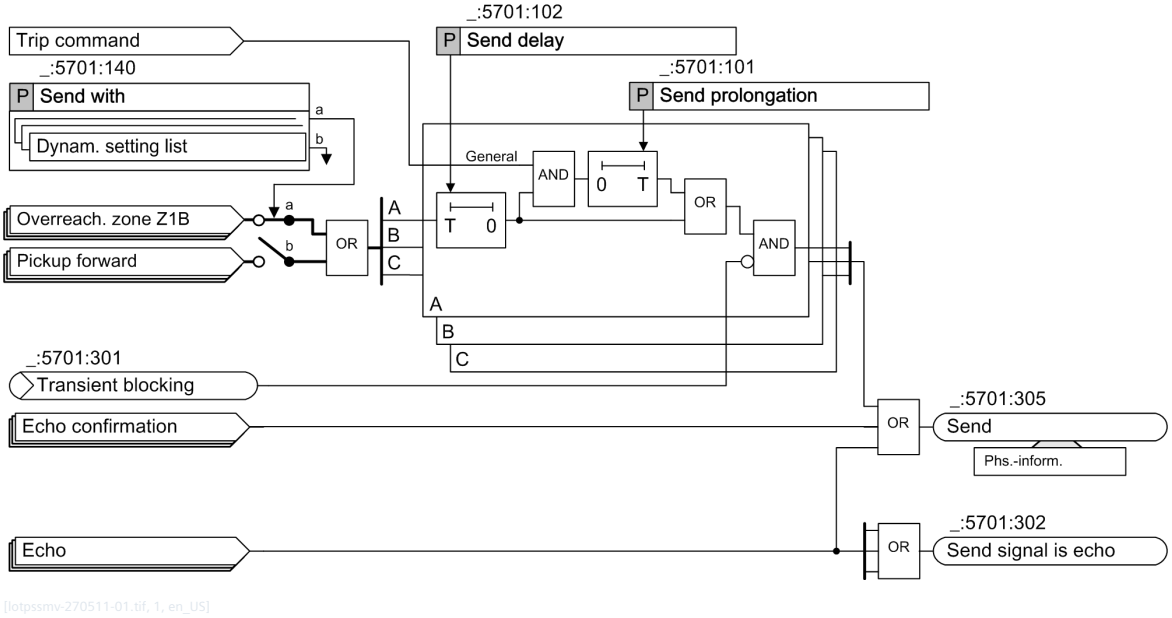
6.18.5 Permissive Overreach Transfer Trip

6.18.5.1 Description



[dwtpsver-010612-01.tif, 1, en_US]

Figure 6-353 Function Block: Permissive Schemes (85-21 Perm. overr.)

If a fault occurs within the overreaching zone, for example zone Z1B for the distance protection, a send signal is sent to the opposite end. In the distance protection device, the received signal leads to accelerated tripping if the fault is also detected in the forward direction.

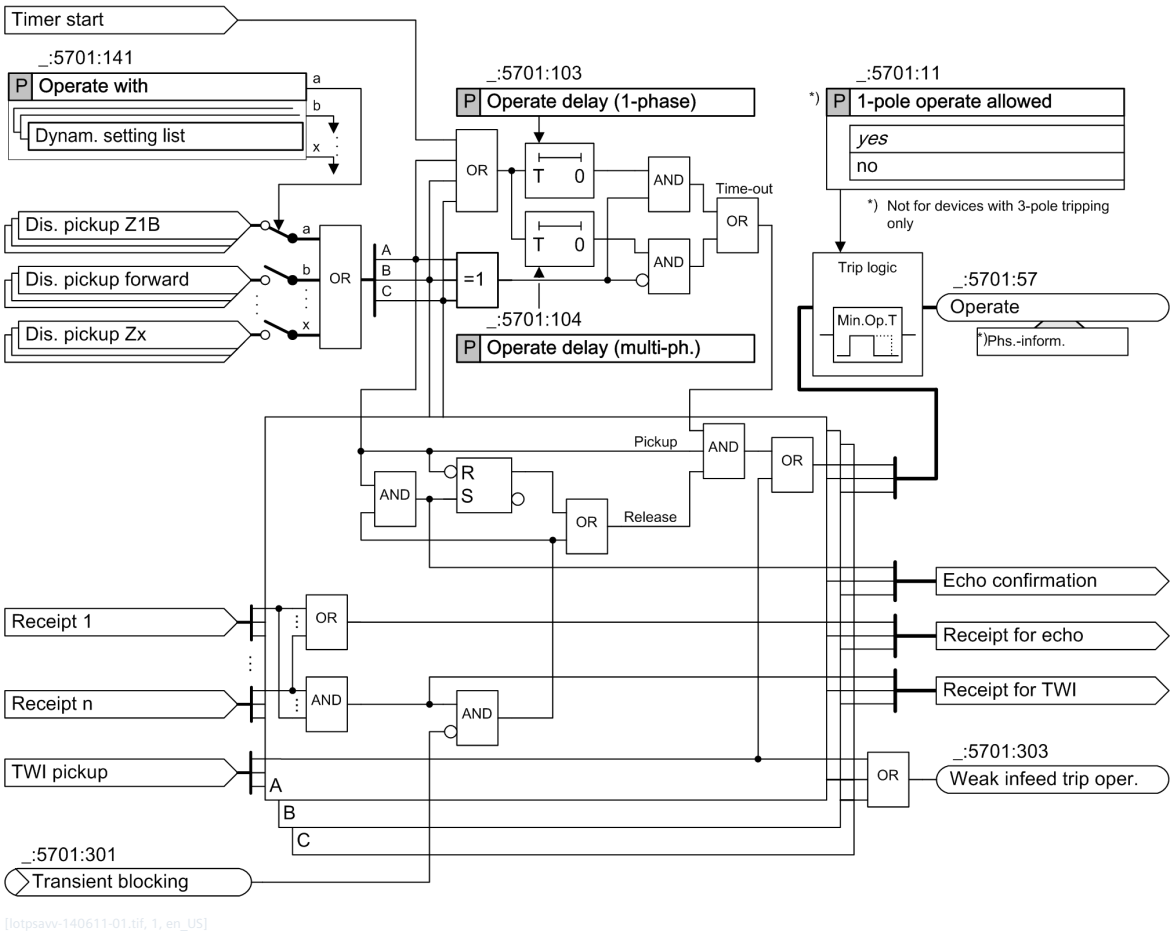
Sending Logic, Permissive Schemes

[lotpssmv-270511-01.tif, 1, en_US]

Figure 6-354 Sending Logic for Permissive Schemes

Sending takes place upon pickup in the selected overreaching zone or optionally upon pickup in the forward direction. The send signal can be extended by a parameterizable time **(_:5701:101) Send prolongation** if the protection has already issued a trip command. This allows for the release of the other line end even if the short circuit there only leads to pickup after the short-circuit current at the opposite end has been deactivated. With this, pickup differences between the cable ends and signal delays can be considered.

If needed, the transmission signal can be delayed with **(_:5701:102) Send delay**.



Transient blocking (signal **Transient blocking**) provides additional security against false signals caused by a change of direction after disconnection of external faults (for example, on parallel lines). No transmission signal is sent in the event of transient blocking.

For applications with 1-pole tripping, the selectivity of the permissive scheme for double faults can be improved on parallel lines if 3 phase-selective transmission signals are transmitted per communication direction. Transmission and reception signals can thus be used phase-specifically for L1, L2 and L3 or phase-jointly as individual signals (general).

Related Topics

6.18.8.1 Description

Trip Logic, Permissive Schemes

[lotpsavv-140611-01.tif, 1, en_US]

Figure 6-355 Trip Logic for Permissive Schemes

The distance protection provides the pickup information to the teleprotection scheme. The tripping for the relevant zone is undertaken by that teleprotection scheme with which the distance protection works together.

If a receive signal is present, the zone set through the parameter **(_:5701:141) Operate with** will be released for tripping. The trip can be delayed. For 1-phase faults, set the time delay under **(_:5701:103) Operate delay (1-phase)**. For multi-phase faults, use the parameter **(_:5701:104) Operate delay (multi-ph.)**.

The parameter **(_:5701:11) 1-pole operate allowed** can be used by the trip logic to allow 1-pole tripping in 1-pole/3-pole tripping devices. This parameter does not apply to devices that only have 3-pole trip.

If the permissive scheme for the protection of a line configuration with more than 2 ends is used, the reception signals from all line ends are combined for the tripping with AND.

A trip signal results from simultaneous presence of the distance zone activation, the release signal and the time sequence. For applications with time-delayed tripping, a receipt signal once received is retained until the distance zone pickup drops out. This ensures that the release signal is still present if the expiration of the corresponding time delay releases the tripping, and the transmission signal of the protection from the remote end is no longer present.

The transient blocking (signal *Transient blocking*) prevents the release of the tripping in the permissive scheme. It ensures additional security from false signals caused by a change of direction after disconnection of external faults (for example on parallel lines).

Related Topics

6.18.8.1 Description

Measures in the Event of Weak Infeed

If no or only a weak infeed is available at a line end, the protection does not pick up the phase information or it does so incorrectly. With this, neither a trip command nor a transmission signal can be sent. With the permissive scheme, the line end cannot be tripped quickly with increased infeed because no release signal is transferred from the end with the weak infeed.

The teleprotection schemes have special measures to enable a rapid trip at both line ends in such cases:

- For the trip of the cable end with a strong infeed, the echo function can be made effective with a weak infeed.
- In order for the cable end to also be tripped with a weak infeed, the teleprotection scheme has a function for trip with weak infeed.

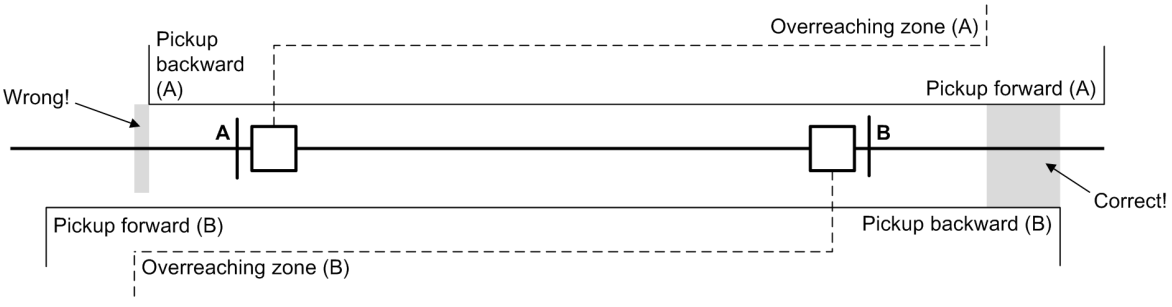
Related Topics

6.14.4 Tripping on Weak Infeed (TWI Function)

6.18.5.2 Application and Setting Notes for Permissive Schemes, General

Setting the Process

The various permissive schemes can be implemented using the 2 parameters **`Send with`** and **`Operate with`** (see *Figure 6-354* and *Figure 6-355*). In addition, the selection of the receive block must be observed.



The following methods can be set:

Methods	Parameter: Send with	Parameter: Operate with
Signal permissive overreach transfer trip	Overreaching zone, type Z1B	Overreaching zone, type Z1B
Directional permissive overreach transfer trip	Pickup forward	Pickup forward
Direction unblock process	Overreaching zone, type Z1B	Overreaching zone, type Z1B

However, the selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

Requirements during Distance Protection

When using any kind of permissive overreach transfer trip, make sure that the pickup of the distance protection in the backward direction reaches further than the overreaching zone of the opposite end (see the shaded areas in the following figure on the right)! For this purpose, at least one of the distance-protection stages must be set to *backward* or *non-directional*. In case of a fault occurring in Z1B of the protection in B due to an incorrect setting in the shaded area (left in the figure), the distance protection would pick up. Since an echo function is typically used, an undesired echo signal would be sent from protection A and protection B would trip in an unselective way.

[dw_Dis-prot-vergleich-200314-01.vsd, 1, en_US]

Figure 6-356 Distance-Protection Setting with Permissive Overreach Transfer Trip

Parameter: Send prolongation

- Recommended setting value **(_:5701:101) Send prolongation** = ***0.05 s***

With the parameter **Send prolongation** in the transmission logic, you compensate the differences in the pickup times for both line ends. If SIPROTEC distance protection devices are used at all line ends, Siemens recommends the setting value ***0.05 s***.

Parameter: Send delay

- Recommended setting value **(_:5701:102) Send delay** = ***0.00 s***

With the parameter **Send delay**, you set an additional tripping delay. Since the teleprotection scheme should lead to a fast and selective tripping, Siemens recommends the setting value ***0.00 s***.

Parameter: Operate delay (1-phase)

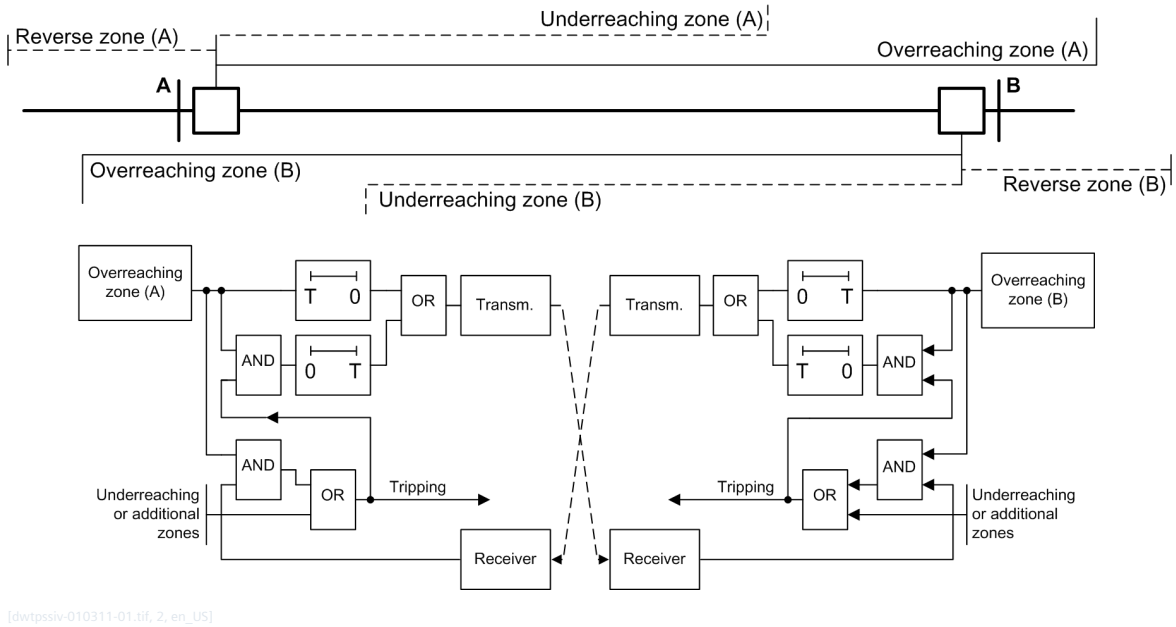
- Recommended setting value **(_:5701:103) Operate delay (1-phase)** = ***0.00 s***

With the parameter **Operate delay (1-phase)**, you set the tripping delay for 1-phase ground faults. Since the teleprotection scheme should lead to a rapid and selective tripping, Siemens recommends the setting value ***0.00 s***.

Parameter: Operate delay (multi-ph.)

- Recommended setting value **(_:5701:104) Operate delay (multi-ph.)** = ***0.00 s***

With the parameter **Operate delay (multi-ph.)**, you set the tripping delay for multi-phase faults. Since the teleprotection scheme should lead to a fast and selective tripping, Siemens recommends the setting value ***0.00 s***.



Parameter: 1-pole operate allowed

- Recommended setting value **(_:5701:11) 1-pole operate allowed** = ***Yes***

This parameter allows 1-pole tripping of the teleprotection scheme in the event of 1-phase short circuits or multiphase short circuits and 1-phase reception. In devices with 1-pole tripping, Siemens recommends the setting ***Yes***. In devices with 3-pole trip, this parameter does not apply.

6.18.5.3 Application and Setting Notes for the Permissive Overreach Transfer Trip Scheme (Distance Protection with Overreaching and Release)

A send signal is sent to the remote end in the event of a fault in the overreaching zone. If the fault is also detected there in the overreaching zone, the received signal leads to tripping.

[dwtpssiv-010311-01.tif, 2, en_US]

Figure 6-357 Function Diagram of the Permissive Overreach Transfer Trip Scheme

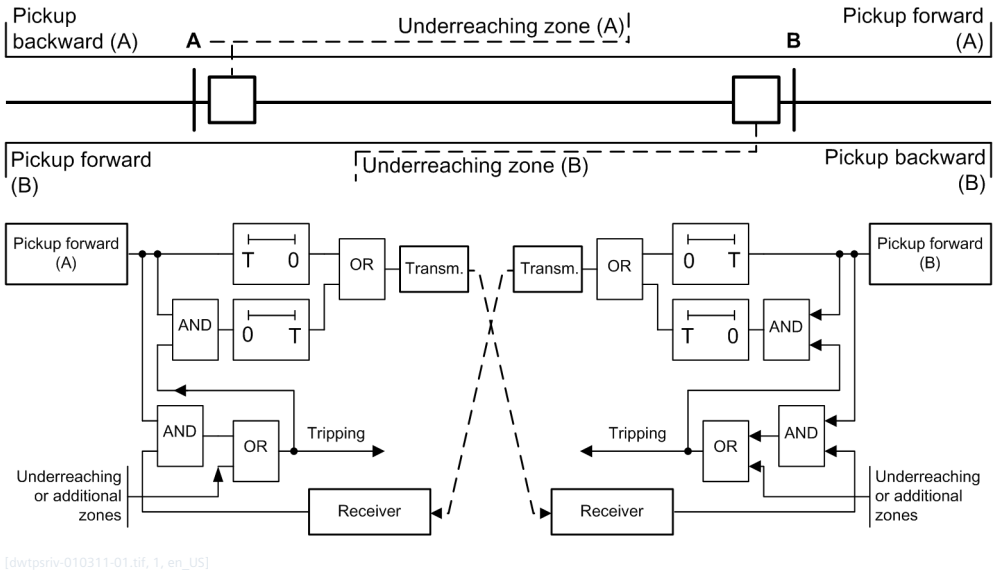
You can use the following settings to configure the permissive overreach transfer trip scheme:

Parameter: `Send with`

- Recommended setting value **`(_:5701:140) Send with`** = ***Z1B***

With the parameter **`Send with`**, you select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

Parameter: `Operate with`



- Recommended setting value **`(_:5701:141) Operate with`** = ***Z1B***

With the parameter **`Operate with`**, you select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

For applications in which the ranges for phase and ground faults are to be set differently, there are 2 overreaching distance zones. For example Z1B(Ph-gnd) then takes effect for ground faults and Z1B(Ph-Ph) for phase faults. In this case, you must select both zones as send zones or tripping zones in the teleprotection scheme. This applies to parameters **`Send with`** and **`Operate with`**.

6.18.5.4 Application and Setting Notes for the Directional-Comparison Method

If the distance protection detects a fault in the line direction after an activation, it sends a release signal to the remote end. If the opposite end receives the release signal and also recognizes an error in the cable direction, the trip signal is created.

[dwtpsriv-010311-01.tif, 1, en_US]

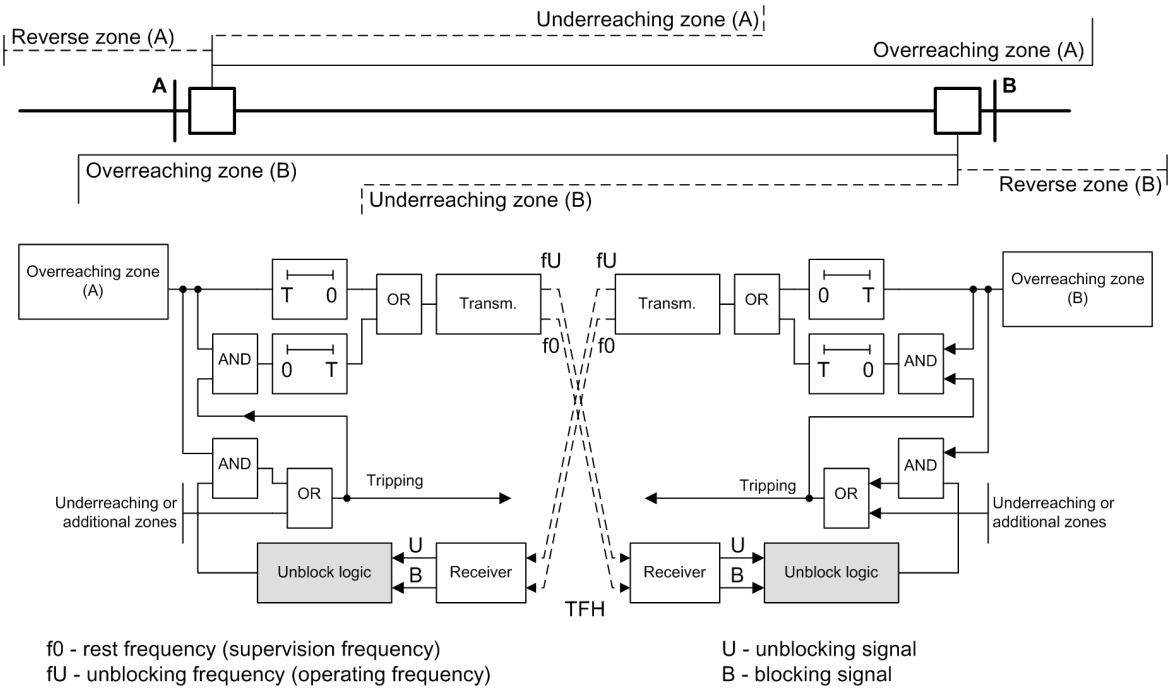
Figure 6-358 Function Scheme of the Directional Comparison Procedure

With the following settings, you can configure the directional comparison:

Parameter: **Send with**

- Recommended setting value **(_:5701:140) Send with** = ***Dis pickup fwd***

The parameter **Send with** is used to set the send condition to ***Dis pickup fwd.***.



Parameter: **Operate with**

- Recommended setting value **(_:5701:141) Operate with** = ***Dis pickup fwd.***

The parameter **Operate with** is used to set the trip condition to ***Dis pickup fwd.***.

6.18.5.5 Application and Setting Notes for the Directional Unblocking Method (Distance Protection with Overreaching and Unblocking)

The directional unblocking method corresponds with the permissive overreach transfer trip with a preceding function block **Rec.unblk.sig**. Thus, compared to the permissive overreach transfer trip, a tripping is also possible without a release signal from the opposite end. The directional unblocking method cannot be operated with a communication via a protection interface owing to the way it functions.

[dwtpsubl-010311-01.tif, 2, en_US]

Figure 6-359 Function Scheme of the Directional Unblocking Method

With the following settings, you can configure the directional unblocking method:

Parameter: `Send with`

- Recommended setting value **`(_:5701:140) Send with`** = ***`Z1B`***

With the parameter **`Send with`**, you select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

Parameter: `Operate with`

- Recommended setting value **`(_:5701:141) Operate with`** = ***`Z1B`***

With the parameter **`Operate with`**, you select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

For applications in which the ranges for phase and ground faults are to be set differently, there are 2 overreaching distance zones. For example Z1B(Ph-Gnd) then takes effect for ground faults and Z1B(Ph-Ph) for phase faults. In this case, you must select both zones as send or tripping zones in the teleprotection scheme. This applies to the parameters **`Send with`** and **`Operate with`**.

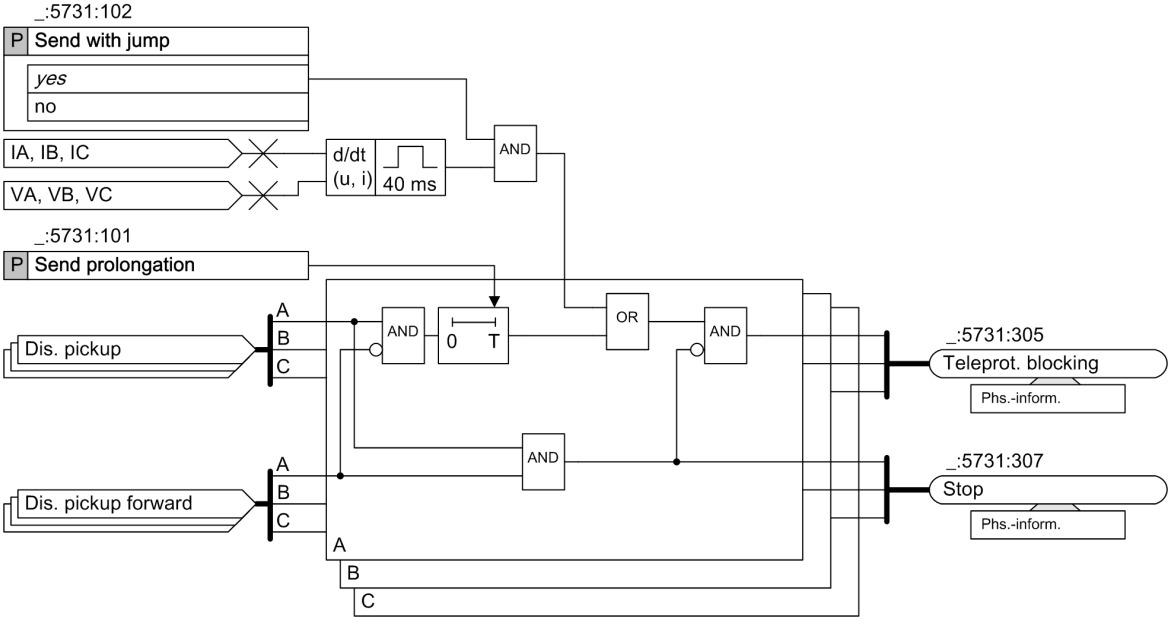
6.18.6 Blocking Method

6.18.6.1 Description



[dwtpsblo-040311-01.tif, 1, en_US]

Figure 6-360 Function Block: Blocking Method (85-21 Blocking)

If the protection function recognizes a fault in the reverse direction, the blocking signal is sent to the opposite end. If the protection device does not receive a blocking signal at the receiving line end, it generates the trip signal after a short time delay.

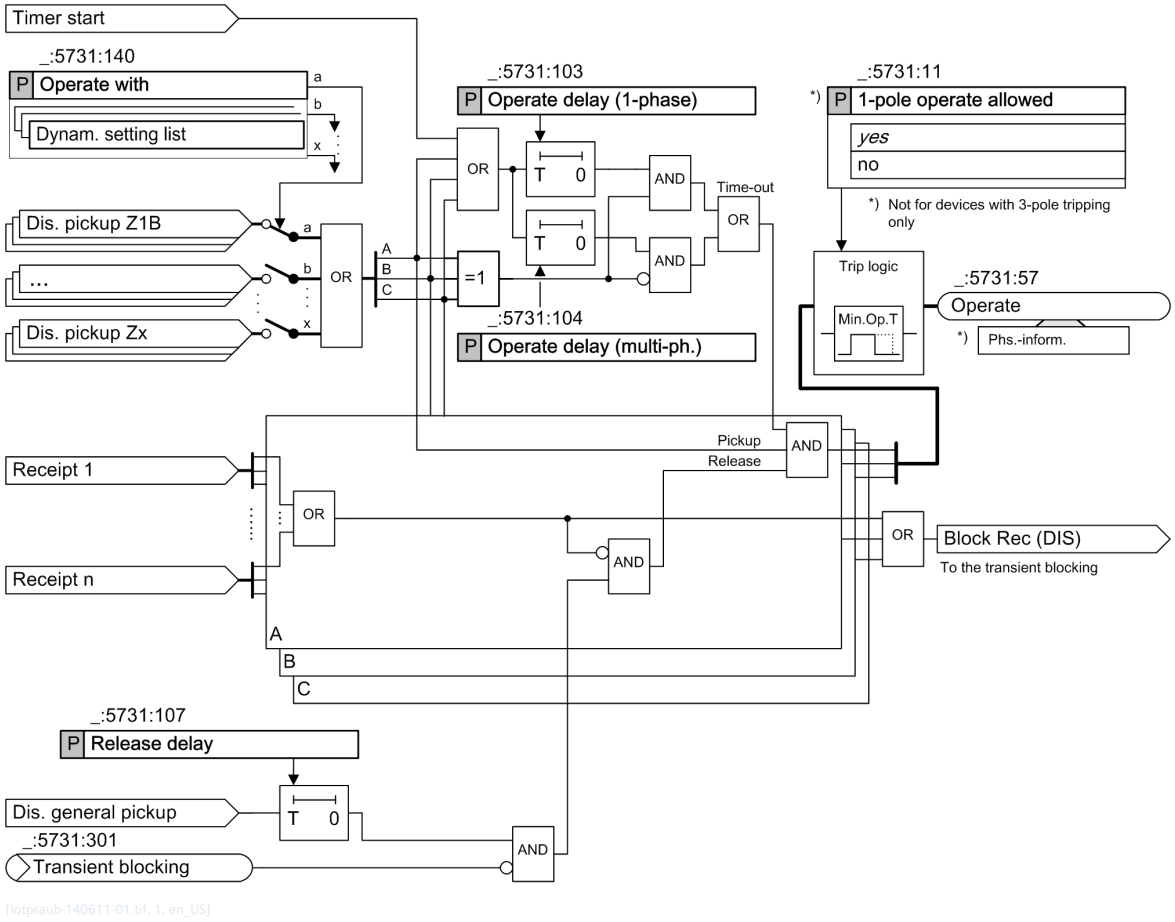
Sending Logic Blocking Method

[lotpssbl-040311-01.tif, 1, en_US]

Figure 6-361 Sending Logic for the Blocking Method

The blocking signal is generated on the activation of the distance protection in the **reverse** direction or **non-directionally**. The logic is designed in a phase-selective manner. With the parameter **(_:5731:101) Send prolongation**, you can extend the blocking signal. In this way, the opposite end can continue to be blocked, even if the fault has already been cleared locally.

The blocking signal can also be sent immediately with jump detection (parameter **(_:5731:102) Send with jump**). If the communication channel can react very quickly to the absence of the blocking signal, you can use this jump signal, because the jump signal appears for every jump in the dimensions. If the



distance protection detects a fault in the forward direction, the blocking signal is stopped immediately and the indication **Stop** is generated.

For applications with 1-pole trip, the selectiveness of the blocking method for double faults can be improved on parallel lines if 3 phase-selective transmission signals are transferred per communication direction. Transmission and reception signals can therefore be used phase-specifically for A, B, and C or phase-jointly as individual signals.

Related Topics

6.18.8.1 Description

Trip Logic Blocking Method

[lotpsaub-140611-01.tif, 1, en_US]

Figure 6-362 Trip Logic for the Blocking Method

The distance protection provides the pickup information to the teleprotection scheme. The tripping for the relevant zone is undertaken by that teleprotection scheme with which the distance protection works together.

If a receive signal is not present, the zone that is set through the parameter **(_:5731:140) Operate with** will be released for tripping. The trip of the blocking method must be delayed due to possible differences in the pickup times of the devices at both cable ends and because of the transmission time. The time delay is set with the **(_:5731:107) Release delay** parameter.

Tripping can also be delayed . For 1-phase faults, set the time delay under **Operate delay (1-phase)**; for multi-phase faults, use the parameter **Operate delay (multi-ph.)**.

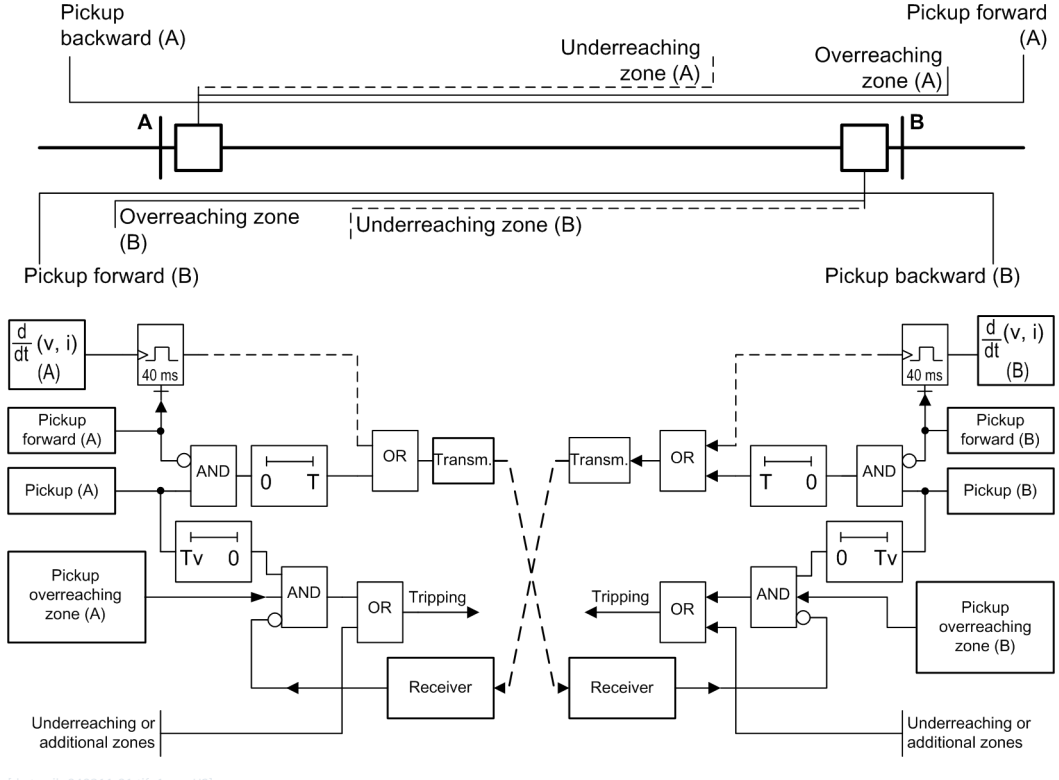
The trip indication therefore results when there is a simultaneous presence of the distance zone activation, the internal release signal and the time sequences.

No release of the trip occurs for an upcoming reception signal. The trip is blocked so that an activation in the selected overreaching zone in the forward direction does not quickly shut down the external fault at the remote end.

If the blocking method for the protection of a line configuration with more than 2 ends is used, the reception signals from all cable ends are combined with OR.

The **(_:5731:11) 1-pole operate allowed** parameter can be used to allow 1-pole tripping in 1-pole/3-pole tripping devices. This parameter does not apply to devices that only have 3-pole trip.

Measures in the Event of Weak Infeed



Owing to the process, there is no option in the blocking method for achieving a trip command release at weak infeed by the opposite end. Rather, the advantage of the blocking method lies in the fact that tripping can also occur rapidly at the infeed end without release, as no blocking signal can be formed from the non-feeding end.

6.18.6.2 Application and Setting Notes for the Blocking Method

The blocking method is used frequently:

- If the signal is transmitted with PLC[49] through the protected line and if the attenuation of the transmission signal at the fault location is so large that reception from the other line end cannot be guaranteed.
- For the protection of line configurations with more than 2 ends with different infeed

If the protection function detects a fault in the backward direction, a blocking signal is generated. If the other line end does not receive a blocking signal, the protection function trips in the event of a fault in the overreaching zone. For this, the overreaching zone must be set to approximately 120 % of the line length. In the case of multi-terminal lines, the overreach zone must extend over the longer line section, regardless of whether or not an additional infeed is possible via the branching point. Since no release signal is required from the opposite end, single infeed short circuits are quickly switched off with the blocking method.

[dwtpsrib-040311-01.tif, 1, en_US]

Figure 6-363 Function Diagram of the Direction Blocking Method

49 PLC = power-line carrier transmission

Requirements during Distance Protection

When using the blocking method, observe that the pickup of the distance protection in the backward direction must reach further than the overreach zone of the opposite end! For this purpose, at least one of the distance-protection stages must be set to *backward* or *non-directional*. If a fault has been removed in Z1B (after B) of the protection in A *Figure 6-363*, the distance protection in B must safely pick up in the backward direction, in order to be able to send a blocking signal from protection B to protection in A.

Parameter: Send with jump

- Recommended setting value **(_:5731:102) Send with jump** = ***Yes***

With the parameter **Send with jump**, you set whether the blocking signal is sent without delay with the jump detection. Siemens recommends using the fast blocking with jump and retaining the setting.

Parameter: Send prolongation

- Recommended setting value **(_:5731:101) Send prolongation** = ***0.05 s***

With the parameter **Send prolongation** in the transmission logic, you compensate the differences in the pickup and dropout times at both line ends. If SIPROTEC distance protection devices are used at all line ends, Siemens recommends the setting value ***0.05 s***.

Parameter: Operate delay (1-phase)

- Recommended setting value **(_:5731:103) Operate delay (1-phase)** = ***0.00 s***

With the parameter **Operate delay (1-phase)**, you set the tripping delay for 1-phase ground faults. Since the teleprotection scheme should lead to fast and selective tripping, Siemens recommends the setting value ***0.00 s***.

Parameter: Operate delay (multi-ph.)

- Recommended setting value **(_:5731:104) Operate delay (multi-ph.)** = ***0.00 s***

With the parameter **Operate delay (multi-ph.)**, you set the tripping delay for multi-phase faults. Since the teleprotection scheme should lead to fast and selective tripping, Siemens recommends the setting value ***0.00 s***.

Parameter: Operate with

- Recommended setting value **(_:5731:140) Operate with** = ***Z1B***

With the parameter **Operate with**, you select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations which you specify during the zone configuration in the function Distance protection. The selection text for the overreaching distance zone can therefore also be different from Z1B.

For applications in which the ranges for phase and ground faults are to be set differently, there are 2 overreaching distance zones. For example Z1B(Ph-E) then takes effect for ground faults and Z1B(Ph-Ph) for phase faults. In this case, you must select both zones as tripping zones.

Parameter: Release delay

- Recommended setting value **(_:5731:107) Release delay** = ***0.020 s***

With the parameter **Release delay**, you must set the release delay after a pickup. The trip of the blocking method must be delayed due to possible differences in the pickup times of the devices at both cable ends and because of the transmission time. Siemens recommends a setting value of ***0.020 s***.

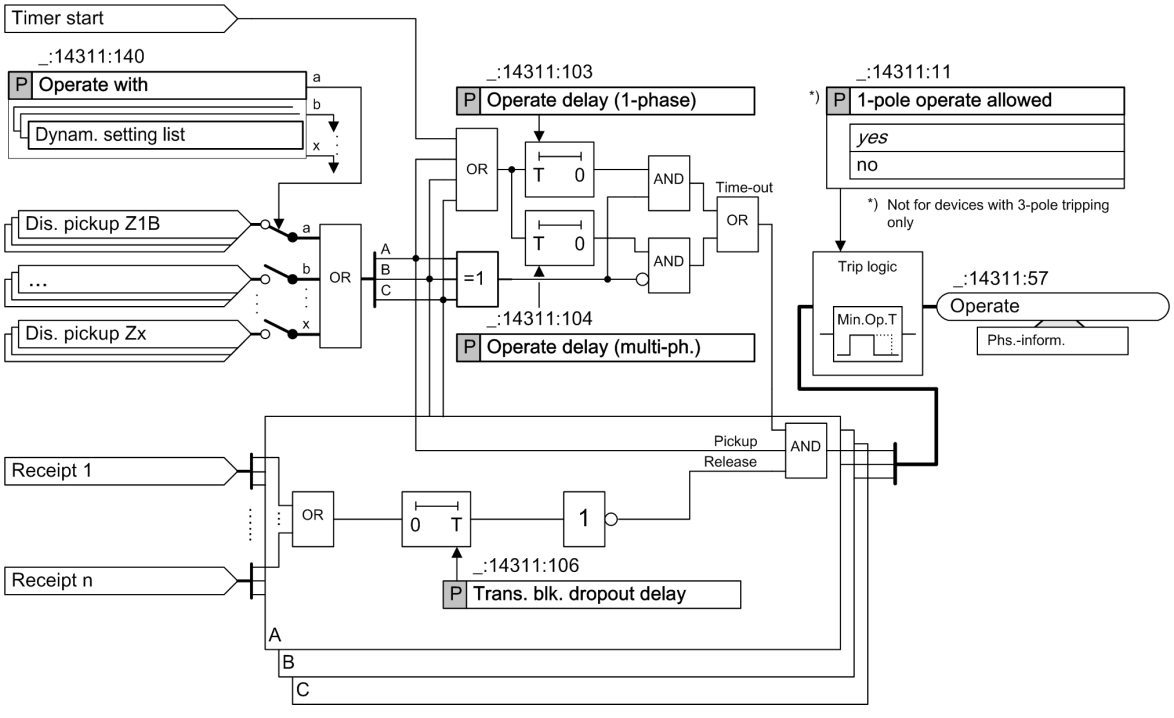
6.18.7 Reverse Interlocking

6.18.7.1 Description



[dwtpsrwv-260613-01.tif, 2, en_US]

Figure 6-364 Function Block: Reverse Interlocking (85-21 Rev. interlock.)

If a fault occurs within the crossover zone and none of the subordinate protection devices transmits a blocking signal, this will initiate tripping of reverse interlocking.

Trip Logic Reverse Interlocking

[loruever-260613-01.tif, 1, en_US]

Figure 6-365 Trip Logic for Reverse Interlocking

The distance protection provides the pickup information to the teleprotection scheme. The tripping for the relevant zone is undertaken by that teleprotection scheme with which the distance protection works together.

If a receive signal is not present, the zone that is set through the parameter **(_:14311:140) Operate with** will be released for tripping.

The tripping can be delayed. For 1-phase faults, set the time delay under **Operate delay (1-phase)**; for multi-phase faults, use the **Operate delay (multi-ph.)** parameter.

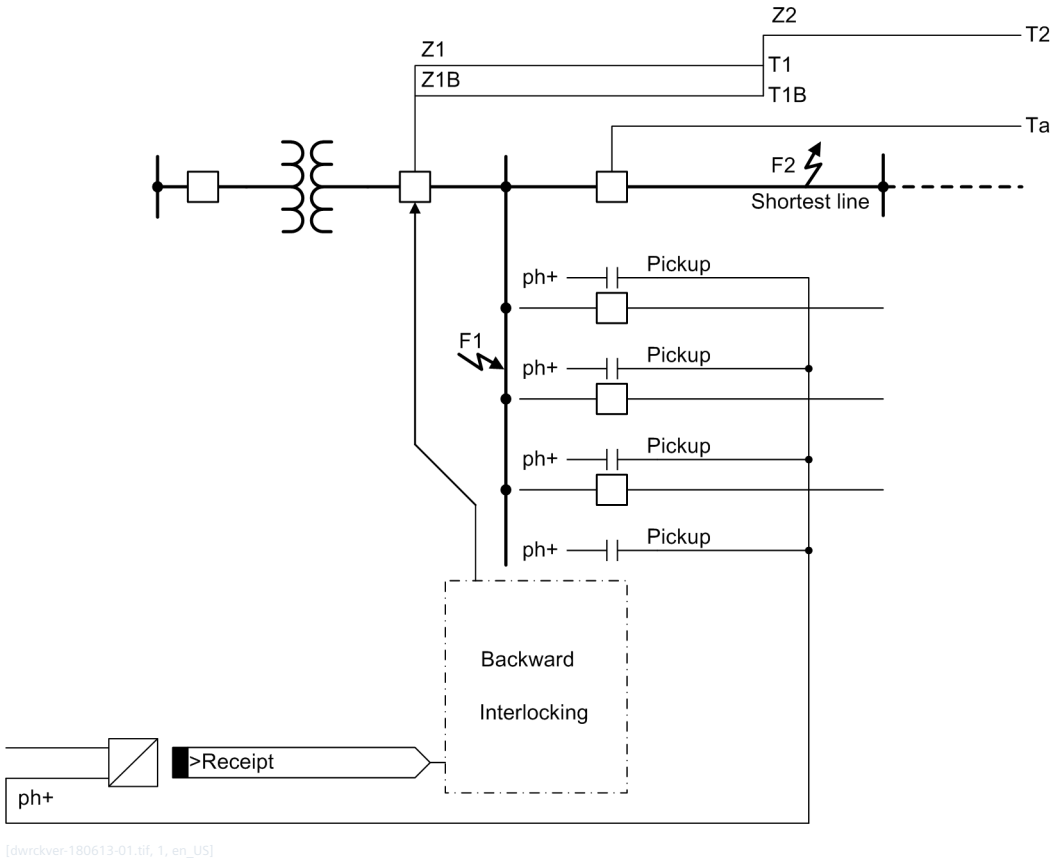
The trip indication therefore results when there is a simultaneous presence of the distance zone activation, the internal release signal and the time sequences.

If a receiving signal is pending, tripping will be blocked in order to ensure that a pickup in the selected crossover zone does not disconnect quickly the short circuit on the outbound line.

If the Reverse interlocking function is used with several receiving blocks, the receiving signals from all receiving blocks will be linked with OR.

The **(_:14311:11) 1-pole operate allowed** parameter can be used by the trip logic to allow 1-pole tripping in 1-pole/3-pole tripping devices. If the device is capable of only 3-pole tripping, the parameter **1-pole operate allowed** does not apply and is not visible.

6.18.7.2 Application and Setting Notes for Reverse Interlocking



If the distance protection is used as backward protection at a transformer tap fed in from one side, you can protect the busbar via reverse interlocking via quick-operating time. The selectivity of the distance protection for faults on outgoing lines will not be jeopardized.

The distance zones **Z1** and **Z2** according to *Figure 6-366* serve as reserve stage for errors on the out-bound lines, for example, in **F2**. Consider the shortest following line for distance staggering.

Typically, the crossover zone **Z1B** provides the pickup information for the reverse interlocking. The time delay for the reverse interlocking must be set higher than the pickup time **Ta** of the protection devices on the out-bound lines. In the event of subordinate protection pickup, tripping of the reverse interlocking is blocked. The pickup signals of the subordinate protection devices will be transmitted as receiving signal to reverse interlocking (see *Figure 6-366*). If none of the subordinate protection devices picks up, reverse interlocking generates a operate indication. This enables quick disconnection in the following scenarios:

- Short circuit on the busbar, for example, in **F1**
- If the circuit breaker fails during a fault in **F2**.

If the pickup signals of the subordinate protection devices drop faster than the pickup of the selected cross-over zones, the transient blocking time prevents an unwanted tripping of the reverse interlocking.

[dwrckver-180613-01.tif, 1, en_US]

Figure 6-366 Functional Schematic of Reverse Interlocking

Parameter: Operate delay (1-phase)

- Recommended setting value **(_:14311:103) Operate delay (1-phase)** = ***0.04 s***

You can use the **Operate delay (1-phase)** parameter to set the tripping delay for 1-phase ground faults. Due to possible differences in the pickup times of the devices and due to signal transmission times, tripping of the reverse interlocking must be delayed. Siemens recommends a setting of ***0.04 s***.

Parameter: Operate delay (multi-ph.)

- Recommended setting value **(_:14311:104) Operate delay (multi-ph.)** = ***0.04 s***

You can use the **Operate delay (multi-ph.)** parameter to set the tripping delay for multi-phase faults. Due to possible differences in the pickup times of the devices and due to signal transmission times, tripping of the reverse interlocking must be delayed. Siemens recommends a setting of ***0.04 s***.

Parameter: Operate with

- Recommended setting value **(_:14311:140) Operate with** = ***Z1B***

With the **Operate with** parameter, you can select the overreaching distance zone. The overreaching distance zone is typically designated with Z1B. The selection texts are identical to the designations which you specify during the zone configuration in the distance protection function. The selection text for the overreaching distance zone can therefore also be different from Z1B.

For applications in which the ranges for phase and ground faults are to be set differently, there are 2 overreaching distance zones. For example, Z1B(L-E) takes effect for ground faults and Z1B(L-L) for phase faults. In this case, you must select both zones as tripping zones.

Parameter: Trans. blk. dropout delay

- Recommended setting value **(_:14311:106) Trans. blk. dropout delay** = ***0.05 s***

With the **Trans. blk. dropout delay** parameter, you can determine the duration of the transient blocking. Set the **Trans. blk. dropout delay** to prevent an unwanted tripping of the reverse interlocking during a fast dropout of the pickup signal of the protection devices. Siemens recommends a setting of ***0.05 s***.

6.18.7.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting

6.18.8 Transient Blocking

6.18.8.1 Description

Transient blocking provides additional security from fault signals caused by a change of direction after disconnection of external faults, on parallel lines for example. The transient blocking is used for blocking and permissive overreach transfer trips, but not for a permissive underreach transfer trip.

[lotpstrb-310511-01.tif, 3, en_US]

Figure 6-367 Logic Diagram of the Transient Blocking

If a pickup in the reverse direction or non-directionally is present (non-forward fault), the transient blocking occurs after a waiting period **`Trans. blk. pickup delay`**. The *`Transient blocking`* signal has an effect on send and trip logic of the permissive overreach transfer trips as well as on the trip logic of the blocking method. After the elimination of the blocking criterion, the transient blocking will be maintained for a set time **`Trans. blk. dropout delay`**. If a trip command is generated in the underreaching zone during a transient blocking (signal **Release Trip forward (DIS)**, the transient blocking time is triggered. In this way, the blocking of the teleprotection in the event of an internal fault is prevented.

The teleprotection schemes for distance protection and ground-fault protection can affect one another. Use the **`Trans. block. with`** parameter to set whether the transient blocking of the teleprotection scheme for the ground-fault protection is to affect that of the distance protection. The reciprocal influence is advisable if the teleprotection schemes for distance protection and ground-fault protection work with a common communication channel.

6.18.8.2 Application and Setting Notes for Transient Blocking

Trans. Block through

- Default setting **`(_:5731:141) Trans. block. with`** = ***`EF: TrBlock XBlk`***

Set the parameter **`Trans. block. with`** to ***`EF: TrBlock XBlk`***, if the teleprotection scheme for the distance protection works on the same communication channel as a teleprotection scheme for the ground-fault protection. Set the parameter to ***`invalid`*** if you are using separate communication channels. If no teleprotection scheme is used for the ground-fault protection, it will not be possible to set the settings and the link will be automatically deactivated.

Parameter: Trans. blk. pickup delay

- Recommended setting value **`(_:5731:105) Trans. blk. pickup delay`** = ***`0.02 s`***

With the parameter **`Trans. blk. pickup delay`**, you set how long a reverse or non-directional pickup should remain before the transient blocking occurs. Siemens recommends a setting value of ***`0.02 s`***.

NOTE

The time **Trans. blk. pickup delay** may not be set to zero. This makes sure that the transient-blocking time **Trans. blk. dropout delay** is not already started if the directional information comes in a delayed manner compared to the function pickup. Depending on the time of the circuit breaker on the parallel line or the circuit breaker lying in a reverse direction, settings between 10 ms and 20 ms are recommended.

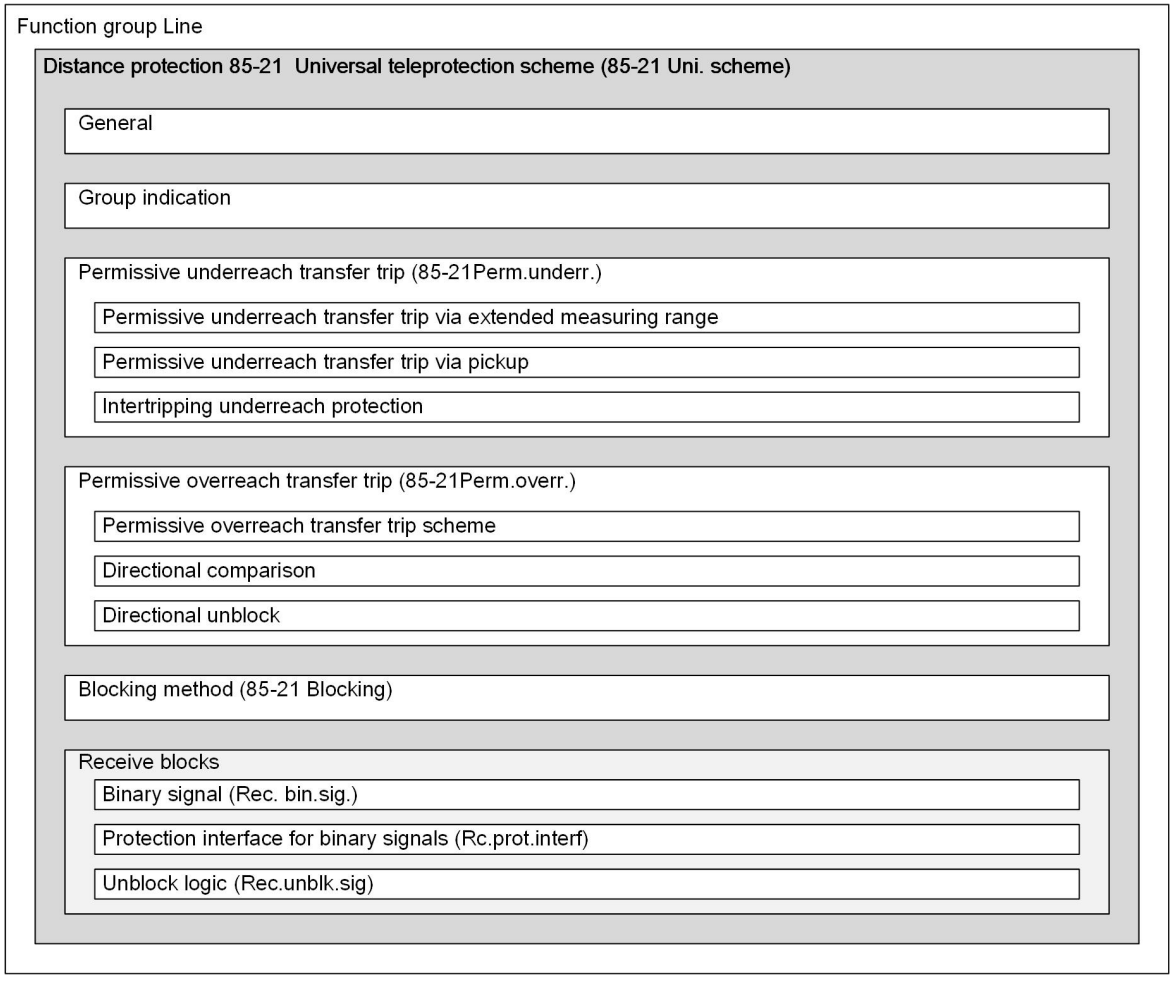
Parameter: Trans. blk. dropout delay

- Recommended setting value **(_:5731:106) Trans. blk. dropout delay** = ***0.05 s***

With the parameter **Trans. blk. dropout delay**, you determine the duration of the transient blocking. The time must be set longer than the duration of the transient compensation methods for the occurrence or switching of exterior short circuits.

6.19 Universal Teleprotection with Distance Protection

6.19.1 Overview of Functions



The universal teleprotection with distance protection (**85-21 Uni. scheme**) include the same functionalities as described in *6.18 Teleprotection with Distance Protection*. The difference is that all functionalities, except the scheme **85-21 Rev. interlock.**, are compactly grouped together within the function **85-21 Uni. scheme**. This can be an advantage if a switchover of the functionalities using settings changes is desired.

Since there are no functional differences between the teleprotection scheme with distance protection, only the special features are described in the following.

6.19.2 Structure of the Function

The function **85-21 Uni. scheme** is used in the function group **Line** in combination with the function Distance protection.

The functions shown in the following figure are available:

[dw_funct-line_universal, 1, en_US]

Figure 6-368 Structure/Embedding of the Function

In addition to the individual teleprotection with distance protection schemes, the universal teleprotection schemes contain the function blocks (FBs) **General** and **Group indicat.**.

You will find the function **85-21 Uni. scheme** in the DIGSI library under **FG Line** > **Teleprotection scheme** > **DIS universal scheme**.

The following functionalities are preinstantiated when the function **85-21 Uni. scheme** is instantiated:

- FB **General**
- FB **Group indicat.**
- FB **Permissive underreach transfer trip** (**85-21Perm.unde**)
- FB **Permissive scheme** (**85-21Perm.over**)
- FB **Blocking method** (**85-21 Blocking**)
- FB **Receive block for binary signal 1** (**Rec. bin.sig.** 1)
- FB **Receive block for binary signal 2** (**Rec. bin.sig.** 2)
- FB **Receive block, protection interface for binary signals** (**Rec. PI**)

The function blocks have the following properties:

Function Block	Deletable	Number of Instances	Default Setting, Mode
General	No	1	On
Group indicat.	No	1	On (cannot be changed)
85-21Perm.unde	Yes	5	Off
85-21Perm.over	Yes	5	Off
85-21 Blocking	Yes	5	Off
Rec. bin.sig.	Yes	5	Off
Rec. PI	Yes	1	Off
Rec.unblk.sig	Yes	5	Off

NOTE

As most function blocks are deactivated following preinstantiation, Siemens recommends checking these default settings.

NOTE

In contrast to the individual teleprotection schemes with distance protection, the function blocks **Rec. bin.sig.**, **Rec. PI** and **Rec.unblk.sig** have the parameter **Mode** and appear for this reason in the configuration view.

FB General

With the parameter **General** FB, you can power the function **85-21 Uni. scheme** on and off via the **Mode** parameter or the **Mode (controllable)** controllable.

In addition, the general indications of the function **85-21 Uni. scheme** are made available.

FB Group indicat.

The FB **Group indicat.** the information of all permissive underreach transfer trips, permissive schemes and blocking methods in one central location. If you are using several teleprotection schemes and you can switch between them using parameter changes, you can simplify the routing of indications in this way.

For more information about the teleprotection scheme, see:

- *6.18.4 Permissive Underreach Transfer Trip*
- *6.10.4 Permissive Overreach Transfer Trip*

- *6.10.5 Blocking Method*
- *6.19.3 Receive Blocks*

6.19.3 Receive Blocks

Several receive blocks **Rec. bin.sig.** as well as the receive block **Rec. PI** can be present at the same time.

If the line ends communicate using binary signals, the necessary receive blocks are connected to ***on*** via the **Mode** parameter. If a teleprotection scheme is configured, for example, with a total of 3 ends, exactly 2 receive blocks must be activated. All additional receive blocks that can be installed, even the **Rec. PI** receive block, must be deactivated.

If the line ends are to communicate via a protection interface, you must activate the **Rec. PI** receive block. All other receive blocks must be deactivated. A mixture of communication to the line ends using a protection interface and binary signals is not possible.

For more information on the operation of receive blocks, see *6.18.3 Receive Blocks*.

6.19.4 Application

The universal teleprotection with distance protection allows you to create a common configuration for several use cases. If, for example, you want to use permissive underreach transfer trip across an expanded measuring range and permissive underreach transfer trip by way of pickup in your plants, you can instantiate the permissive underreach transfer trip twice in the universal teleprotection scheme and configure it appropriately for each application. For the specific use in a plant, you simply need to switch the desired scheme to ***on*** via the **Mode** parameter.

It is equally possible to create a common configuration for the different options of communication with the other line ends. If you have plants with, for example, both 2 and 3 ends and either binary signals or a protection interface are used for communication, you can create 2 **Rec. bin.sig.** receive blocks as well as one **Rec. PI** receive block for this purpose, set their parameters appropriately and route the indications. The receive blocks needed for the specific use are switched to ***on*** via the **Mode** parameter.

For communication using the protection interface, you set the identity and the number of devices participating in the teleprotection scheme for the protection of the line configuration by using the configuration of the protection interface. For more information, see *3.6.5.4 Configuration of the Protection Interface in DIGSI 5* or *3.6.6.4 Configuration of the Advanced Protection Communication in DIGSI 5*.

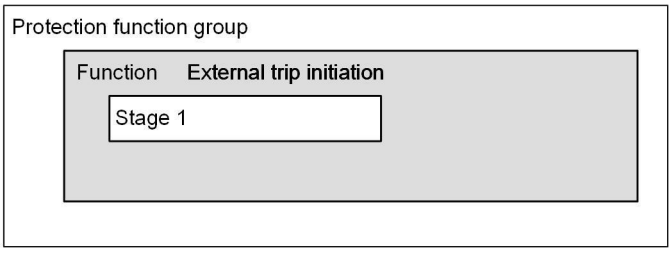
6.20 External Trip Initiation 3-Pole



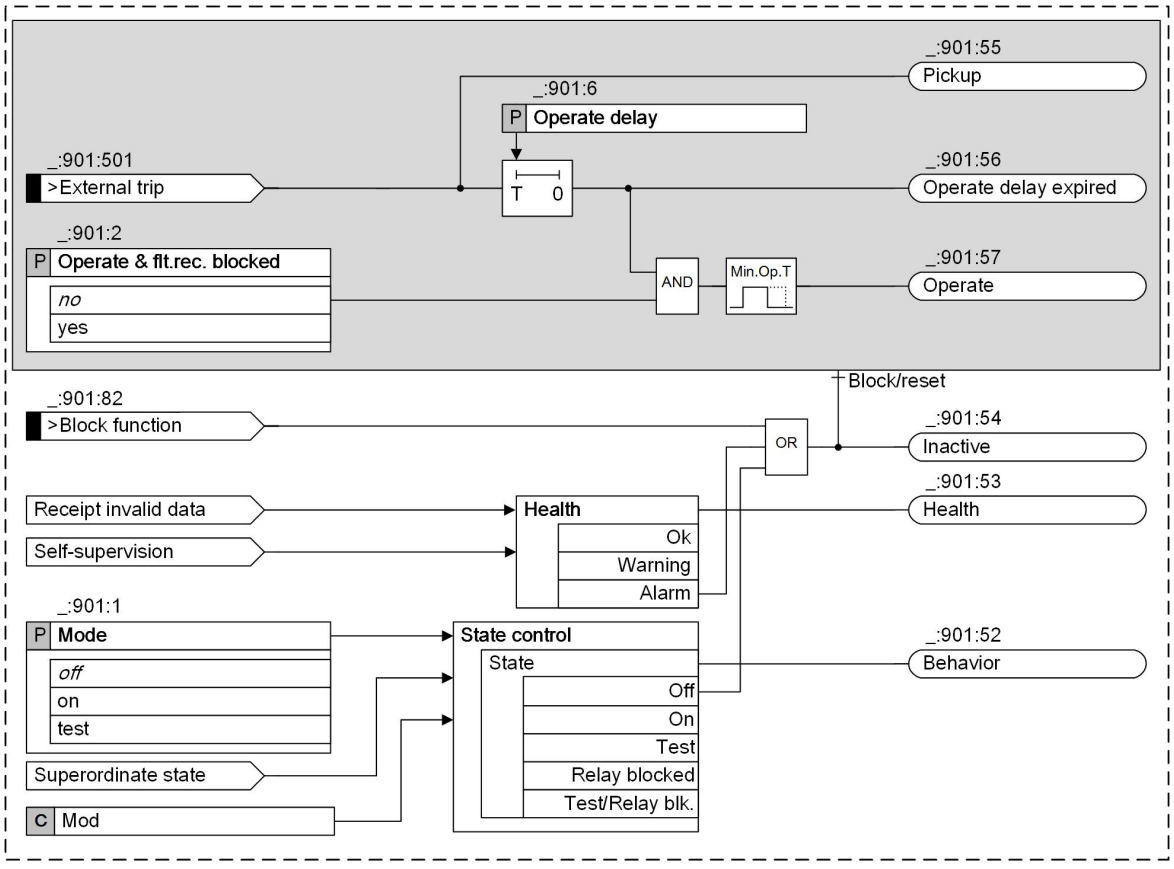
6.20.1 Overview of Functions

The **External trip initiation** function:

- Processes any signals from external protection or supervision devices
- Enables the integration of any signals from external protection equipment in the indication and tripping processing, for example from transient ground-fault relays or Buchholz protection
- Enables direct tripping of the circuit breaker in conjunction with busbar-protection applications
- Enables direct tripping of the circuit breaker in the case of circuit-breaker failure at the other line end

6.20.2 Structure of the Function

The function **External trip initiation** includes one stage. You can instantiate the **External trip initiation** function in DIGSI 5 multiple times.



[dw_strext, 2, en_US]

6.20.3 Stage Description

Logic of the Stage

[lo_ext-trip-initiation, 3, en_US]

Figure 6-370 Logic Diagram for the External Trip-Initiation Stage

Binary Input Signal >External Trip

The binary input signal **>External trip** starts the **Pickup** and the **Operate delay**.

Blocking the Stage

The stage can be switched to ineffective via a number of signals. If the stage is in the pickup state at the time of blocking, it will be immediately reset. However, the operate indication remains stopped for the minimum operating time **(_:102) Minimum operate time**.

6.20.4 Application and Setting Notes

Parameter: Operate delay

- Recommended setting value **(_:901:6) Operate delay** = ***0.00 s***

The **Operate delay** parameter must be set for the specific application. After expiry of the **Operate delay** the time-out and tripping are signaled. The duration of the initiation signal as well as the adjustable minimum command time determine the signal duration of the **Operate**.

6.20.5 Settings

Addr.	Parameter	C	Setting Options	Default Setting

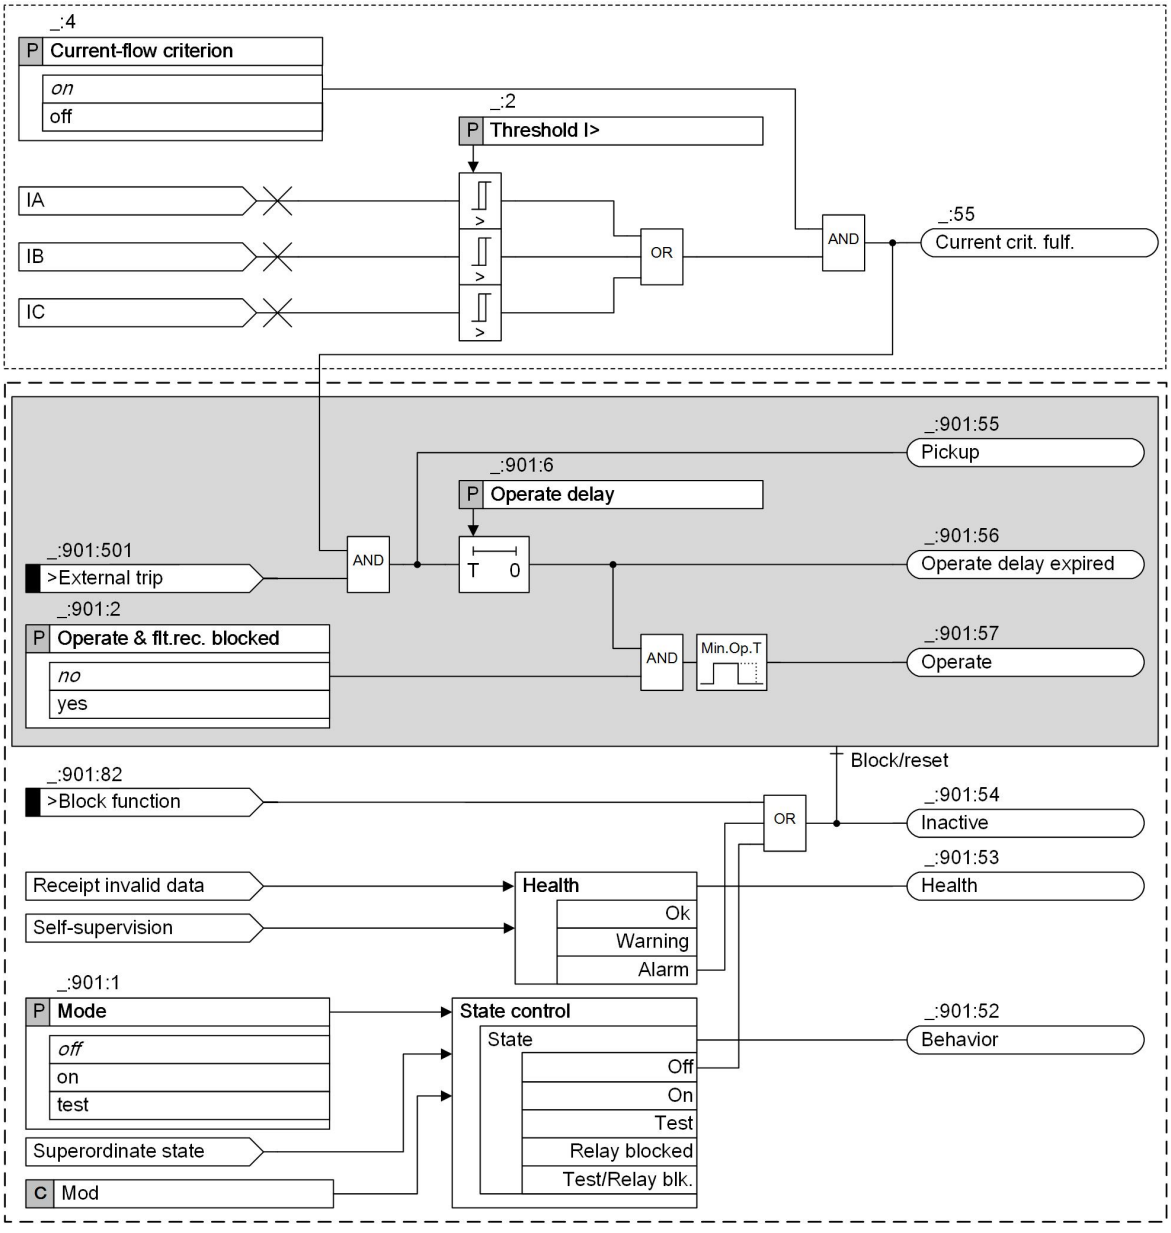
6.21 External Trip Initiation with Current-Flow Criterion 3-Pole

6.21.1 Overview of Functions

The **External trip initiation with current-flow criterion** function enables the use of a current-flow criterion. Otherwise, the function operates as the **External trip initiation** (see *6.20.1 Overview of Functions*).

6.21.2 Structure of the Function

The **External trip initiation with current-flow criterion** function contains 2 fixed steps. You can instantiate the **External trip initiation with current-flow criterion** function in DIGSI 5 multiple times.



[dw_strext_CfC-051021, 1, en_US]

Figure 6-371 Structure/Embedding of the Function

6.21.3 Stage Description

Stage Logic

[lo_ext-trip-initiation_CFC, 1, en_US]

Figure 6-372 Logic Diagram of the Stage External Trip Initiation with Threshold Value I>

Binary Input Signal >External Trip

The binary input signal **>External trip** starts the **Pickup** and the **Operate delay**.

Blocking the Stage

The stage can be switched to ineffective via a number of signals. If the stage is in the activate state at the time of blocking, it will be immediately reset. However, the operate indication remains for the minimum operating time **(_:102) Minimum operate time**.

6.21.4 Application and Setting Notes

Parameter: Operate delay

- Recommended setting value **(_:901:6) Operate delay** = *0.00 s*

The **Operate delay** parameter must be set for the specific application. After the expiry of the **Operate delay**, the time-out and tripping are signaled. The duration of the initiation signal and the adjustable minimum command time determine the signal duration of the **Operate**.

Parameter: Current-flow criterion

- Recommended setting value **(_:4) Current-flow criterion** = *on*

With the parameter **Current-flow criterion**, you can switch off the stage. When switched off, the external trip initiation can work without current criterion.

Parameter: Threshold I>

- Recommended setting value **(_:2) Threshold I>** = *0.05 A*

The **Threshold I>** parameter must be set for the specific application. The tripping is only output if the current exceeds the **threshold value I>**. This is also signaled by *(_:55) Current crit. fulf.*.

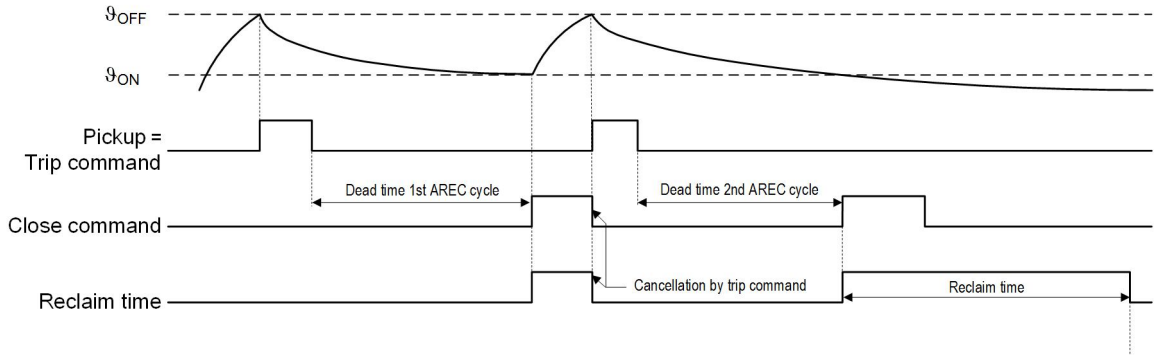
6.22 Automatic Reclosing Function

6.22.1 Overview of Functions

The Automatic reclosing function (ANSI 79/RREC)

- Automatically closes overhead lines after arc short-circuits
- Is only permissible for overhead lines, because only the possibility of self-activated extinguishing of an arc short-circuit exists here
- Can be controlled by integrated protection functions and by external protection devices
- The automatic reclosing can be controlled via an external automatic reclosing function via binary input signals.

The automatic reclosing function (AREC) takes over automatic reclosing after a switch off via a short-circuit protection. The following figure shows an example for the normal procedure with a two-time automatic reclosing where the 2nd automatic reclosing attempt is successful.

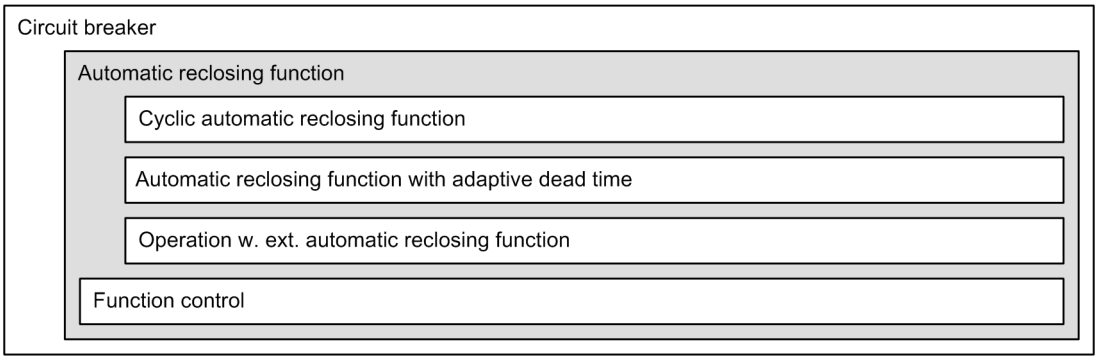


[dw_2awewz, 1, en_US]

Figure 6-373 Process Diagram of a Two-Time Reclosing with Action Time (2nd AREC Successful)

The integrated Automatic reclosing function allows up to 8 reclosing attempts. Each of the 8 disruption cycles can work with different parameters.

The following figure shows an example for normal procedure with a two-time automatic reclosing after disconnection via the internal overload protection. The 2nd automatic reclosing attempt is successful.



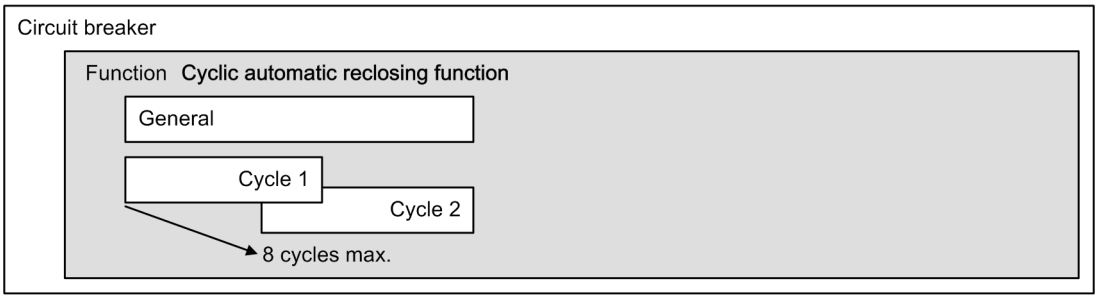
[dw_ablaufdiagramm_2-AWE-nach Abschalt-Thermo, 1, en_US]

Figure 6-374 Process Diagram of a Two-Time Reclosing after Disconnection via Overload Protection

The integrated Automatic reclosing function allows up to 8 reclosing attempts here as well. In contrast to disconnection through the short-circuit protection, each of the 8 disruption cycles can work with its own parameters that are the same for all cycles.

6.22.2 Structure of the Function

The Automatic reclosing function is used in function groups for circuit breakers. In a function group for circuit breakers, one of the 3 types of functions illustrated in the following figures can be used. The Automatic reclosing function has a central function control.



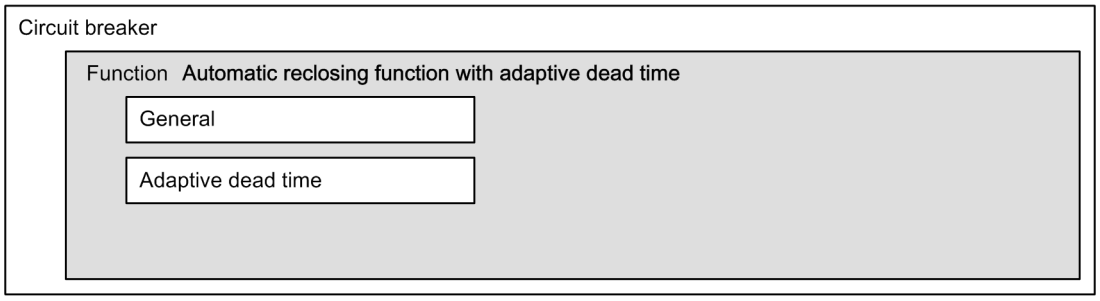
[dw_fkt_awe, 1, en_US]

Figure 6-375 Structure/Embedding of the Function

Cyclic Automatic Reclosing Function

The Cyclic automatic reclosing function (*Figure 6-376*) allows up to 8 reclosing attempts. Here each disruption cycle can work with different settings.

For the Cyclic automatic reclosing function, 1 cycle is preset. The preset cycle cannot be deleted. You can add and delete additional cycles from the function library in DIGSI 5.

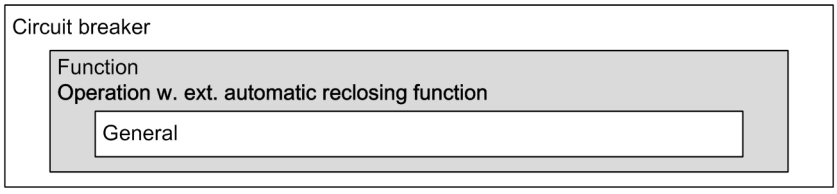


[dw_zyk_awe, 1, en_US]

Figure 6-376 Structure/Embedding of the Cyclic Automatic Reclosing Function

Automatic Reclosing Function with Adaptive Dead Time

The Automatic reclosing function with adaptive dead time (ADT) works without set disruption cycles (*Figure 6-377*). The requirement for the usage of ADT is that voltage transformers on the line-side are connected or there is a possibility for the transmission of a close command to a remote line end. With the ADT, the Automatic reclosing function decides independently if and when an automatic reclosing is reasonable and permissible and when it is not. The criteria is the phase-to-ground voltage, which is switched through after reclosing from the opposite line end. The Automatic reclosing function with ADT occurs as soon as it is known that the line from the opposite end has been placed back under voltage.

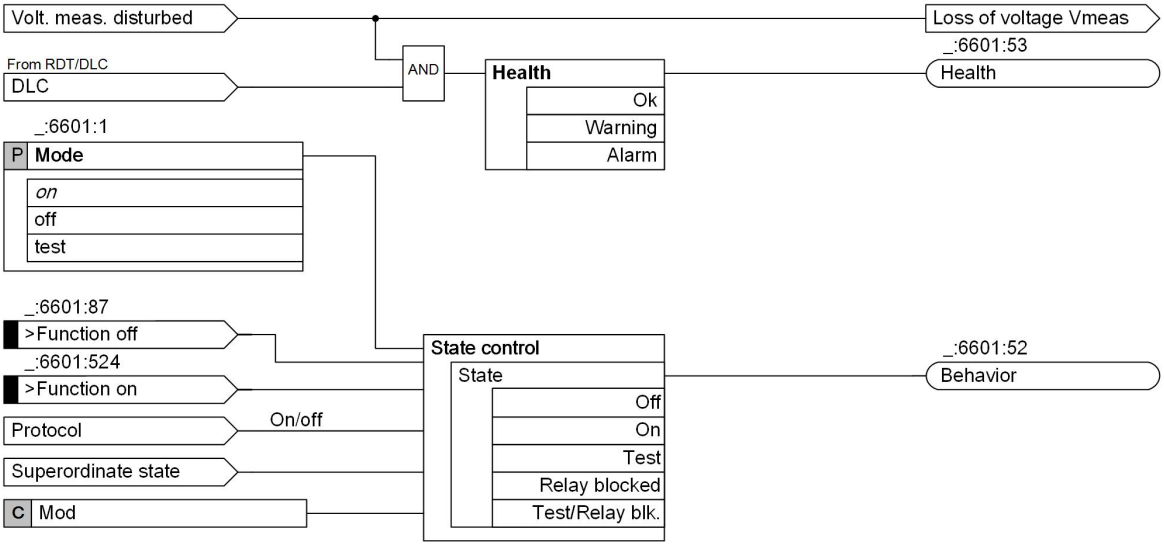


[dw_aweasp, 1, en_US]

Figure 6-377 Structure/Embedding of the Automatic Reclosing Function With Adaptive Dead Time (ADT)

Operation with External Automatic Reclosing Function

If an external reclosing device operates together with the SIPROTEC protection device, use the function type **Operation with external automatic reclosing function** (*Figure 6-378*). The function only provides binary inputs for the influence of the protection functions in the SIPROTEC protection device. The external reclosing device delivers the close command. The SIPROTEC protection functions then provide for the trip commands.



[dw_extawe, 1, en_US]

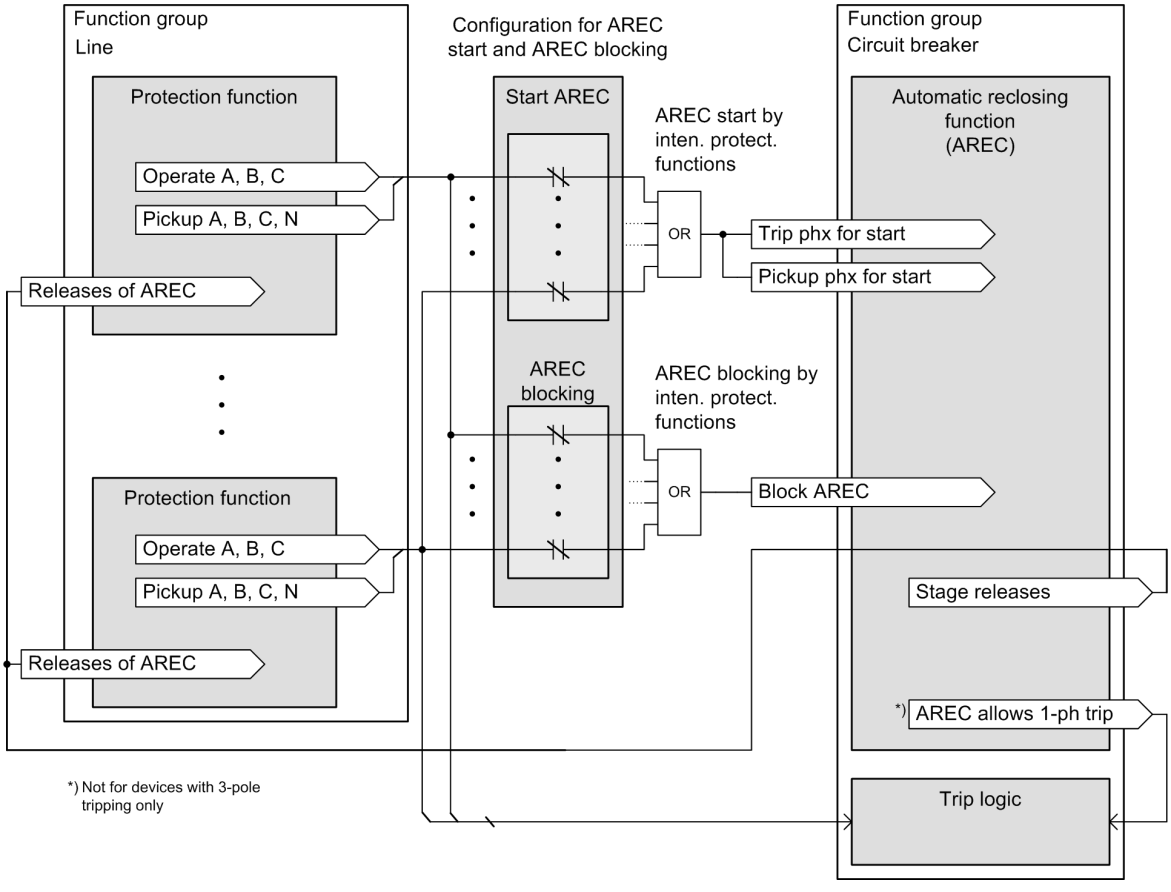
Figure 6-378 Structure/Embedding of the Operating Function With External Automatic Reclosing Function

Function Control

The Automatic reclosing function contains a central function control, see the following figure. You can find detailed information on the function control in the chapter **Function/Stage Control**.

[lo_arc_fkt, 2, en_US]

Figure 6-379 Function Control for the Automatic Reclosing Function



6.22.3 Cooperation of the Automatic Reclosing Function and Protection Functions

The automatic reclosing function (AREC) can be influenced by the protection functions in the following way:

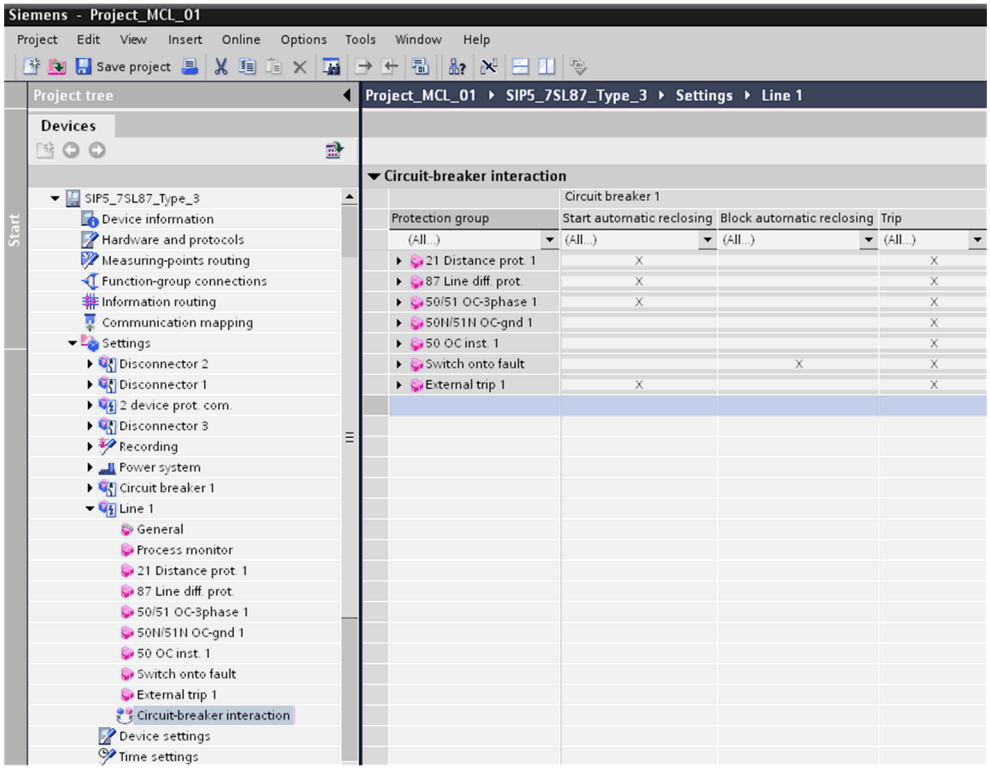
- The AREC is started through pickup indications and operate indications by the selected protection functions or protection stages. The start is independent of the set operating mode for the AREC.
- Individual protection functions or protection stages can be configured so that their operate indication blocks the AREC. If such a blocking exists, the AREC cannot be started. If the AREC is already started, the blocking will lead to the cancellation of the AREC.

The automatic reclosing device can thus have an influence on the effects of the protection functions. The following influence possibilities exist:

- The AREC provides signals that can be used by protection functions for the blocking or release of special stages or zones. An example is the release of overreaching zones with distance protection.
- For applications with 1-pole tripping, the automatic reclosing function provides a signal, based on which the protection functions can turn off the 1-pole circuit breaker.
- For the application with 1-pole tripping and stage or zone release through the automatic reclosing function, this function provides a signal that uses the protection functions that lets the stage and zone release act only if a 1-pole faults occurs.

[loawesig-160611-01.tif, 1, en_US]

Figure 6-380 Signals between Protection Functions and Automatic Reclosing Functions



The configuration of the interaction between internal protection functions and automatic reclosing functions can be set separately for each protection function, see *Figure 6-380*. The configuration occurs in a matrix view in DIGSI, see *Figure 6-381*.

If a protection function or the stage of a protection function is connected with the AREC through the matrix, this means that the respective pickup and operate indications are forwarded to the AREC.

The links can be created separately

- For starting the automatic reclosing function and
- For the blocking of the automatic reclosing function.

The automatic reclosing function also has the corresponding binary inputs and binary outputs through which the external protection devices can be connected to the internal automatic reclosing function.

[scdigsia-080311-01.tif, 1, en_US]

Figure 6-381 Configuration of the Protection Functions for Starting and Blocking the Automatic Reclosing Function in DIGSI 5

6.22.4 Cyclic Automatic Reclosing Function

6.22.4.1 Operating Modes for Cyclic Automatic Reclosing Function

For the cyclic automatic reclosing function, there are 4 operating modes, from which one can be selected for the parameterization (parameter **(_:6601:101) 79 operating mode**).

The selection of the operating mode is dependent on the tripping behavior of the protection functions and the circuit breaker.

For applications with 3-pole tripping, all 4 operating modes are available. For applications with 1- and 3-pole tripping, one can select between 2 operating modes.

Their connections are displayed in the following table.

Table 6-9 Operating modes of the cylindrical automatic reclosing function in accordance with tripping behaviors

Operating Mode of the Cyclic Automatic Reclosing Function (AREC)	Tripping Behavior	
	3-Pole Tripping	1-Pole and 3-Pole Tripping
Operating mode 1 ***with op., with act. time***	X	X
Operating mode 2 ***w.pickup, w. action time***	X	-
Operating mode 3 ***with op., w/o act. time***	X	X
Operating mode 4 ***w.pickup, w/o act. time***	X	-

Operating mode 1: with op., with act. time

The operating mode ***with op., with act. time*** allows different automatic reclosing cycles depending on the tripping type and operate time of the protection function(s). With this operating mode, the automatic reclosing must be started with the operate indications. Additionally, the general pickup must also be considered.

With raising general pickup, the action times of the configured automatic reclosing cycles start. The general pickup is in this connection the group indication of all internal protection functions configured for starting the automatic reclosing and the external binary input for general pickup *>Gen. pickup for start*.

Through the time between the raising general pickup and clearing operate indication, the automatic reclosing cycle to be started will be determined. Here for multiple automatic reclosing cycles, the sequence of the expiring automatic reclosing cycles is not fixed, like the operating modes without action time.

- During a 3-pole trip indication, the automatic reclosing cycle(s) start(s), for which 3-pole dead times are set.
- During a 1-pole trip indication, the automatic reclosing cycle(s) start(s), for which 1-pole dead times are set.

The following example in *Figure 6-382* shows a 1-pole tripping that comes after expiration of the action time of cycle 1, but still before the expiration of the action times from cycle 2 and cycle 3. Cycle 2 is set to make a 1-pole tripping possible. Cycle 2 will now become active with the settings for 1-pole tripping.

Within the following reclaim time, there will be another pickup and a 3-pole tripping. Since cycle 2 is already complete, these and all lower cycles are no longer able to expire. The second trip command comes during the current action time of cycle 3. Thus, cycle 3 becomes active with the settings for 3-phase trippings.

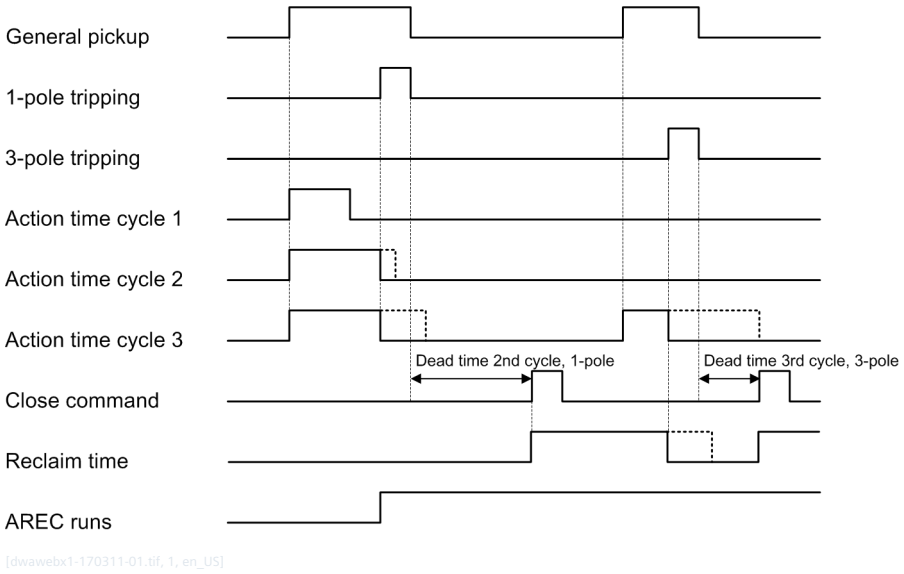


Figure 6-382 Operating-Mode Signal Examples: With Tripping/With Action Time

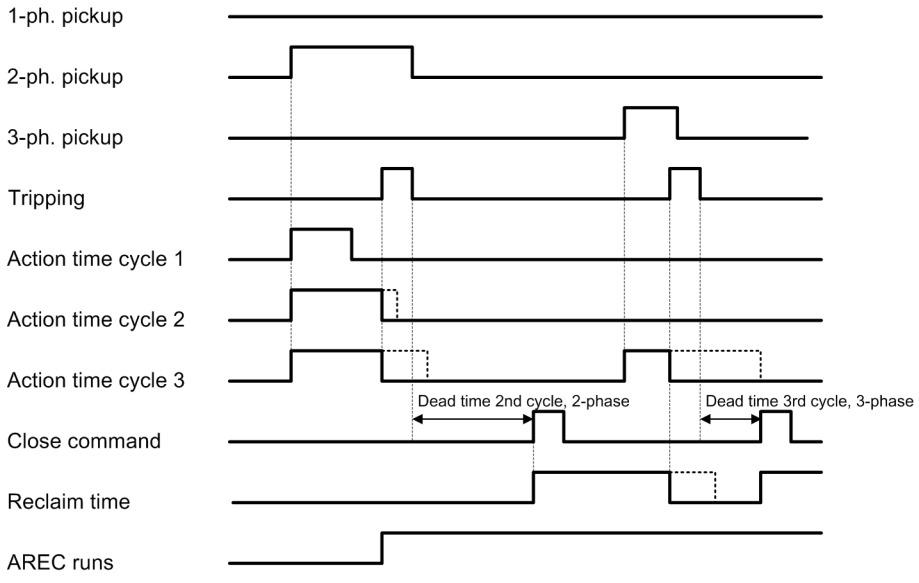
Through the action time, there is a direct influence on the dead time behavior of the automatic reclosing function. With faults with short operate times, other dead times can be realized than for removed faults with longer tripping time. With faults with short operate time, an automatic reclosing is executed, with removed faults this does not occur with longer operate time. The operating mode ***with op., with act. time*** allows for different automatic reclosing cycles depending on 1- or 3-pole tripping and the trip time of the protection function(s).

Operating mode 2: w.pickup, w. action time

The operating mode ***w.pickup, w. action time*** allows different automatic reclosing cycles depending on the operate time and type of fault. It is only suitable and applicable for applications with 3-pole tripping.

With this operating mode, the automatic reclosing must be started with the operate indications from the protection functions. Additionally, the pickup sample from the conductor pickups and the general pickup are considered:

- With 1-phase pickup, the automatic reclosing cycles set for 1-phase dead times are activated. 1-phase pickup includes both pickup samples **phase-to-ground** and **only grounding**.
- With 2-phase pickup, the automatic reclosing cycles set for 2-phase dead times are activated.
- With 3-phase pickup, the automatic reclosing cycles set for 3-phase dead times are activated.



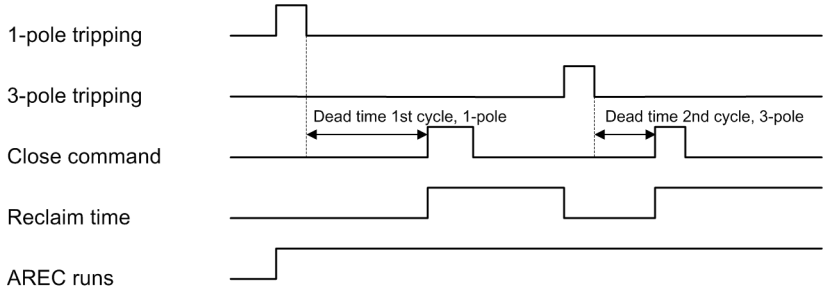
With each automatic reclosing cycle, it is checked to see if it is a 1-phase, 2-phase or 3-phase pickup.

With raising general pickup, the action times of the configured automatic reclosing cycles start. The general pickup is in this connection the group indication of all internal protection functions configured for starting the automatic reclosing and the external binary input for general pickup *>Gen. pickup for start*.

Through the time between the raising general pickup and raising trip command, the automatic reclosing cycle to be started will be determined. Here for multiple automatic reclosing cycles, the sequence of the expiring automatic reclosing cycles is not fixed, like the operating modes without action time.

The following example shows a tripping that comes after expiration of the action time of cycle 1, but still before the expiration of the action times from cycle 2 and cycle 3. Since it is a 2-phase pickup, cycle 2 is active with the dead-time setting for 2-phase faults.

After reclosing, there will be another, this time 3-phase, pickup and tripping within the following reclaim time. Since cycle 2 is already complete, these and all lower cycles are no longer able to expire. The trip command comes during the current action time of cycle 3. Thus, cycle 3 is active, with the dead time setting for 3-phase faults.



[dw_arcbm2, 1, en_US]

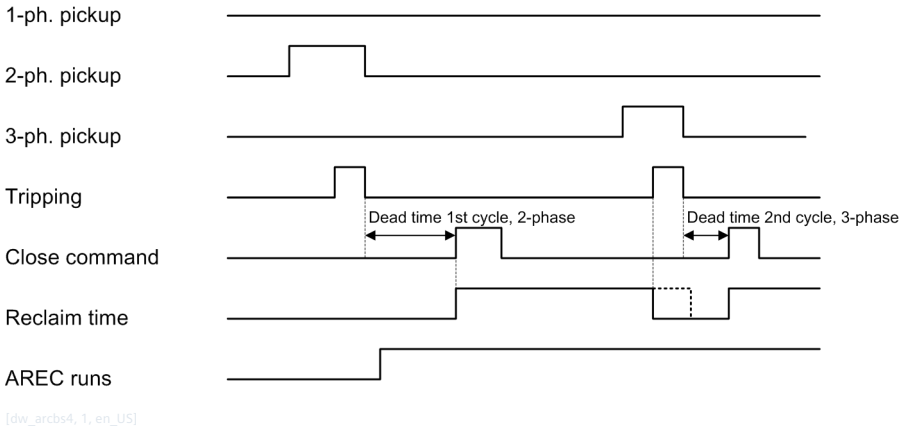
Figure 6-383 Operating-Mode Signal Examples: With Pickup/With Action Time

Operating mode 3: with op., w/o act. time

With the operating mode ***with op., w/o act. time***, the respective dead time is started after each trip command. The sequence of the automatic reclosing function is exclusively control by the operate indications. The pickups are not considered. Unless parameters are not set otherwise, a 3-pole operate indication initiates the 3-pole dead time start, a 1-pole operate indication initiates the 1-pole dead time start. If more than one automatic reclosing cycle is configured, the sequence of the expiring automatic reclosing cycles is identical with the cycle number (1, 2, and 3.).

[dwawebs3-010612-01.tif, 1, en_US]

Figure 6-384 Operating-Mode Signal Examples: With Tripping/Without Action Time



Operating mode 4: w.pickup, w/o act. time

With the operating mode ***w.pickup, w/o act. time***, the automatic reclosing must be started with the operate indications from the protection functions. It is only suitable and applicable for applications with 3-pole tripping.

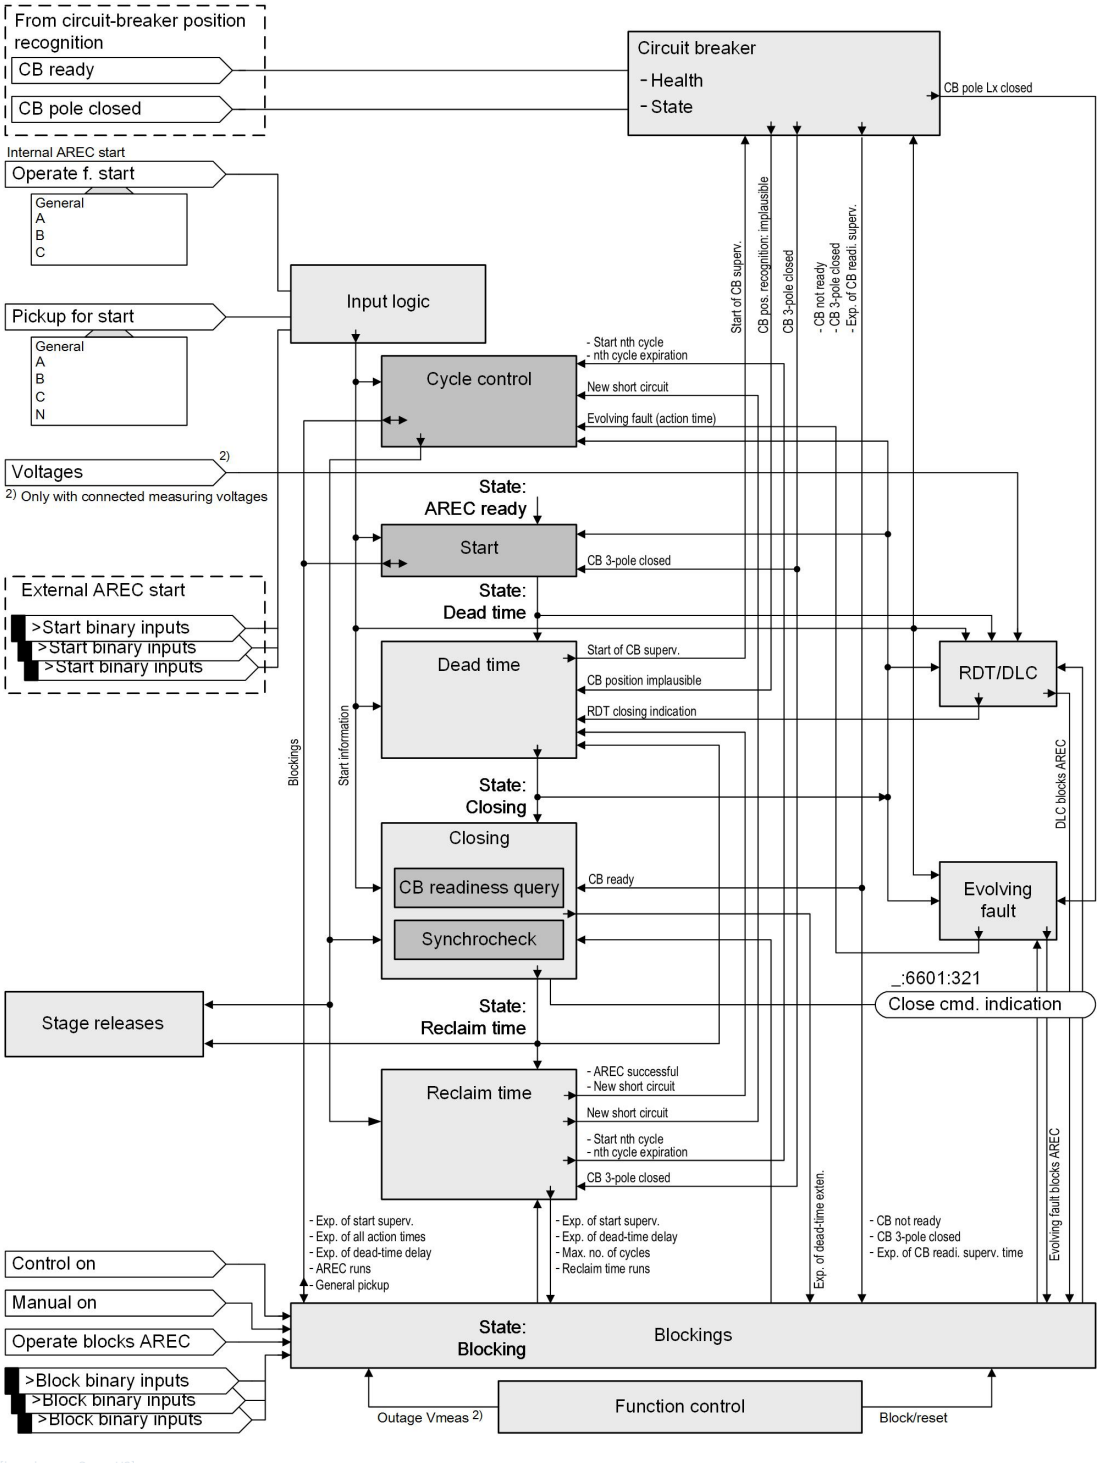
The start of the dead time occurs after each trip command. Additionally, the pickup sample from the conductor pickups is considered:

- With 1-phase pickup, the automatic reclosing cycles set for 1-phase dead times are activated. 1-phase pickup includes both pickup samples **phase-to-ground** and **only grounding**.
- With 2-phase pickup, the automatic reclosing cycles set for 2-phase dead times are activated.
- With 3-phase pickup, the automatic reclosing cycles set for 3-phase dead times are activated.

With each automatic reclosing cycle, it is checked to see if it is a 1-phase, 2-phase or 3-phase pickup. If more than one automatic reclosing cycle is configured, the sequence of the expiring automatic reclosing cycles is identical with the cycle number (1, 2, 3, etc.).

[dw_arcbs4, 1, en_US]

Figure 6-385 Operating-Mode Signal Examples: With Pickup/Without Action Time



6.22.4.2 Structure of the Cyclic Automatic Reclosing Function

In *Figure 6-386*, the functional structure of the cyclic automatic reclosing function is illustrated as a block diagram. The figure displays the important signals, coming from outside of the cyclic automatic reclosing function, and the most important signals between the individual function blocks.

The automatic reclosing function works as a state machine. From the idle state **AREC ready**, the automatic reclosing function gets through the tripping or pickup indications of the protection functions to the **Dead time** state. After expiration of the dead time, the subsequent state is reached with the closing indication. The reclaim time is also started together with the closing indication. If the reclaim time can expire without further operate or pickup indications, the automatic reclosing is successful and the automatic reclosing function turns back to idle state.

If the automatic reclosing function is restarted during the current reclaim time, there will be either a dynamic blocking or other reclosing cycles will be executed. If other reclosing cycles are possible, there will be a dead time start and the described process starts again.

After the end of a dynamic blocking, the automatic reclosing function switches back to idle state or it goes into the state **Static Blocking** if the blocking condition is permanently present. In the following sections, the individual function blocks are described in detail.

[lo_zyk_awe, 2, en_US]

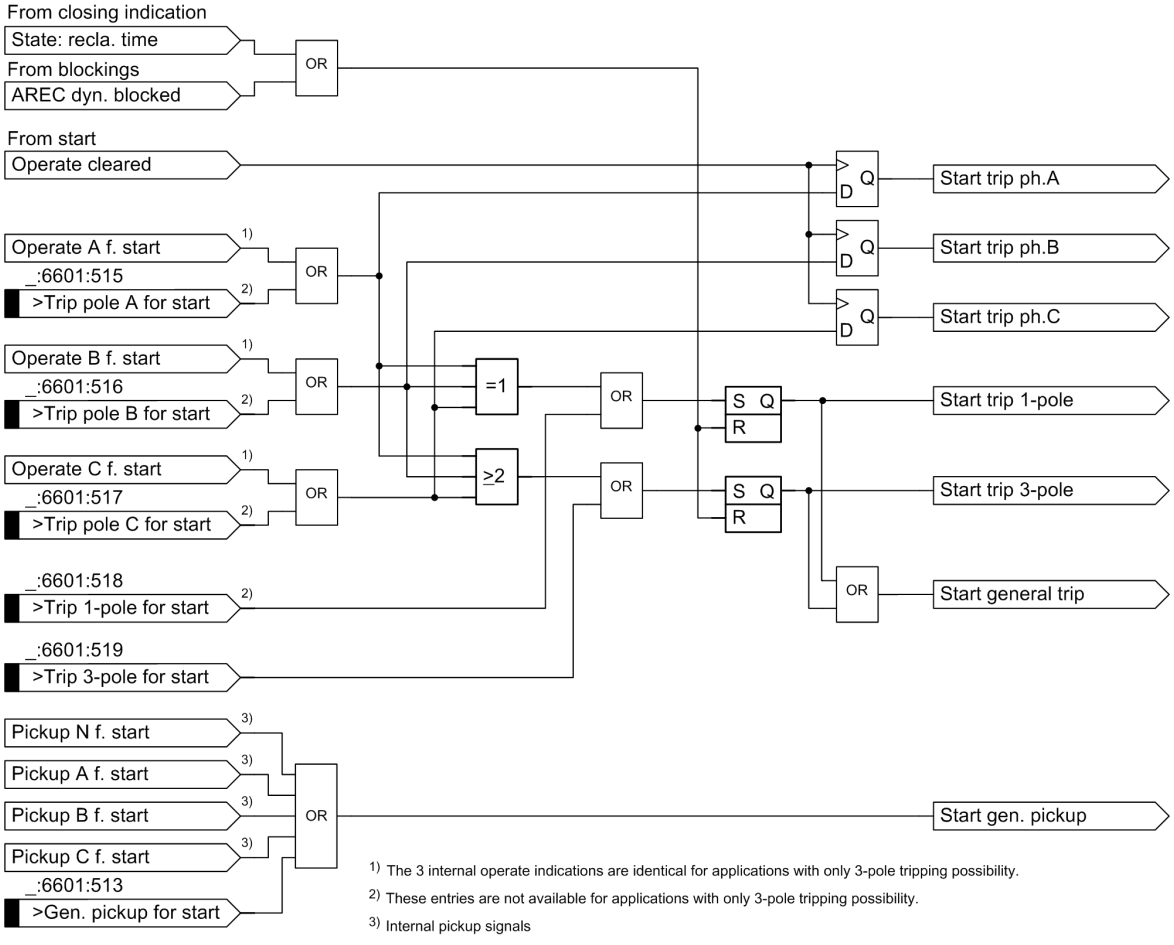
Figure 6-386 Cyclic Reclosing Function: Block Diagram of Automatic Reclosing

6.22.4.3 Input Logic for Operating Modes with Tripping

The operate indications are used as starting signals. For operating modes **with action time**, the start of the action time(s) occurs with the pickup indications. During all operating modes, the pickup indications are also required during the processing of faults and for supervision during the reclaim time.

Applications with 3-Pole Tripping

For applications with only 3-pole tripping options, the internal operate indications are always 3-pole. For external starts, there is a binary input, which signalizes a 3-pole tripping of the external protection device.



The outputs of the input logic signalize that the reclosing start has occurred through a 3-pole operate indication.

Application with 1-Pole and 3-Pole Tripping

Depending on the generated protection function, during the application with 1-pole and 3-pole tripping options, the internal trip indication may be phase-selective or 3-phase. If an external start via binary input is selected, phase-selective inputs as well as inputs for 3-pole start are available.

The outputs of the input logic indicate whether the reclosing start has occurred through a 1-pole or 3-pole operate indication. A start initiated by a 3-pole tripping is recognized if more than 1 pole signaled a tripping during at least one time lapse within the period from the first incoming operate indication up to the last outgoing operate indication.

At the time of the outgoing operate indication, all tripped poles will be stored. This information is used for the plausibility check between the auxiliary contacts of the circuit breaker and assigned operate indication, see chapter *6.22.4.11 Dead Time for Operating Modes with Tripping*.

[lo_bta_aus, 2, en_US]

Figure 6-387 Input Logic for Operating Modes: With Tripping

6.22.4.4 Input Logic for Operating Modes with Pickup

The operate indications and the pickup indications are used as starting signals. The internal pickup indications are processed selective to the phase. Through binary inputs, the pickup information can also be coupled by external protection devices (*>Pickup A for start*, *>Pickup B for start* and *>Pickup C for*

start). Optionally, the pickup information can be externally captured as a pickup sample, thus, as a 1-phase, 2-phase and 3-phase pickup.

The outputs of the input logic signalize if the automatic reclosing start occurs through a 1-phase, 2-phase, or 3-phase pickup:

- On **Start with 3-phase pickup**, it is recognized if all 3 phases were picked up in the period from the first raising pickup indication up to the last clearing outgoing pickup indication.
- On **Start with 2-phase pickup**, it is recognized if all 2 phases were picked up in the period from the first raising pickup indication up to the last clearing pickup indication and at no time 3 phases.
- On **Start with 1-phase pickup**, it is recognized if only 1 phase was picked up in the period from the first raising pickup indication up to the last clearing pickup indication.

For operating modes **with action time**, the start of the action time(s) occurs with the pickup indications. During operating modes **with pickup**, the pickup indications affect the selection of the dead times. During all operating modes, the pickup indications are also required during the processing of faults and for supervision during the reclaim time.

The automatic reclosing operating modes **with pickup** are only ideal for applications with 3-pole tripping. Therefore, the outputs of the input logic always signal 3-pole operate indications.

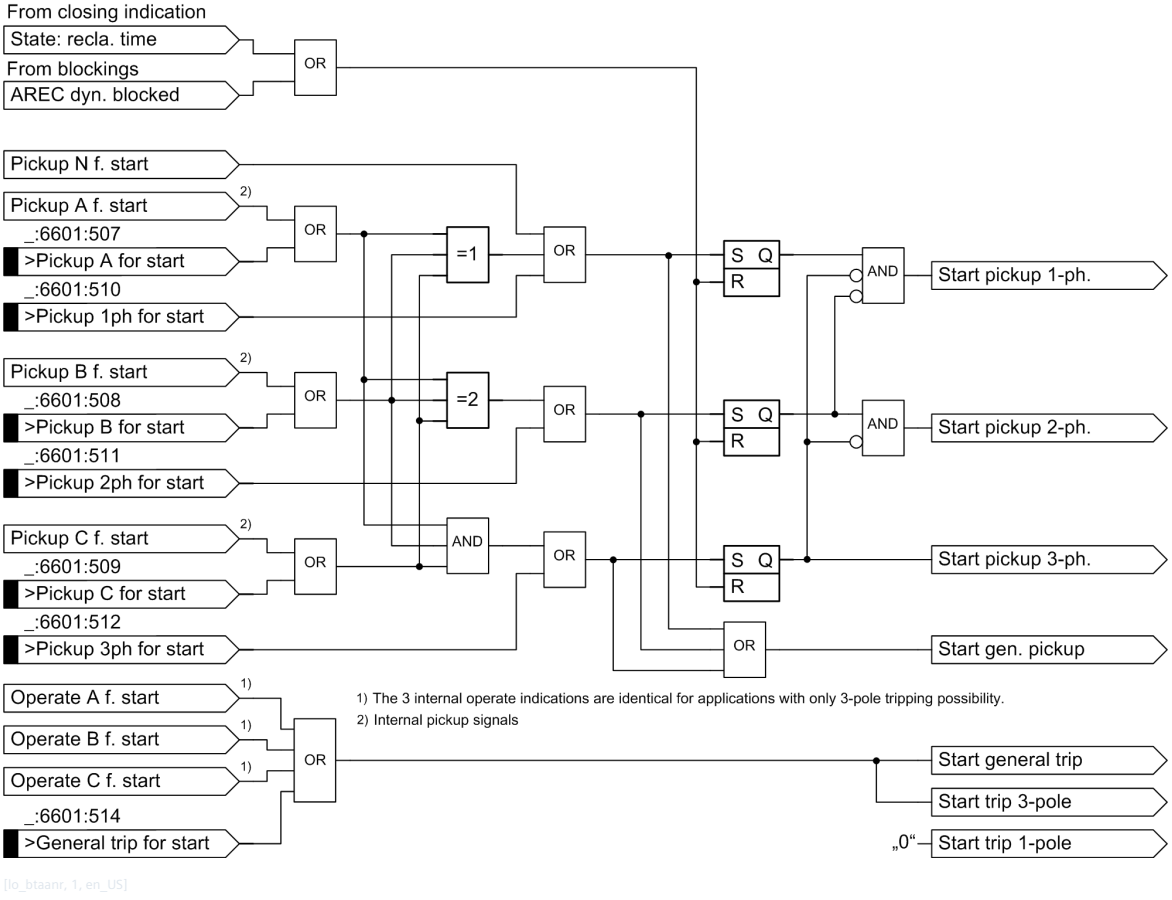


Figure 6-388 Input Logic for Operating Modes: with Pickup

6.22.4.5 Start

In the **Start** function block, the automatic reclosing function is switched from the idle state **AREC ready** to the state **Dead time**, see *Figure 6-389*. The length of the starting signals is controlled with a supervision time.

Start-Signal Supervision Time

The start-signal supervision stops the automatic reclosing if the short circuit is not switched off within the normal time; for example, in the case of a circuit-breaker failure.

With the first raising operate indication, the start-signal supervision time is initiated, parameter **`Start signal supervis.time`**. The time is stopped as soon as no operate indication is active.

The automatic reclosing function is blocked if there is an expiration of the start-signal supervision time through a long operate indication. The blocking lasts until the operate indication stops, extended by a further 0.5 s.

Transition to the Dead-Time State

The transition of the automatic reclosing function to the **dead-time** state occurs for:

- Clearing operate indications if none of the signal inputs for operate indications are active
- Or if the circuit breaker can no longer be recognized as 3-pole closed
- And the start-signal supervision time is not expired

Additionally, the following conditions must be fulfilled:

- The circuit breaker signalizes the readiness for automatic reclosing typically through a binary input. If the circuit breaker is not ready, the automatic reclosing function can be statically blocked. In this situation, the automatic closing function is not in idle state **automatic closing function ready**. The control of the circuit-breaker readiness is optional and can be turned off through settings, see also chapter *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition* and *6.22.4.17 Blockings*.
- The circuit breaker must be 3-pole closed before the trip command. This condition is not considered if the circuit-breaker auxiliary contacts are not connected to the protection device.

You can delay the transition to the **dead-time** state through the binary input **>Dead Time Start Delay.** As long the corresponding binary signal is present, the dead time of the automatic reclosing function will not be started. The maximum duration of this binary signal is monitored through a time stage that can be set, parameter **`Max. dead-time delay`**. Upon expiration of this time stage, that is, if the binary signal is present longer than permitted, the automatic reclosing function will be blocked until the end of the binary signal, additionally extended by another 0.5 s. See also chapter *6.22.4.17 Blockings*.

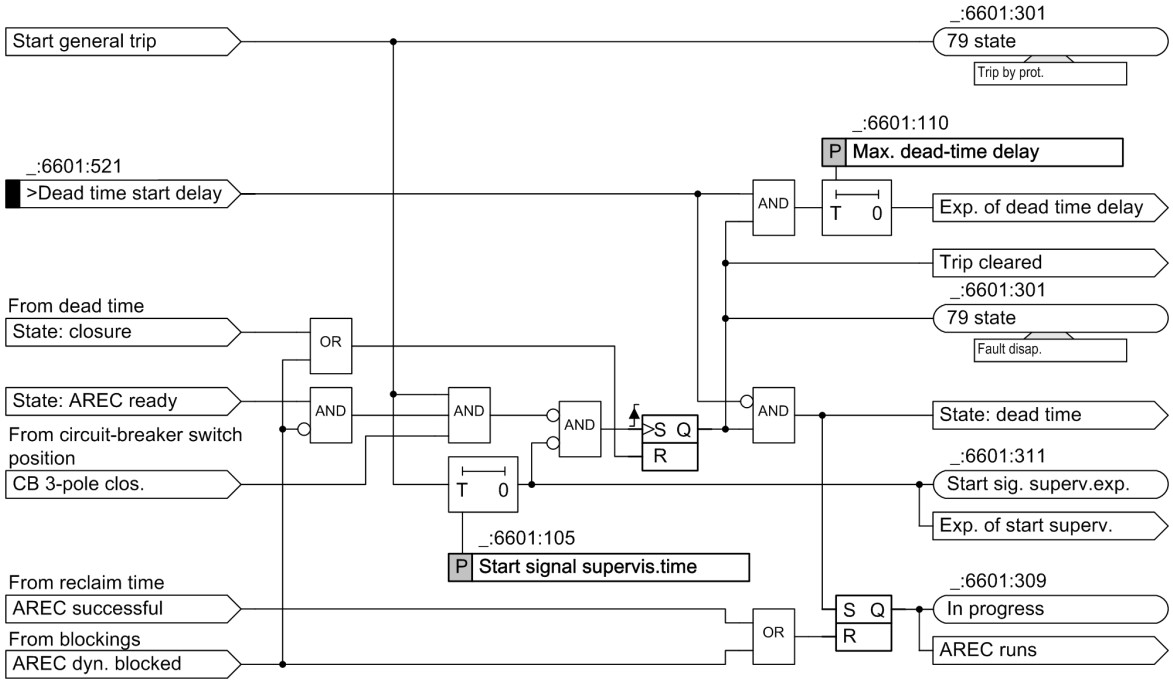

Figure 6-389 Logic for Function-Block Start

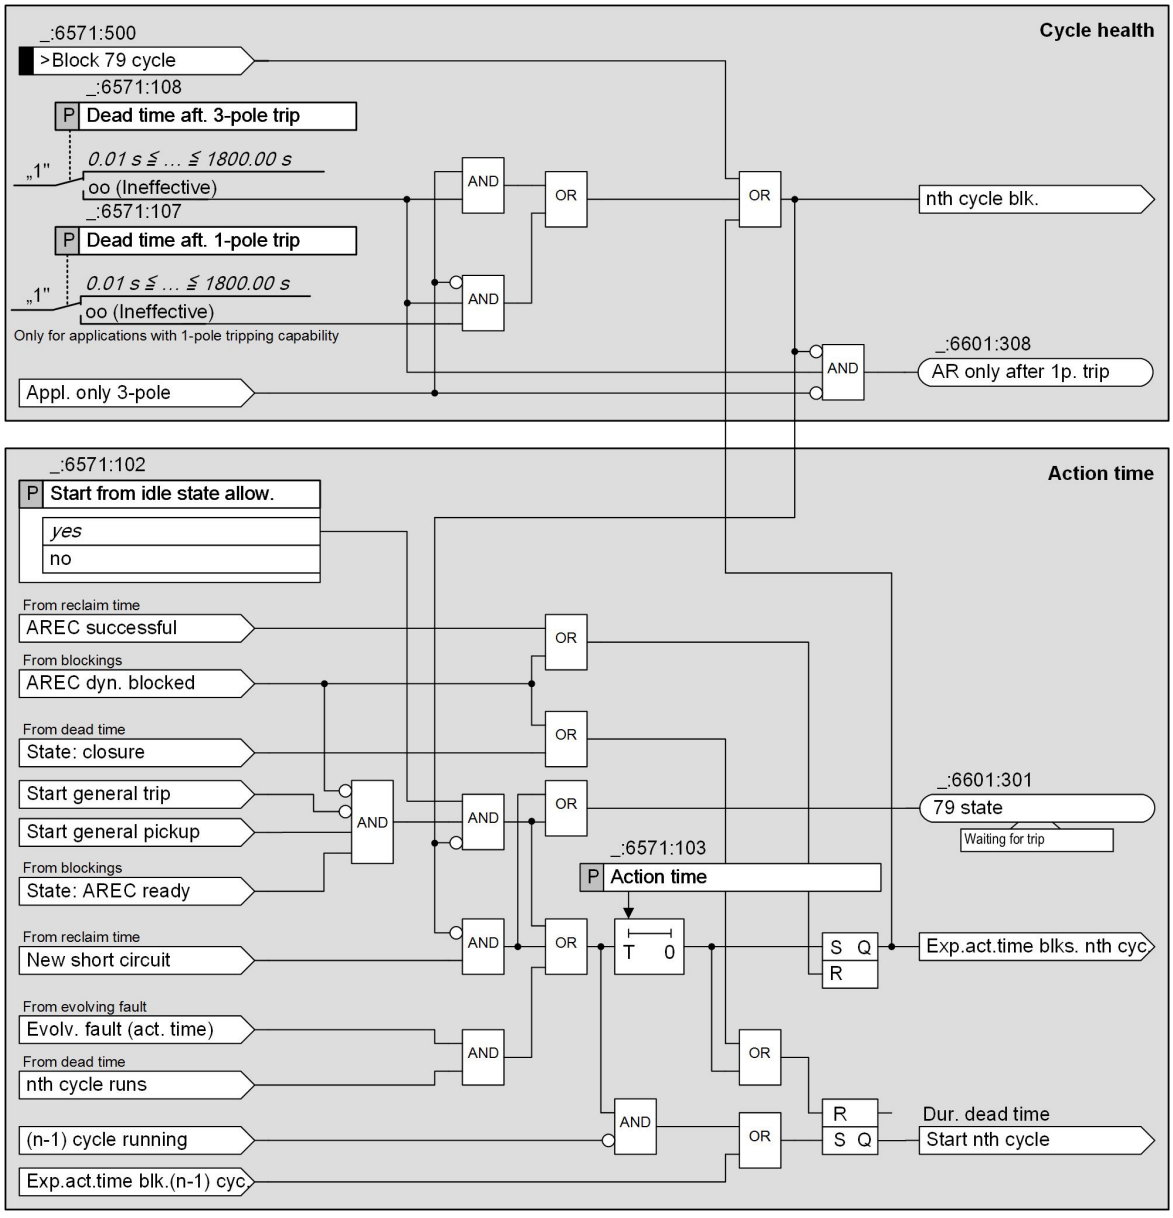
6.22.4.6 Cycle Control with Operating Mode 1: with Tripping/with Action Time

The cycle control checks the readiness for each automatic reclosing cycle and controls the process of the action time(s). In *Figure 6-390*, the cycle control is illustrated.

Cycle Availability

The cycle availability is influenced through the parameterization of the dead time and through a binary input. In this way, setting the parameter **Dead time aft. 3-pole trip** to ***invalid*** avoids an automatic reclosing after 3-pole tripping. Accordingly, the automatic reclosing does not occur if **Dead time aft. 1-pole trip** is set to ***invalid***. If both dead times are set to ***invalid***, the respective automatic reclosing cycle will be completely blocked. With the binary input *>Block 79 cycle*, you can block the associated automatic reclosing cycle.

For applications with 1-pole tripping, the cycle control provides a signal, based on which the protection functions can recognize that the automatic reclosing function only occurs after 1-pole tripping (*AR only after 1p. trip*). The approval or switch over of special protection stages only occurs for types of faults that lead to 1-pole tripping.



Action Time

If the automatic reclosing function is in the idle state **automatic reclosing function ready**, an incoming general pickup will affect the start of the action time. This applies for the reclosing function cycles that are released through the parameter **Start from idle state allow.** and not blocked.

During one of the started action times, the corresponding reclosing cycle is blocked and the reclosing cycle is assigned the next highest cycle number, whose action time is running and is not blocked.

With raising trip commands, the action times are stopped and reset. The process state of the action times existing at this moment determines the automatic reclosing cycle that should be started.

If all initiated action times expire without capturing a tripping, the automatic reclosing function does not take place. However, if a tripping function is initiated after expiry of the action time, the automatic closing function is blocked for 3 seconds. A new start of the reclosing function is only possible if the general pickup is no longer active.

[lo_auswir, 2, en_US]

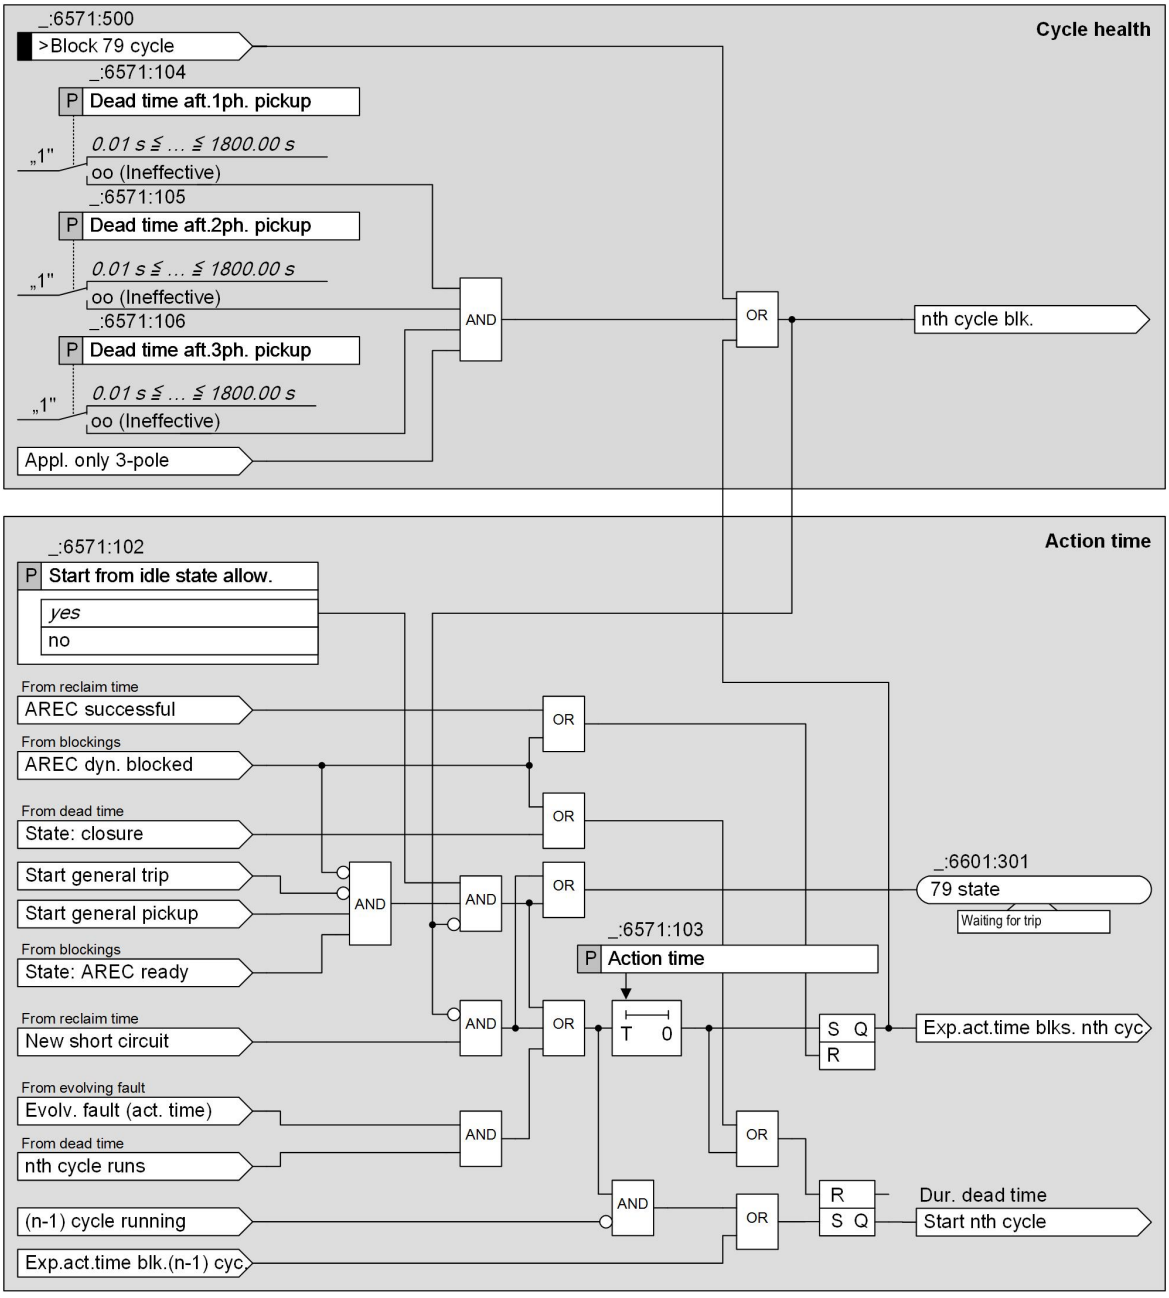
Figure 6-390 Cycle Control with Operating Mode: With Tripping/With Action Time

6.22.4.7 Cycle Control with Operating Mode 2: With Pickup/With Action Time

The cycle control checks the readiness for each automatic reclosing cycle and controls the process of the action time(s). In *Figure 6-391*, the cycle control is illustrated.

Cycle Availability

The cycle availability is influenced through the parameterization of the dead time and through a binary input. In this way, setting the parameter **Dead time aft.1ph. pickup** to ***invalid*** avoids an automatic reclosing after 3-pole tripping due to 1-phase short circuits. This also applies to **Dead time aft.2ph. pickup** and **Dead time aft.3ph. pickup**. If all 3 dead times are set to ***invalid***, the respective reclosing cycle will be completely blocked. With the binary input *>Block 79 cycle*, you can block the associated automatic reclosing cycle.



Action Time

If the automatic reclosing function is in the idle state **automatic reclosing function ready**, an incoming general pickup will affect the start of the action time. This applies for the reclosing function cycles that are released through the parameter **`Start from idle state allow.`** and not blocked.

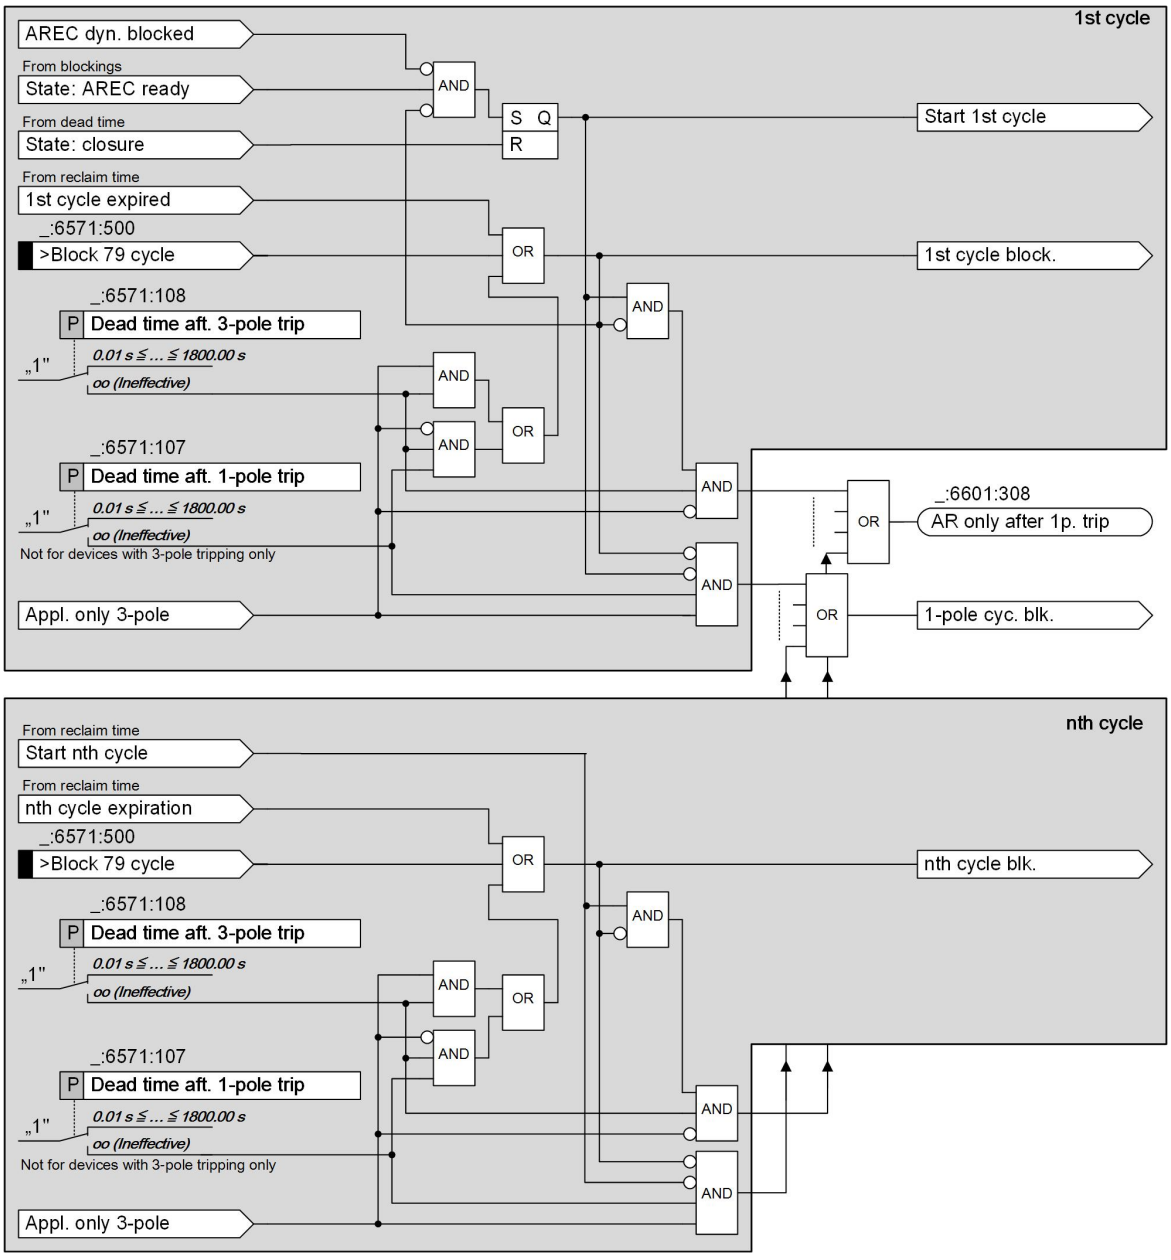
During one of the started action times, the corresponding reclosing cycle is blocked and the reclosing cycle is assigned the next highest cycle number, whose action time is running and is not blocked.

With raising trip commands, the action times are stopped and reset. The process state of the action times existing at this moment determines the automatic reclosing cycle that should be started.

If all initiated action times expire without capturing a tripping, the automatic reclosing function does not take place. However, if a tripping function is initiated after expiry of the action time, the automatic closing function is blocked for 3 seconds. A new start of the reclosing function is only possible if the general pickup is no longer active.

[lo_anrwir, 2, en_US]

Figure 6-391 Cycle Control with Operating Mode: With Pickup/With Action Time



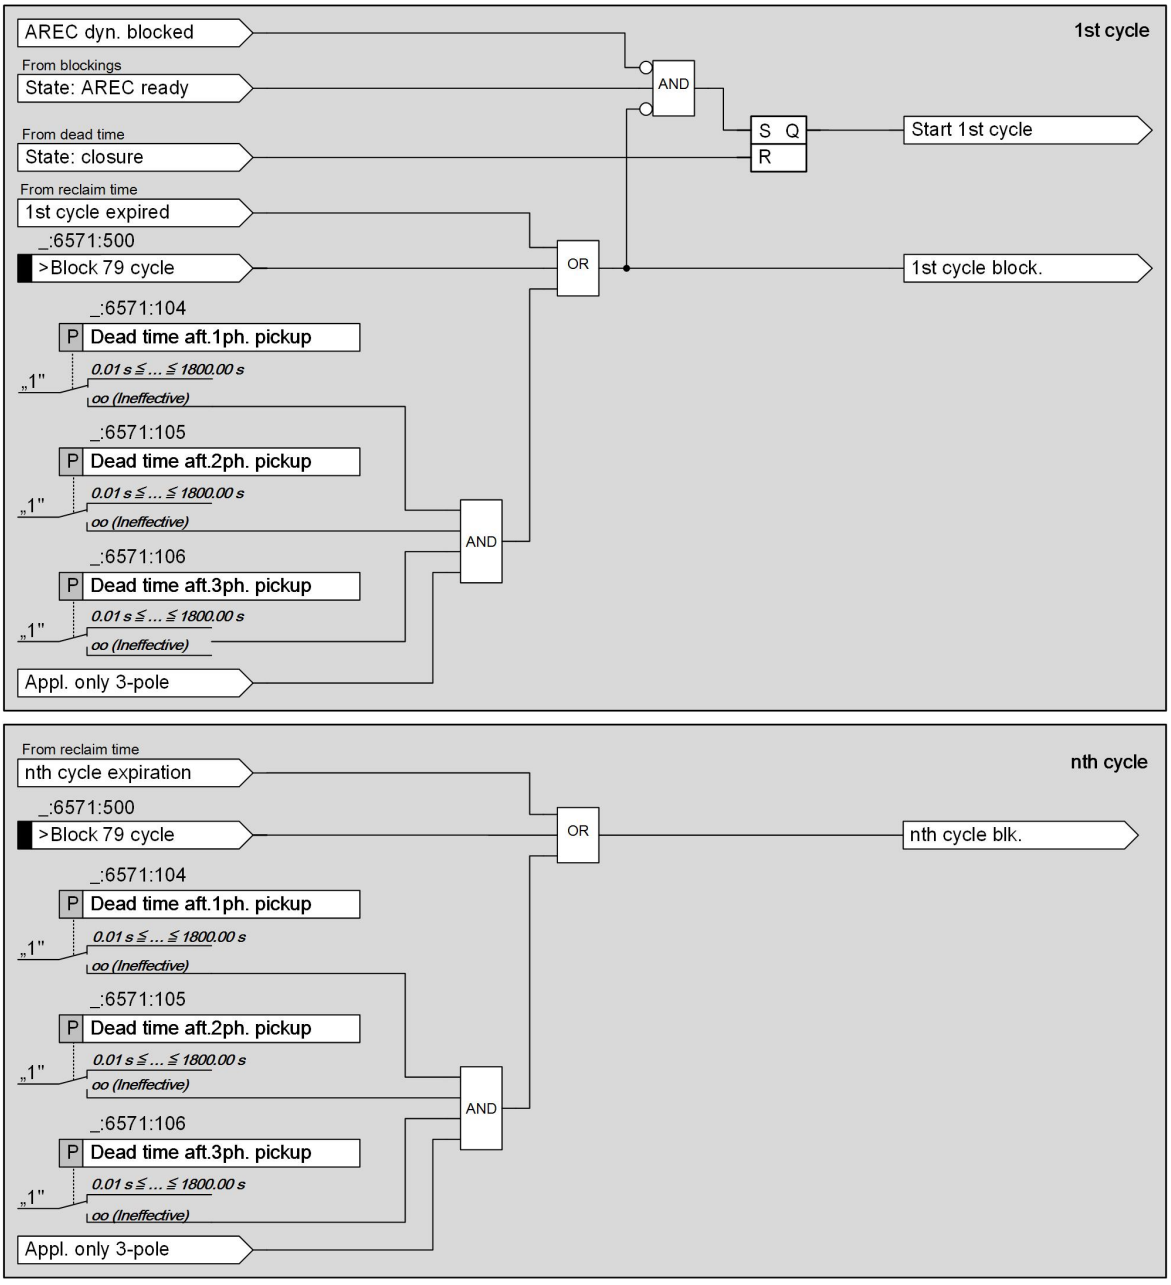
6.22.4.8 Cycle Control with Operating Mode 3: With Tripping/Without Action Time

The cycle control checks the availability for each automatic reclosing cycle. In *Figure 6-392*, the cycle control for the 1st automatic reclosing cycle and other reclosing cycles is illustrated. The further automatic reclosing cycles are generally described with the cycle number **n** and apply for all other configured automatic reclosing cycles.

The cycle availability is influenced through the parameterization of the dead time and through a binary input.

In this way, setting the parameter **Dead time aft. 3-pole trip** to ***invalid*** avoids an automatic reclosing after 3-pole tripping. Correspondingly, there is no automatic reclosing after 1-pole tripping if **Dead time aft. 1-pole trip** is set to ***invalid***. If both dead times are set to ***invalid***, the respective automatic reclosing cycle will be completely blocked. With the binary input *>Block 79 cycle*, you can block the associated automatic reclosing cycle.

For applications with 1-pole tripping, the cycle control provides a signal, based on which the protection functions can recognize that the automatic reclosing function only occurs after 1-pole tripping (*AR only after 1p. trip*). The approval or switch over of special protection stages only occurs for types of faults that lead to 1-pole tripping.



[lo_auowrk, 2, en_US]

Figure 6-392 Cycle Control with Operating Mode: With Tripping/Without Action Time

6.22.4.9 Cycle Control with Operating Mode 4: with Pickup/without Action Time

The cycle control checks the availability for each automatic reclosing cycle. In *Figure 6-393*, the cycle control for the 1st automatic reclosing cycle and other reclosing cycles is illustrated. The further automatic reclosing cycles are generally described with the cycle number **n** and apply for all other configured automatic reclosing cycles.

The cycle availability is influenced through the parameterization of the dead time and through a binary input. In this way, setting the parameter **`Dead time aft.1ph. pickup`** to ***`invalid`*** avoids an automatic reclosing after 3-pole tripping due to 1-phase short circuits. This also applies to **`Dead time aft.2ph. pickup`** and **`Dead time aft.3ph. pickup`**. If all 3 dead times are set to ***`invalid`***, the respective reclosing cycle will be completely blocked. With the binary input *`>Block 79 cycle`*, you can block the associated automatic reclosing cycle.

[lo_anowrk, 2, en_US]

Figure 6-393 Cycle Control with Operating Mode: with Pickup/without Action Time

6.22.4.10 Stage Release

The function block **Stage release** creates output indications for the release or switching over of special stages for protection functions (stage release in the 1st cycle or stage release in the n. cycle). Examples for this are the release of overreaching zones with distance protection and the dynamic adjustment of delays or threshold values with overcurrent protection.

Figure 6-394 shows the tripping stage release for the 1st automatic reclosing cycle. With available automatic reclosing functions, the tripping stage release typically occurs up to the expiration of the dead time. In this state, the cycle number is 1. However, if the automatic reclosing function cycle is only set to 1-pole, the stage release will be returned at the start of the 1-pole dead time. This is necessary, since every additional evolving fault that occurs within the dead time causes a 3-pole cut-off, and subsequently, the automatic reclosing function can no longer take place.

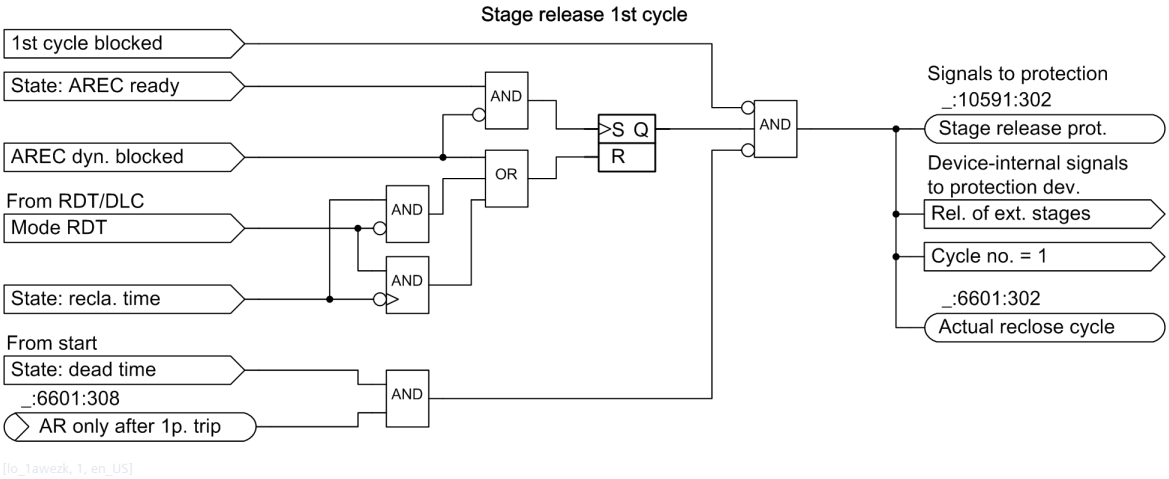


Figure 6-394 Stage Release for Protection Functions in the 1st Automatic Reclosing Cycle

The tripping stage release for higher automatic reclosing cycles is set to the beginning of the reclaim time for rising edge close commands. Simultaneously, the cycle number is increased. The reset condition is identical to the condition for the 1st automatic reclosing cycle. If the reduced dead time (RDT) mode is selected and no additional reduced dead time occurs, the release of the 2nd cycle will be maintained, since it can be assumed that the opposite end is open.

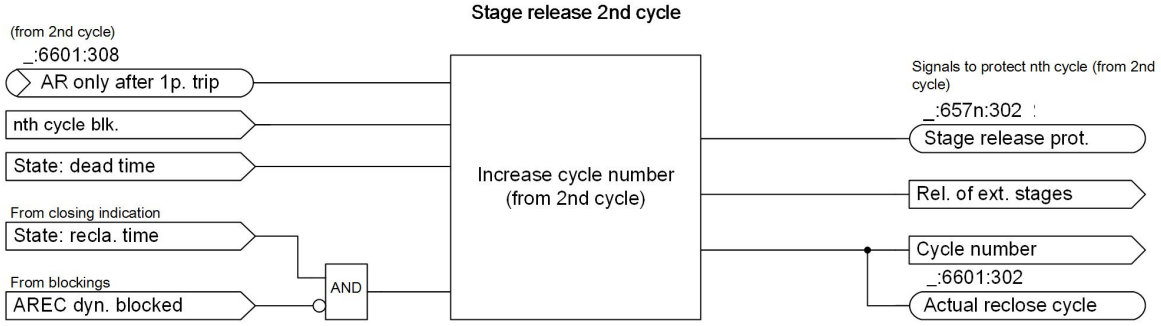

Figure 6-395 Stage Release for Protection Functions Starting with the 2nd Automatic Reclosing Cycle

6.22.4.11 Dead Time for Operating Modes with Tripping

In the **Dead-time** function block, the dead time which corresponds with the previous trip command is started. After expiration of the dead time, the automatic reclosing function changes to the status **Switch on**. *Figure 6-396* shows the dead time logic.

There are 3 time stages that can be set differently:

- Dead time after 3-pole tripping
- Dead time after 1-pole tripping (only available for applications with 1-pole tripping)
- Dead time after evolving fault

In this way, setting the parameter **`Dead time aft. 3-pole trip`** to ***`invalid`*** avoids an automatic reclosing after 3-pole tripping. Correspondingly, if after 1-pole tripping there is no automatic reclosing if **`Dead time aft. 1-pole trip`** is set to ***`invalid`***.

As soon as an evolving fault is recognized (see chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*), switching to an automatic reclosing cycle for 3-pole interruption occurs. With the 3-pole cut-off of the evolving fault, a separate adjustable dead time for the evolving fault begins. The total dead time is composed of the part of the dead time that expired until the evolving fault was stopped for the first disruption plus the dead time for the evolving fault.

3-Pole Coupling of the Circuit-Breaker with 1-Pole Tripping and Implausible Circuit-Breaker Condition

With applications with 1-pole tripping, during the dead time there is a plausibility check between the assigned trip command and the current flow in the open conductor. If the circuit-breaker auxiliary contacts are connected pole-selectively, the plausibility check also occurs with the circuit-breaker auxiliary contacts. More information can be found in the chapter *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition*.

The plausibility check determines whether the circuit-breaker poles that have not been switched off after a 1-pole trip command remain closed.

For an implausible circuit-breaker condition, a 3-pole coupling of the trip command for the circuit breaker is executed, provided the 3-pole coupling of the trip command is permitted through the parameter (parameter **`3-pole operate by 79`**). After this 3-pole tripping, if set and not blocked, more 3-pole automatic reclosing cycles may follow.

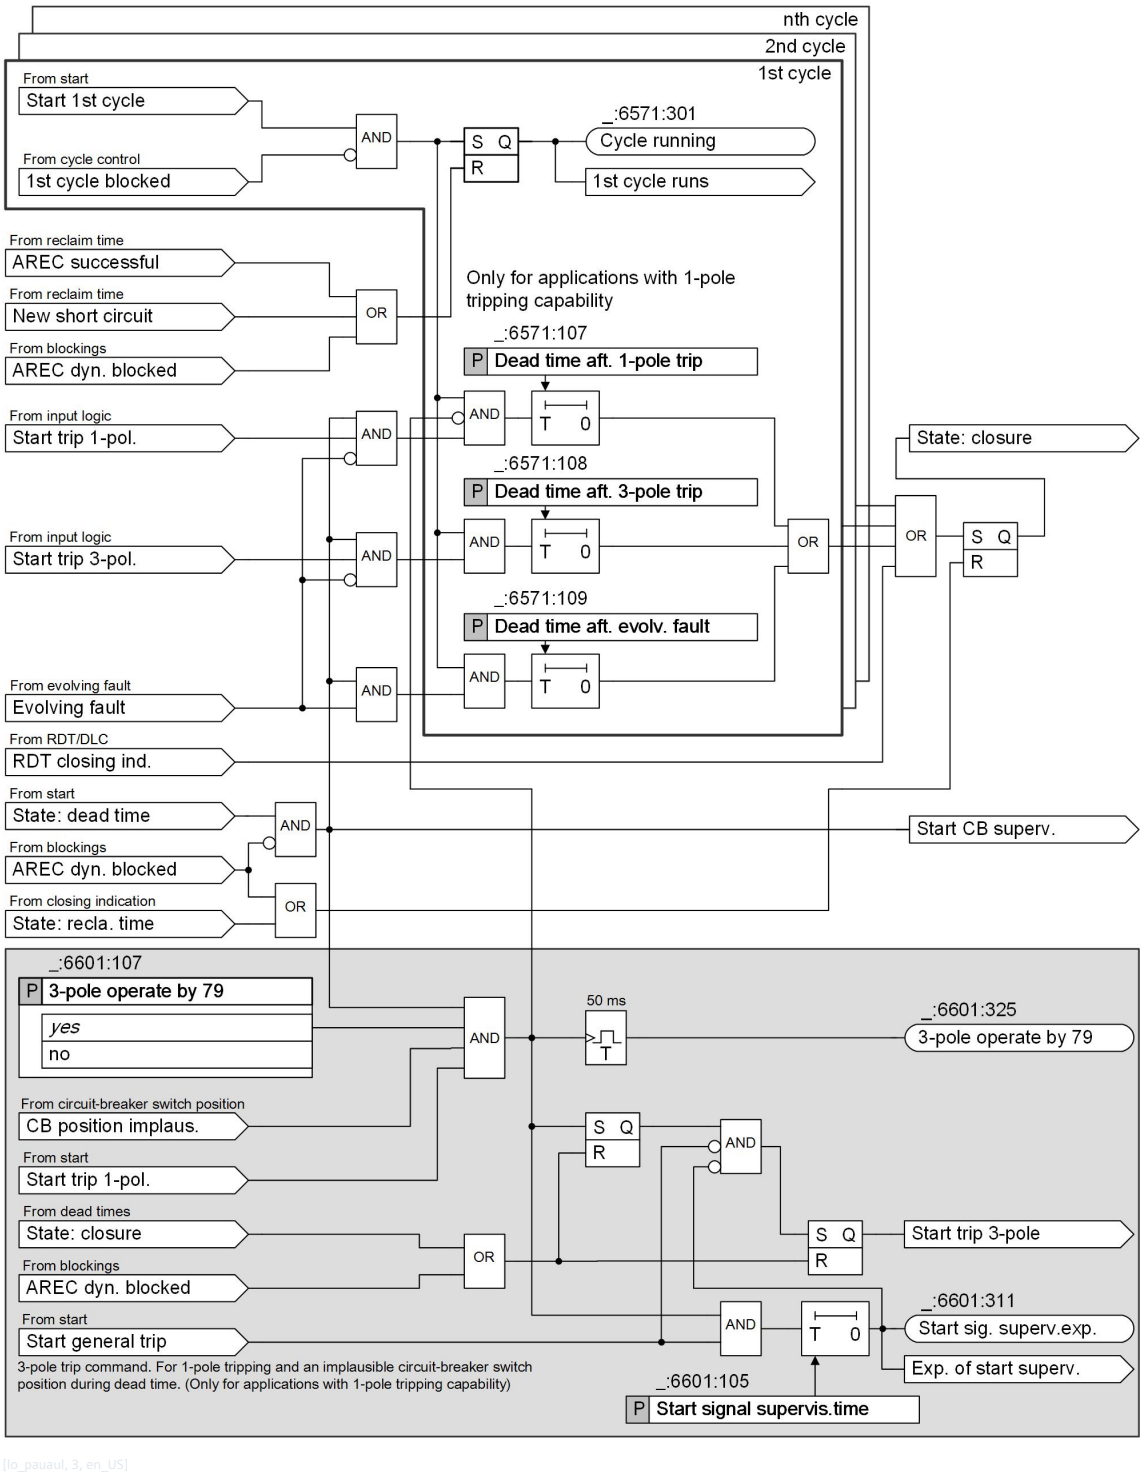

Figure 6-396 Cyclic Automatic Reclosing Function - Logic of the Dead Time for the Operating Modes: With Tripping

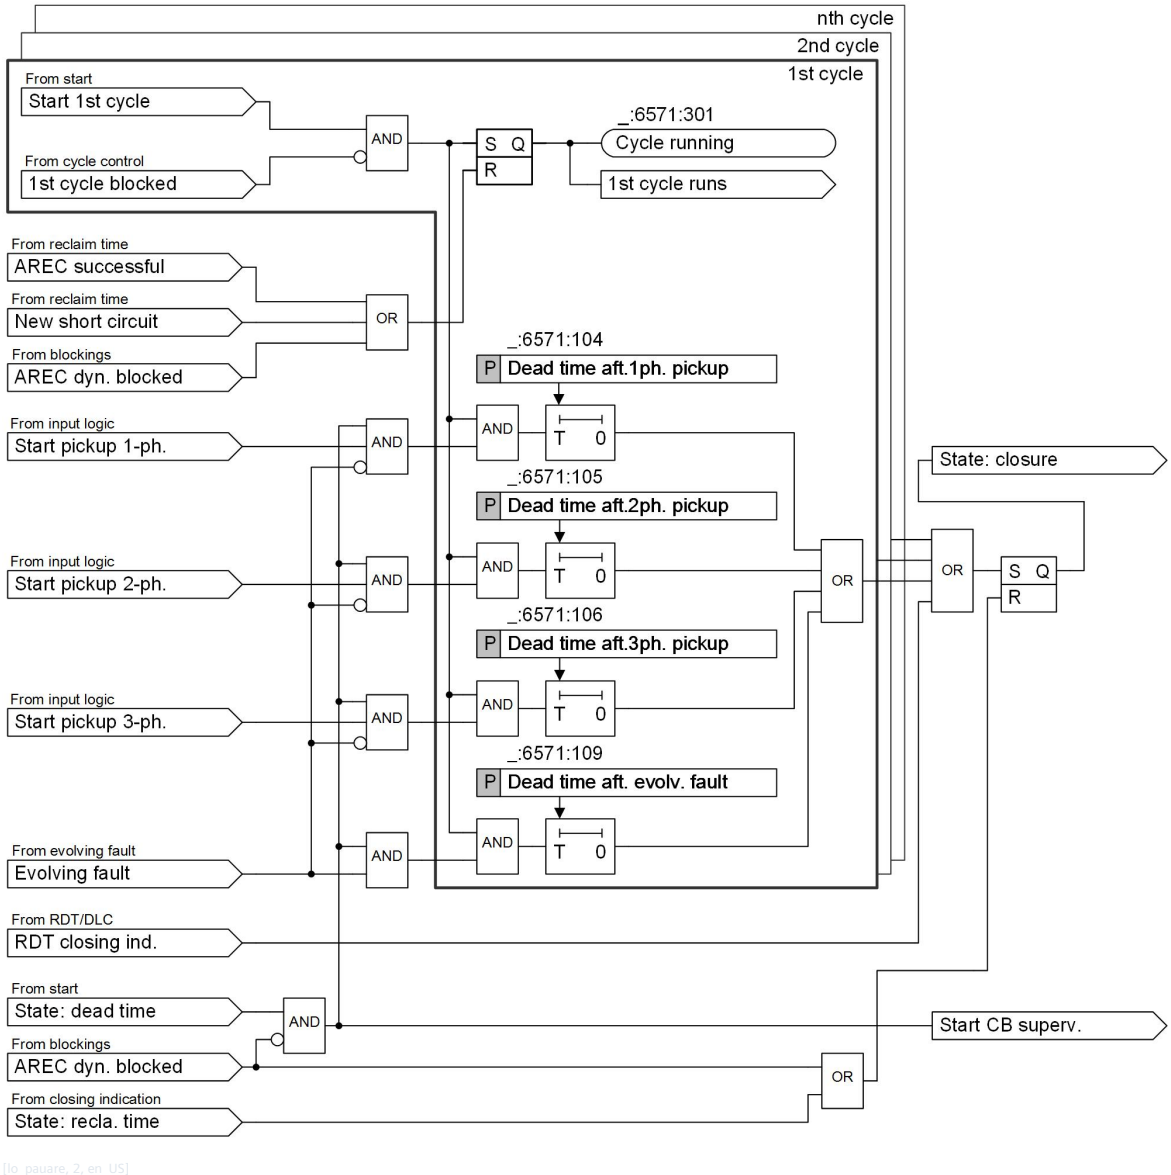
6.22.4.12 Dead Time for Operating Modes with Pickup



In the **dead time** function block, the dead time corresponding to the type of short circuit that led to the trip command is started. The automatic reclosing operating modes **with pickup** are only ideal for applications with 3-pole tripping. After expiration of the dead time, the automatic reclosing function changes to the status **Switch on**. *Figure 6-397* shows the dead time logic.

There are 4 time stages that can be set differently:

- Dead time after 1-phase short circuits
- Dead time after 2-phase short circuits
- Dead time after 3-phase short circuits
- Dead time for evolving faults

In this way, setting the parameter **Dead time aft.1ph. pickup** to ***invalid*** avoids an automatic reclosing after 3-pole tripping due to 1-phase short circuits. This also applies to **Dead time aft.2ph. pickup** and **Dead time aft.3ph. pickup**.

As soon as an evolving fault is recognized (see chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*), a separate dead time for faults begins with the stopping of the fault. The total dead time is composed of the part of the dead time that expired until the evolving fault was stopped for the 1st disruption plus the dead time for the evolving fault. With the setting of the **Dead time aft. evolv. fault** to ***invalid***, no other automatic reclosing cycle is executed after tripping through the evolving fault. The tripping through evolving faults is then finished.

[lo_pauare, 2, en_US]

Figure 6-397 Cyclic Automatic Reclosing Function - Logic of the Dead Time for the Operating Modes: with Pickup

6.22.4.13 Evolving-Fault Detection During the Dead Time

Evolving faults are short circuits, which occur after switching off a short circuit during dead time. This may be the case during 1-pole tripping and there is a short circuit in the non-switched conductors after this.

After 3-pole tripping there may also be evolving faults if the line is fed through a second (non-3-pole) opened circuit breaker, for example, for systems with a 1 1/2 circuit breaker layout. Evolving-fault detection does not start until 50 ms after the dead time starts.

The evolving-fault detection is divided into components:

- Detection of evolving faults
- Evolving faults processing
- 3-pole coupling of the circuit breaker during evolving faults

The procedure during evolving faults is illustrated in *Figure 6-398*.

Detection of Evolving Faults

For the detection of an evolving fault, the following criteria can be selected through parameters:

- Parameter **Evolving-fault detection** = ***with trip***

  For this setting, **any tripping** during the dead time leads to evolving-fault detection. At **any tripping** it is decided if an internal protection function is tripped or if the tripping is signaled through a binary input. Thus, it does not matter if the tripping-protection function is configured for the start of the automatic reclosing function or not.

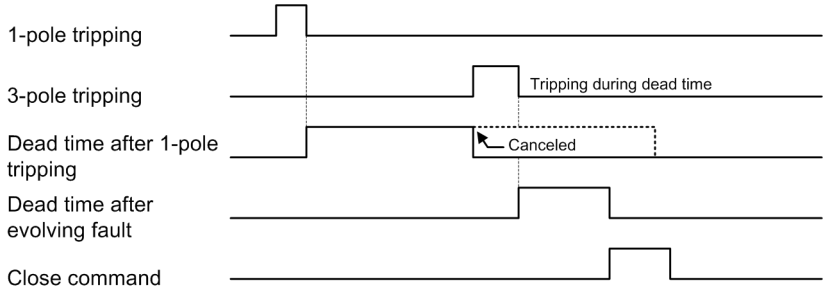
- Parameter **Evolving-fault detection** = ***with pickup***

  Evolving faults are detected if during the dead time a protection function configured for the automatic reclosing function start is picked up or if an external pickup is recognized through a binary input.

- Binary input *>Evolving fault start*

  The evolving-fault detection can also be introduced through a binary input without an internal protection pickup being available.

Reaction to Evolving Faults



After a recognized evolving fault, the automatic reclosing function can be influenced in 2 ways.

- Parameter **Response to evolv. faults** = ***blocks 79***

  As soon as an evolving fault is recognized, the reclosing function will be blocked. There are no other reclosing attempts and the automatic reclosing function is blocked until the pickup and operate indications causing the evolving fault disappear.

- Parameter **Response to evolv. faults** = ***strt. evol.flt.dead time***

  As soon as an evolving fault is recognized, an automatic reclosing cycle for 3-pole interruption is switched to. The automatic reclosing function does not allow any 1-pole tripping until the fault is solved or there is a final switch off; thus, every following trip command will be 3-pole. When the evolving fault is fixed, the separate dead time for faults will start, see also chapter **Dead time**. The further process is as by 3-pole cycles.

[dw_bspffe, 1, en_US]

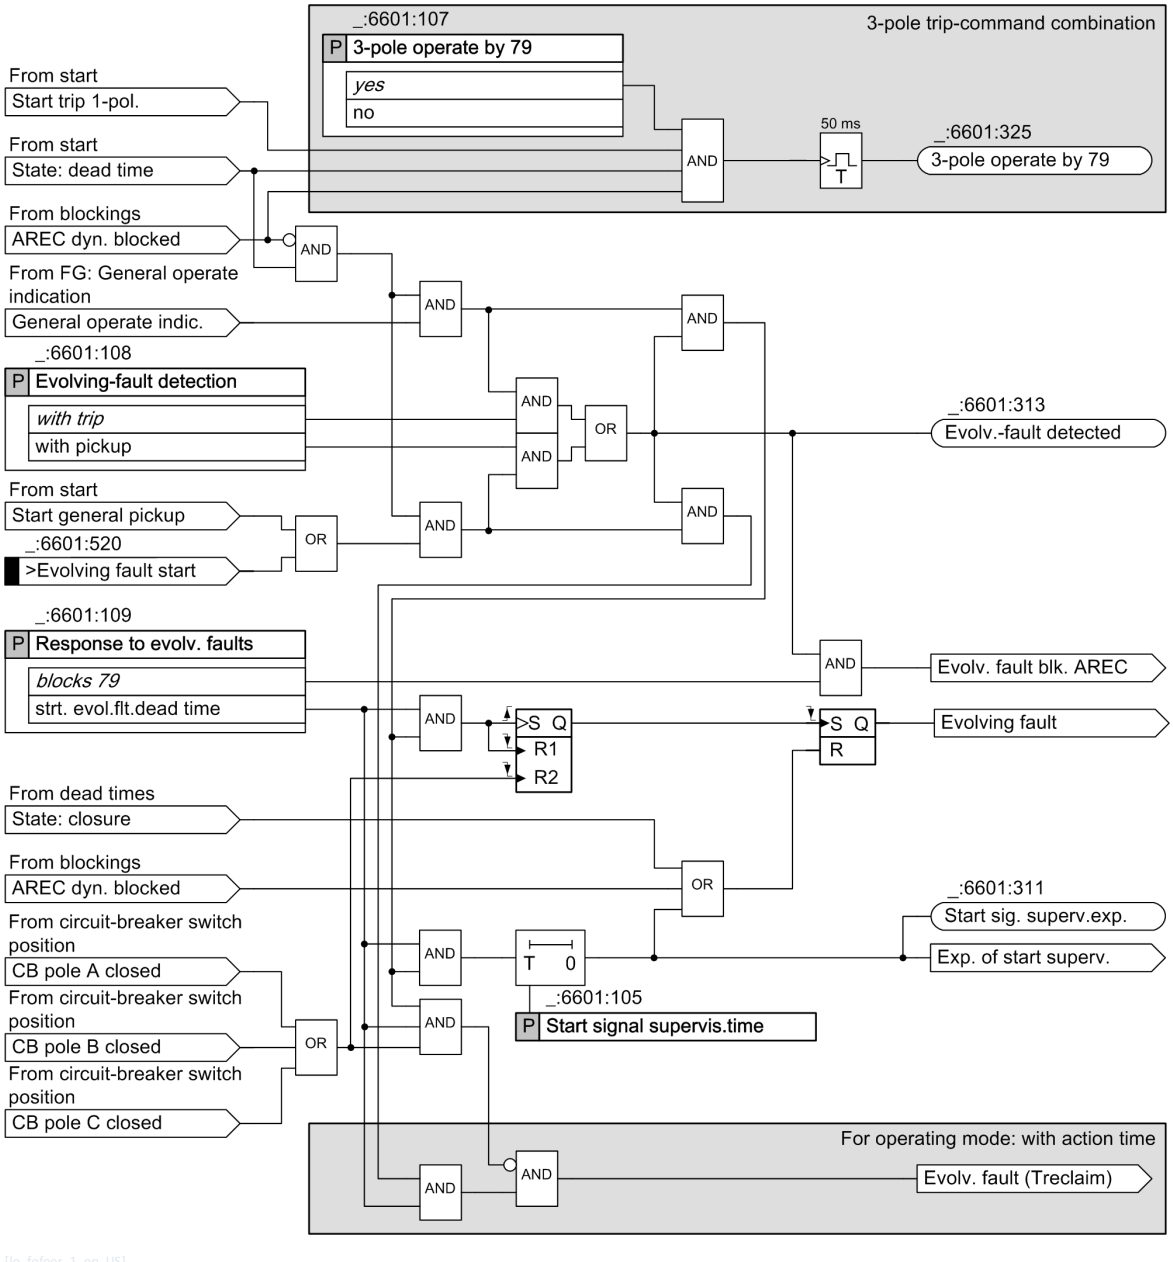


Figure 6-398 Cyclic Automatic Reclosing Function - Example for an Evolving Fault

For tripping through evolving faults, the entire dead time consists of the part of the dead time expired until disconnecting the evolving fault for the 1-pole interruption plus the dead time for the fault together, see *Figure 6-399*.

The dead time for evolving faults is started with the return of the operate indication or with the opening of all 3 circuit-breaker poles, provided the circuit-breaker auxiliary contacts are connected.

3-Pole Tripping of the Circuit Breaker for Automatic Reclosing Function Blocking through Evolving Faults in a 1-Pole Dead Time

If due to an evolving fault there is a blocking of the automatic reclosing function in the 1-pole dead time without a protection function submitting a 3-pole trip command, for example, during an evolving-fault detection with pickup, the automatic reclosing function can create a 3-pole trip command. Thus, the circuit breaker will have 3-pole tripping in which the blocking of the automatic reclosing function will occur.

[lo_fofeer, 1, en_US]

Figure 6-399 Cyclic Automatic Reclosing Function – Logic of Evolving-Fault Detection

6.22.4.14 Closing Indication and Close Command

After the expiration of the dead time, the Automatic reclosing function will be in the **closing** state.

The **closing** state can depend on the following influences, see *Figure 6-400*:

- through a synchrocheck if the circuit breaker was opened during the 3-pole dead time
- Through the readiness of the circuit breaker signaled through the binary input
- Through a binary input for delaying the close command (*>Delay close cmd.*)

The *Close cmd. indication* is a requirement for the assignment of the actual close command to the circuit breaker.

The mentioned criteria must not be fulfilled directly after expiration of the dead time. If a dead-time prolongation is set, the mentioned criteria will be checked during the prolongation. With the release of the closing indication, the automatic reclosing function will switch to the **reclaim time** state.

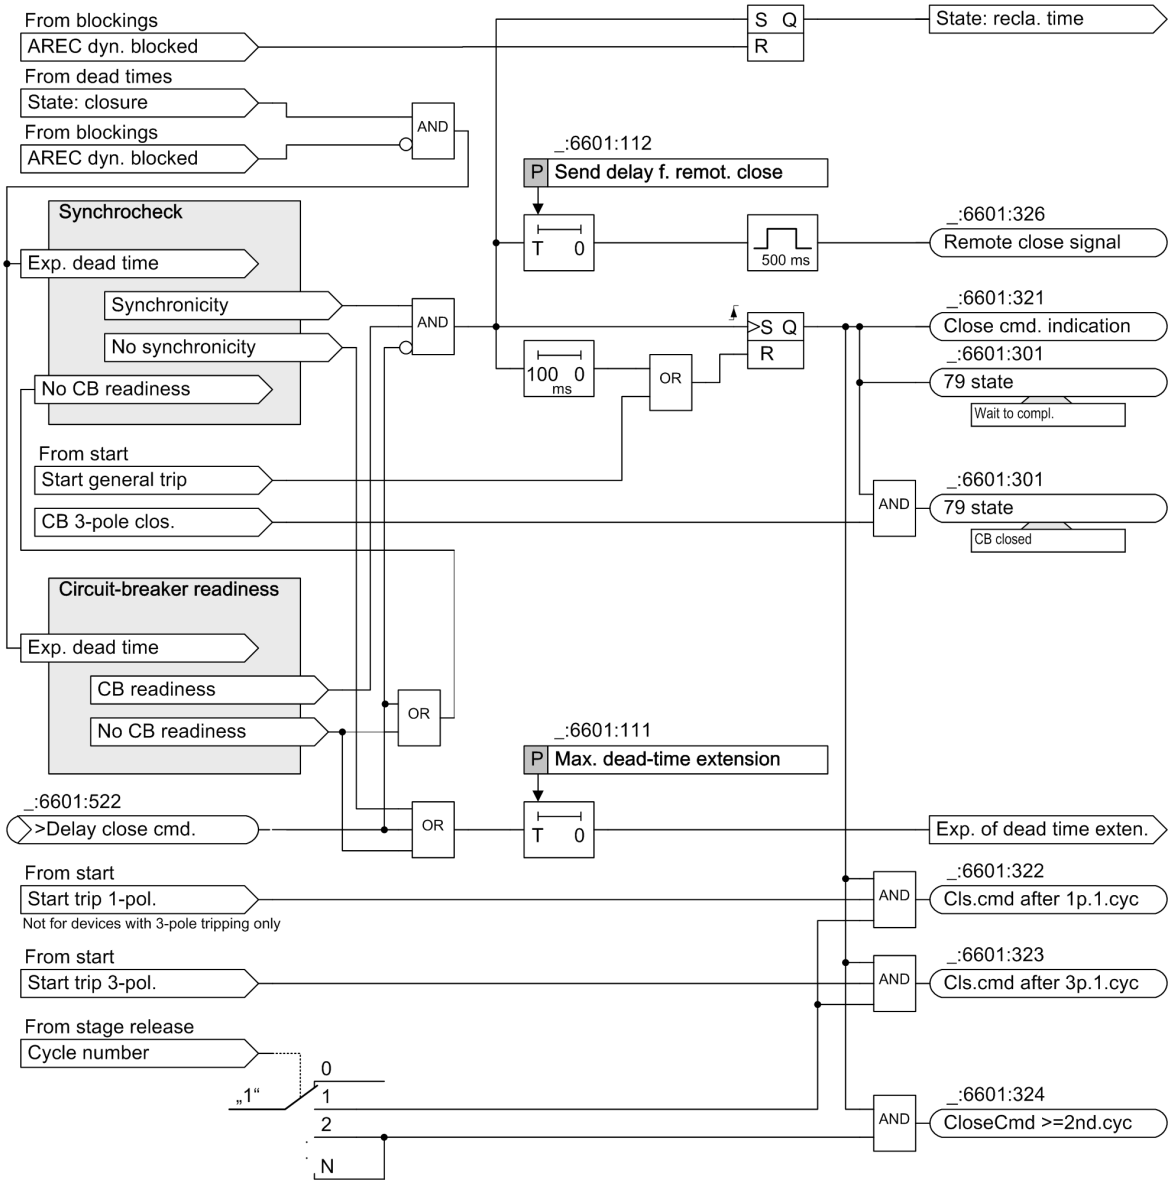

Figure 6-400 Cyclic Reclosing Function: Logic for the Closing Indication

Testing the Circuit-Breaker Readiness Directly before Closing

For each of the automatic reclosing cycles, you can set if a test of the circuit-breaker readiness should occur directly before closing (parameters **`CB ready check bef.close`**, *Figure 6-401*). Independent of this, a test of the circuit-breaker readiness before the start of the 1st automatic reclosing cycle can be set, see Chapter *6.22.4.5 Start* and chapter *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition*.

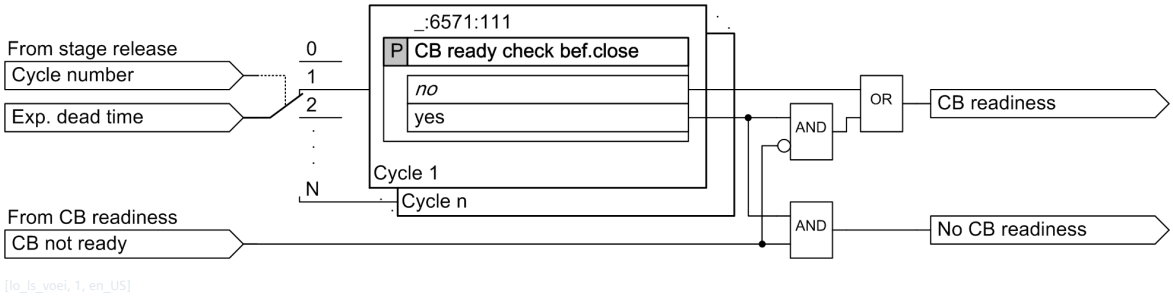

Figure 6-401 Cyclic Reclosing Function: Logic for the Query of the Circuit-Breaker Readiness Directly before Closing

Synchrocheck

For each of the configured automatic reclosing cycles, you can set if a synchrocheck should be executed and which functionality should be used here, see *Figure 6-402*. You may only use the internal synchrocheck if the device is connected to a voltage transformer.

Alternatively, you can also connect an external device with synchrocheck through a binary input.

The measuring request for the synchrocheck is placed if the optional test of the circuit-breaker readiness was positive. The measuring request for the synchrocheck exists until the synchrocheck assigns the allowance for the closure. If the allowance is not given within the set maximum dead time extension, the closure will be cancelled through the blocking of the automatic reclosing function. The minimum duration of the measuring request is 50 ms.

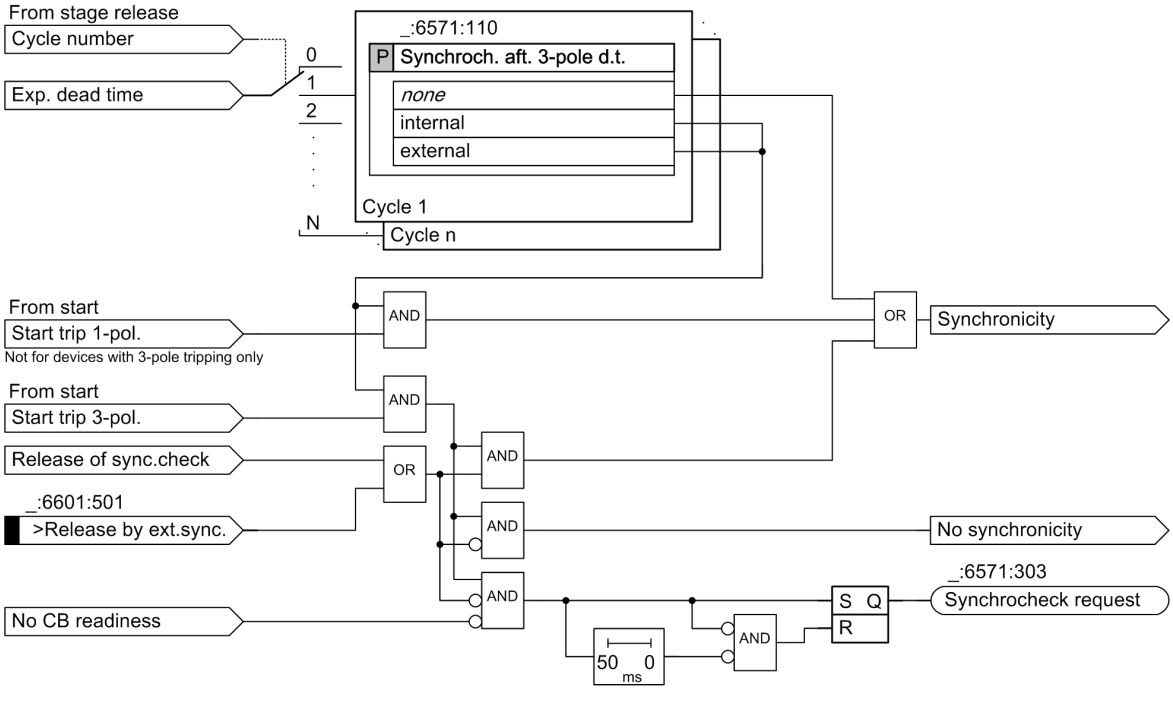

Figure 6-402 Cyclic Reclosing Function: Logic for the Inquiry of the Synchronism

Close Command

As soon as the test of the circuit-breaker readiness and the synchrocheck deliver a positive result, the closing indication will be created. It will be assigned for 100 ms. The actual close command is not created by the automatic reclosing function, but rather from the circuit-breaker function block outside of the automatic reclosing function. Here the set maximum duration of the close command is also considered.

In addition to the closing indication, additional indications will be created that describe the type of closure. These include:

- Close command after 1-pole tripping in the 1st cycle (*Cls.cmd after 1p.1.cyc*)
- Close command after 3-pole tripping in the first cycle (*Cls.cmd after 3p.1.cyc*)
- Close command after 1-pole or 3-pole tripping starting with the second cycle (*CloseCmd >=2nd.cyc*)

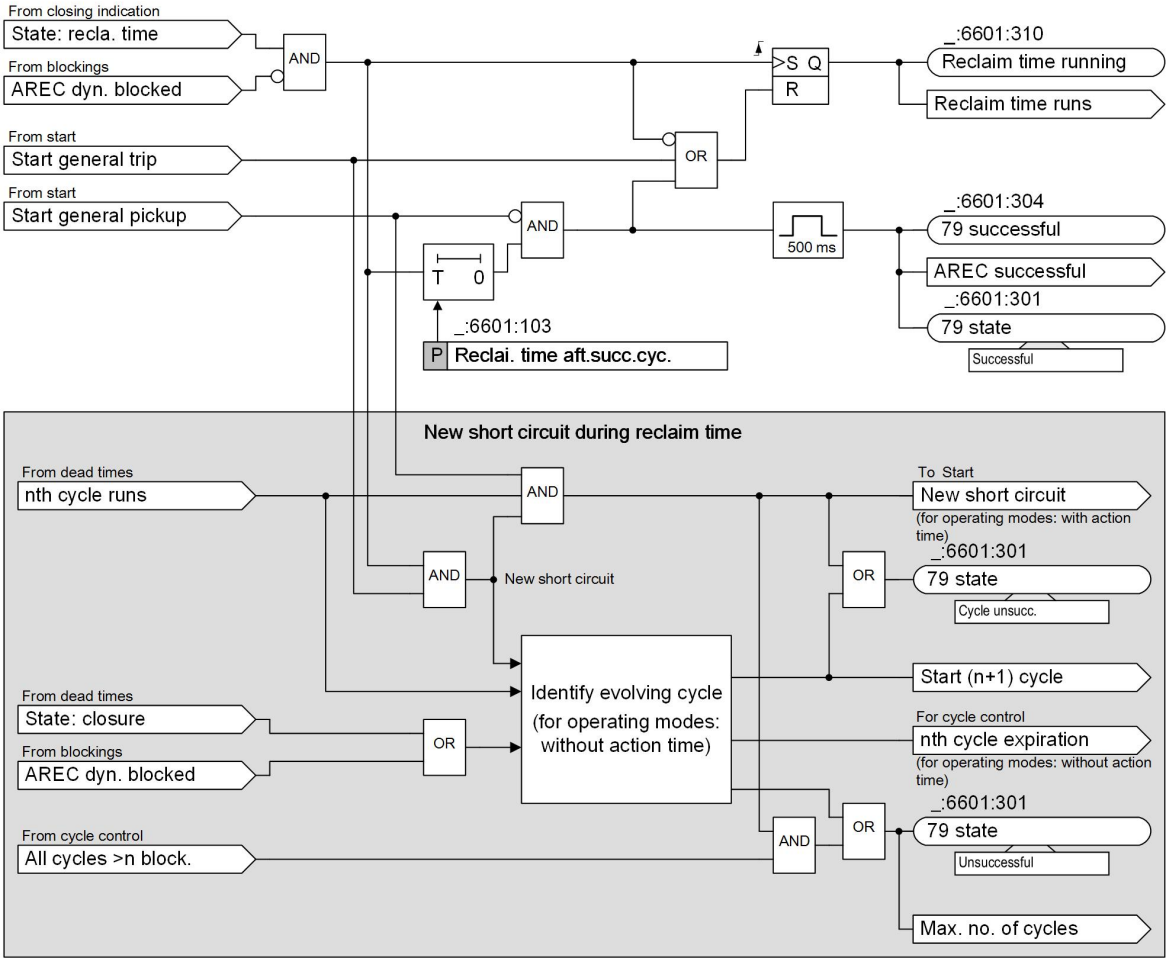
Creation of the Signal Remote close signal

The cyclic automatic reclosing function can create information *Remote close signal*. This information can be transferred to the protection device as a binary signal on the line that is to be protected on the opposite end. From the automatic reclosing function, it can be processed in the operating mode **adaptive dead time**. Furthermore, the binary signal may be arranged as data for transmission via an existing protection interface.

The information *Remote close signal* is created by the closing logic. It can be delayed by a set time over the local close indication. With this delay, you can make sure that information is only set if the automatic reclosing was successful and there was no further tripping. The pulse duration of the inter-close signal has a fixed length of 500 ms.

6.22.4.15 Reclaim Time

With the assignment of the close command, the automatic reclosing function goes into the **reclaim time** state. During this time, it is decided if the current reclosing cycle was successful or not.



- If during the reclaim time no further tripping occurs, the currently running automatic reclosing cycle, and thus the entire automatic reclosing, was successful.
- If during the reclaim time another tripping occurs, the currently running automatic reclosing cycle was not successful. If other automatic reclosing cycles are permitted, one of these cycles will be used to continue the process. If, in contrast, the currently executed cycle was the last permissible cycle, the automatic reclosing process will end and be reported as unsuccessful.

In both cases, the automatic reclosing function switches back to the idle state **automatic reclosing function ready**.

Short Circuits during Running Reclaim Time

A trip command that occurs during a reclaim time leads to a cancelation of the reclaim time. If further automatic reclosing cycles are allowed, the regulation of the next cycle depends on whether the automatic reclosing function is executed in an operating mode **with action times** or **without action times**, see *Figure 6-403*.

- With operating modes **with action time**, the action times of all higher cycles are started with the beginning of the new general pickup if these are not blocked. The cycle with the lowest cycle number is selected, whose action time is not yet expired with the incoming operate indication. If no further cycles are possible or if the action times of all possible cycles are expired before the operate indication, there will be no further reclosing.
- With the operating modes **without action time**, the cycle following the current cycle will always be selected in the set cycle. If this is blocked, the cycle following this one will be selected, etc. If no higher cycles exist or if they are all blocked, there will be no further automatic reclosing.

[lo_sperre, 2, en_US]

Figure 6-403 Cyclic Reclosing Function: Logic for the Reclaim Time

6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition

The automatic reclosing function requires the readiness of the circuit breaker for the following purposes, see *Figure 6-404*:

- Recognition of the circuit-breaker readiness from the beginning:
  In idle state of the automatic reclosing function, an unavailable circuit breaker leads to the blocking of the automatic reclosing function. This monitoring is optional and must be switched off through settings if the readiness signal is not available for the protection device.
- Analysis of the circuit-breaker readiness directly before the close command:
  For each of the configured automatic reclosing cycles, it can be set whether the circuit-breaker readiness is a requirement for the assignment of the close command. This monitoring is also optional.

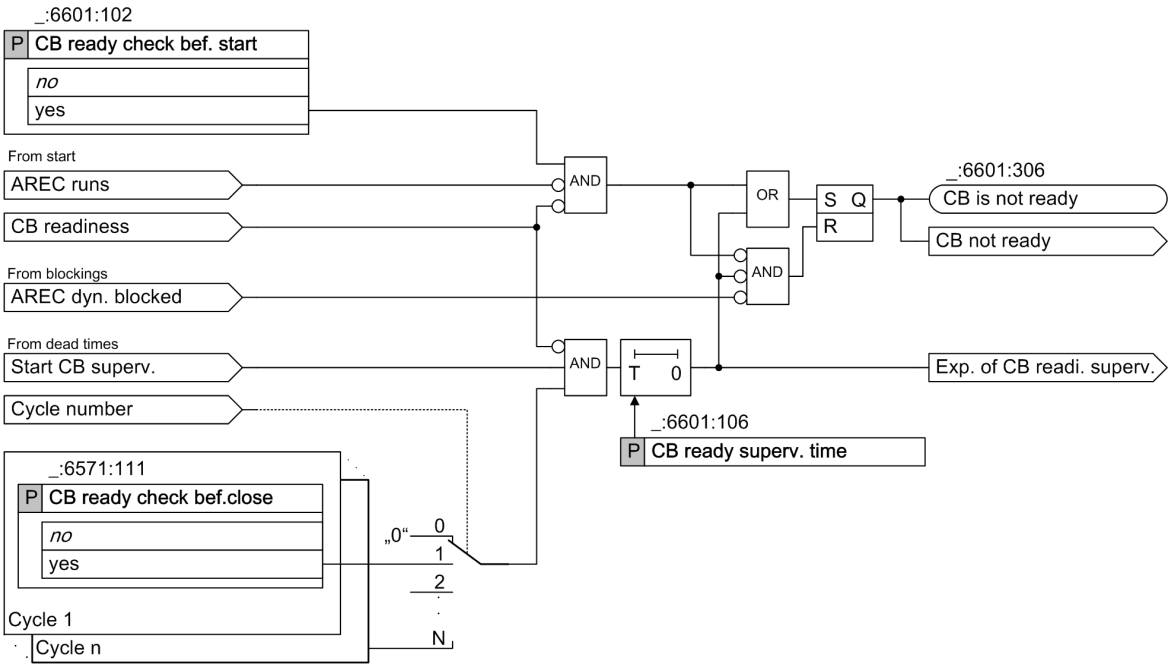


Figure 6-404 Cyclic Reclosing Function: Logic for the Circuit-Breaker Readiness

The automatic reclosing function uses the information from the circuit breaker for the following purposes (see *Figure 6-405*):

- Detection of a non-closed circuit breaker before the start:

  In idle state of the automatic reclosing function, a non-3-pole closed circuit breaker leads to the blocking of the automatic reclosing function, see also chapter *6.22.4.17 Blockings*. This monitoring is not needed if the auxiliary-contact signals are not available.

- Detection of the reaction of the circuit breaker after a trip command:

  The automatic reclosing function dead time is started immediately with the opening of the circuit breaker if the circuit-breaker auxiliary contacts are connected. Here a decision is made based on the opening of the circuit breaker if the circuit breaker is no longer 3-pole closed.

  An exception is the reaction to an evolving fault. As the circuit breaker already has 1 pole open before the occurrence of an evolving fault, the dead time is started if the circuit breaker is detected as having 3 poles open.

  If the circuit-breaker auxiliary contacts are not connected, the automatic reclosing function dead time will start with the dropout of the operate indication.

- After a 1-pole trip, a check is done during the dead time to determine whether the circuit-breaker poles that were not switched off remain closed. The circuit-breaker position recognition is delivered from the central circuit-breaker position recognition of the Circuit-breaker function group.

  For implausible circuit-breaker condition, a 3-pole coupling of the trip command for the circuit breaker is executed provided the settings allows this. After this 3-pole tripping, if set and not blocked, more 3-pole automatic reclosing cycles may follow, see also chapter *6.22.4.11 Dead Time for Operating Modes with Tripping*.

1) From circuit-breaker position recognition

[lo_lsuebe, 1, en_US]

Figure 6-405 Cyclic Reclosing Function: Logic for Circuit-Breaker Condition and Supervision

6.22.4.17 Blockings

The Automatic reclosing function differentiates between 2 types of blockings, see *Figure 6-406*:

- Static blocking
- Dynamic blocking

Static Blocking

The Automatic reclosing function is statically blocked if the function is switched on, but is not ready for reclosing and also cannot be started as long as this blocking is present. The static blocking is signaled with the indication *Inactive*.

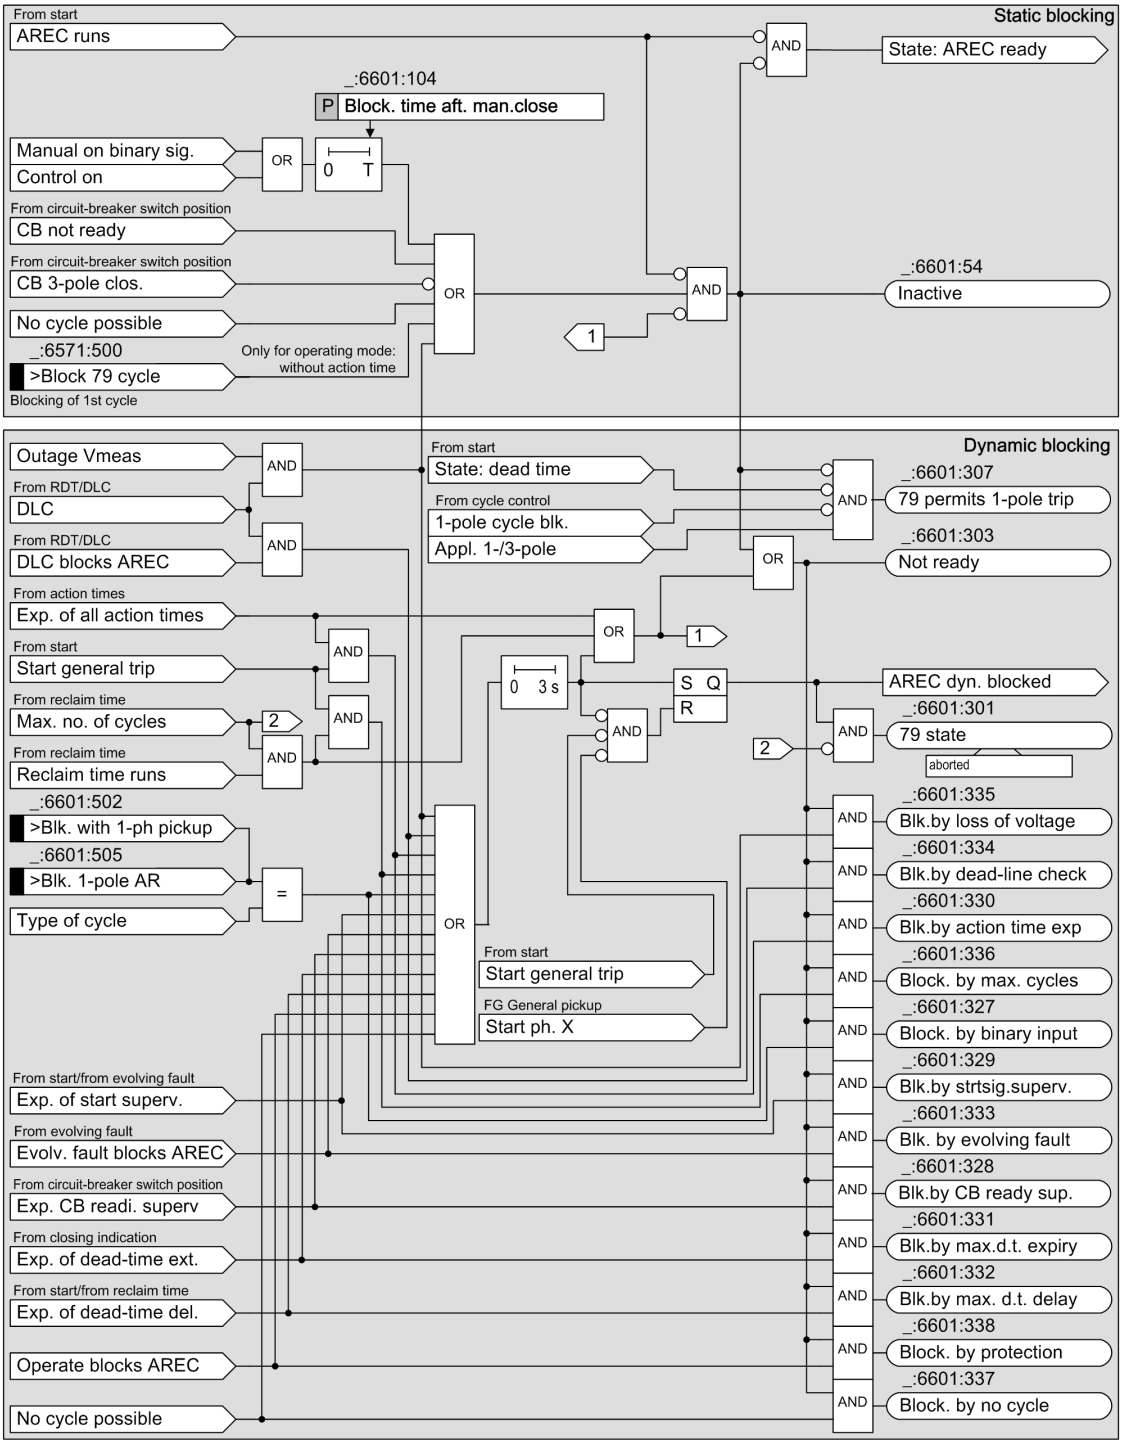
The following conditions lead to static blocking:

Condition	Indication
Manual closing of the circuit breaker, recognition through binary input or internal device control. The blocking is temporary, the duration can be set with the parameter **Block. time aft. man.close**.	Inactive
Circuit breaker not available for AREC, recognition through binary input. This cause can be switched on or off via the parameter **CB ready check bef.close**.	Inactive

Condition	Indication
Circuit breaker not closed on 3-poles, recognition through binary input. This criteria is used if the circuit-breaker auxiliary contacts are connected.	Inactive
No reclosing cycle possible Recognition due to the following causes: • AREC cycle is not set. • AREC cycles are set, but all are blocked, for example, via binary input. • There is no device-internal function and no binary input configured for starting the Automatic reclosing function. • With operating modes **with tripping**: – both 1-pole and 3-pole cycles are blocked via binary inputs • With operating modes **with pickup**: – 1-phase, 2-phase and 3-phase AREC cycles are blocked via binary inputs. • With operating modes **without action time**: – the first automatic reclosing cycle is blocked via binary input. • With the **dead-line check** functionality: – if the voltage measurement is not available or is disrupted	Inactive

Dynamic Blocking

The Automatic reclosing function is **blocked dynamically** if a blocking condition occurs while an Automatic reclosing function is running. The dynamic blocking is signalized with the indication *Not ready*.



After the occurrence of a dynamic blocking, it is checked in intervals of 0.5 s to see if the blocking can be removed. If the blocking condition remains or if a different blocking condition occurs in the meantime, the blocking will remain. If, in contrast, the cause of the blocking disappears, the dynamic blocking will be removed if no general pickup or no tripping configured for the Automatic reclosing function start is available.

A separate indication for logging exists for each individual blocking cause.

The following conditions lead to the dynamic blocking:

Condition	Indication
If no reclosing cycle fitting the fault type is released: • With operating modes **with tripping**: If a 1-pole or 3-pole operate indication occurs at the automatic reclosing function starting process, however, the Automatic reclosing function does not start in accordance with the parameterization for this type of tripping, the respective dead time will be set to ***invalid***. • With operating modes **with pickup**: If a 1-phase, 2-phase or 3-phase pickup indication occurs at the automatic reclosing function starting process, but the Automatic reclosing function may not be started in accordance with the parameterization for this type of pickup.	*Not ready* Block. by no cycle
If a protection function causes the Automatic reclosing function to be blocked in accordance with the configuration	*Not ready* Block. by protection

Condition	Indication
If the maximum set waiting time for the delay of the start of the dead time through the binary input *>Dead time start delay* expires without the binary input becoming inactive during this period of time	*Not ready* Blk.by max. d.t. delay
If the synchrocheck is set and the synchronism conditions after the expiration of the maximum dead-time extension are not fulfilled before the assignment of the close command	*Not ready* *Blk.by max.d.t. expiry*
If the query of the circuit-breaker readiness is switched on directly before the close command through the parameter and the maximum dead-time extension expires	*Not ready* *Blk.by CB ready sup.* *Blk.by max.d.t. expiry*
If the closing indication is delayed through the binary input *>Delay close cmd.* for so long until the maximum dead time extension is exceeded before the assignment of the close command	*Not ready* *Blk.by max.d.t. expiry*
If an evolving fault occurs and the parameter **Response to evolv. faults** is set to ***blocks 79***	*Not ready* *Blk. by evolving fault*
If the starting-signal supervision time for the operate indication starting from the AREC or the starting binary input expires. In this case, a circuit-breaker failure is assumed.	*Not ready* *Blk.by strtsig.superv.*
If after the start of the AREC a dead time is already running and a blocking binary input is active, with the following binary inputs: *>Blk. 1-pole AR*, *>Blk. 3-pole AR*, *>Blk. with 1-ph pickup*, *>Blk. with 2-ph pickup*, >Blk. with 3-ph pickup	*Not ready* *Block. by binary input*
If the maximum number of Automatic reclosing attempts is reached and there is a trip command within the reclaim time	*Not ready* *Block. by max. cycles*
With operating modes **with action time**: If the action times of all released automatic reclosing cycles expire without a trip command	*Not ready* *Blk.by action time exp*
For applications with voltage measurement and switched on functionalities with **dead-line check**: If during the dead time the required voltage criteria is not fulfilled	*Not ready* *Blk.by dead-line check*
For applications with voltage measurement and switched on functionalities with **dead-line check**: If during a running automatic reclosing cycle a failure of the measuring voltage is determined. After the completion of the automatic reclosing cycle, the dynamic blocking becomes static blocking if there is a continued failure of the measuring voltage.	*Not ready* *Blk.by loss of voltage*

[lo_blo_awe, 3, en_US]

Figure 6-406 Cyclic Automatic Reclosing: Blocking Logic as an Example for a 1-Pole Cycle (Static and Dynamic Blocking)

6.22.4.18 1-/3-pole Tripping of the Circuit Breaker

During short circuits, a 1-pole may shut off the circuit breaker if the corresponding protection functions generate trip indications in accordance with the parameterization and short circuit type, and the automatic reclosing function is parameterized such that 1-pole reclosing cycles are allowed.

By displaying the message *79 permits 1-pole trip* (see *Figure 6-406* in Section *6.22.4.17 Blockings*) the automatic reclosing function signals the 1-pole tripping option of the circuit breaker within the associated function group of the circuit breaker.

Subject to the following conditions, the message *79 permits 1-pole trip* will neither be generated nor reset:

- during the current 1-pole automatic reclosing function cycle if a blocking of the automatic reclosing function occurs prior to the reclosing
- If an automatic reclosing function start is signaled with 2-pole tripping, for example, through external binary inputs
- During operating modes **with tripping**, if there is a 1-pole trip indication and the automatic reclosing function does not allow for 1-pole cycles in accordance with their parameterization.
- If during a 1-pole automatic reclosing function cycle the monitoring of the circuit-breaker pole recognizes an implausible condition.

The automatic reclosing function may generate a 3-pole trip command (3-pole intertrip), if a blocking of the automatic reclosing function occurs based on the above-mentioned causes, e.g., during the detection of an evolving fault with pickup and blocking of evolving faults. Thus, the circuit breaker will have 3-pole tripping in which the blocking of the automatic reclosing function will occur, see also Chapter *6.22.4.11 Dead Time for Operating Modes with Tripping*.

6.22.4.19 Dead-Line Check (DLC) and Reduced Dead Time (RDT)

The additional functions **Dead-line check (DLC)** and **Reduced dead time (RDT)**, are only possible for applications with a voltage-transformer connection. Another requirement is that the voltage of the line being switched on can be correctly measured with an open circuit breaker. This is only possible if the voltage transformer is aligned on the line-side - seen from the circuit breaker.

Both additional functions DLC and RDT are mutually exclusive, because the DLC checks if the value falls below a voltage threshold, while the RDT checks if the value exceeds the voltage threshold.

The respectively selected additional function runs in the automatic reclosing state **dead time**.

Reduced Dead Time (RDT)

With the **Reduced dead time**, a close command can be assigned before the expiration of the set dead times if the line to switch on is recognized as fault-free through the measurement of the line voltage.

The voltage measurement occurs with the 3 phase-to-phase-voltages.

In systems with a grounded neutral point, the 3 phase-to-ground voltages are additionally observed.

In systems with compensated or with isolated neutral points, the largest 2 of the 3 phase-to-ground voltages are additionally considered. Through this, a RDT can also be executed with 1-phase ground connections.

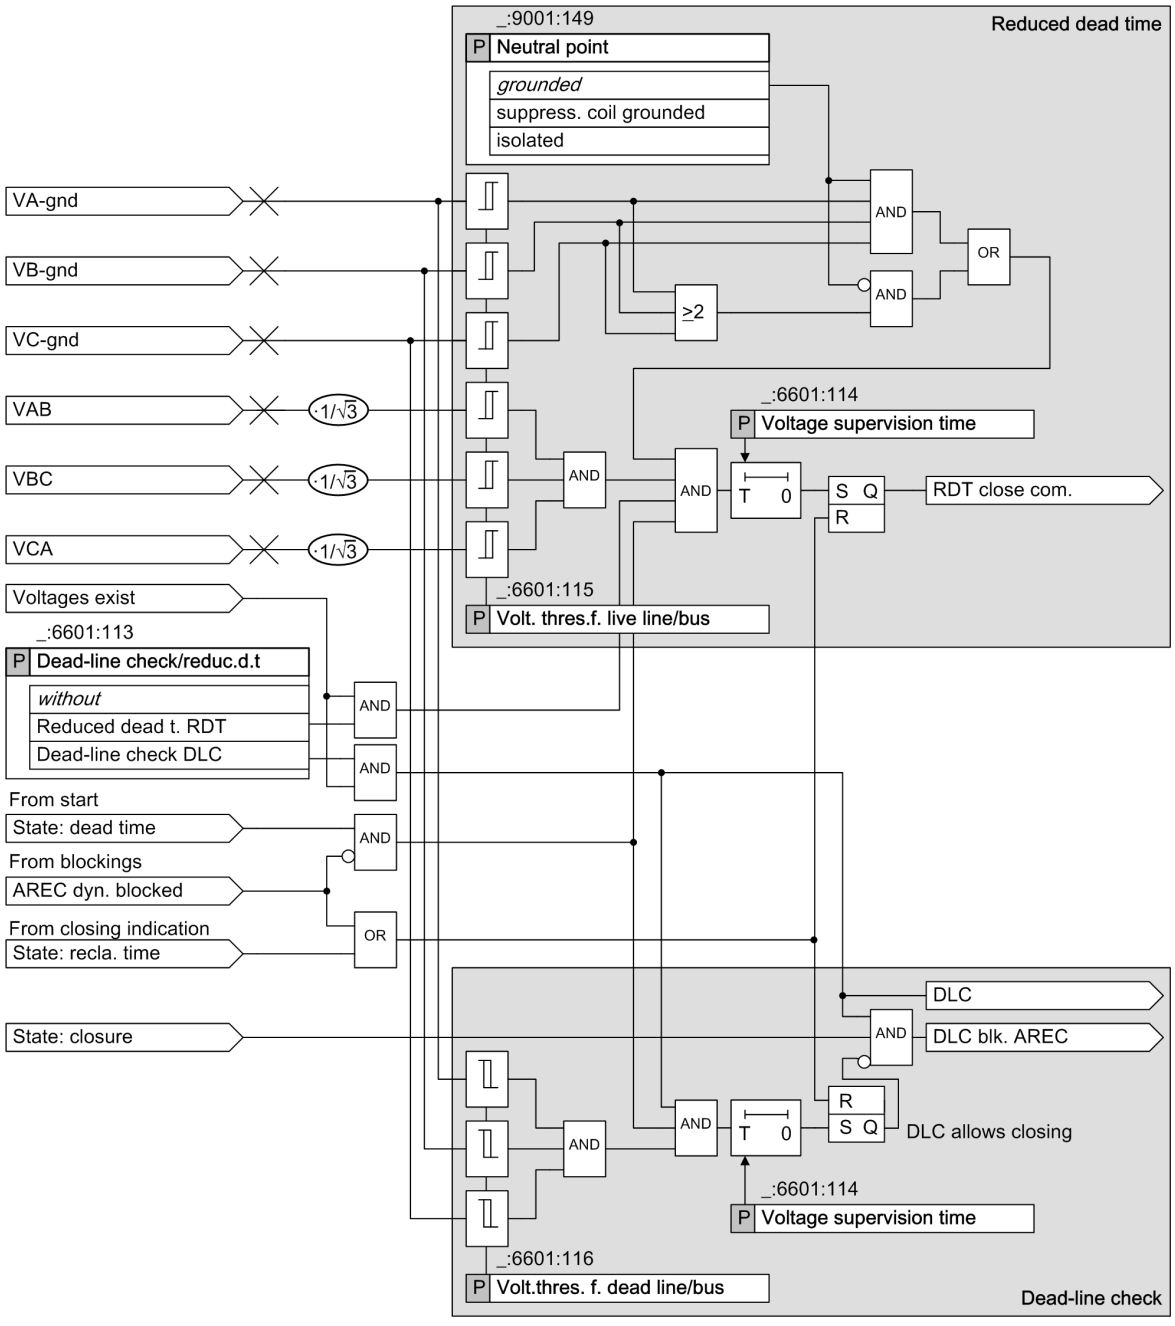
For the approval of the close command with RDT, the following conditions apply:

- The automatic reclosing function is in the state **dead time**.
- Each measured voltage is above the set threshold values **`Volt. thres.f. live line/bus`**
  The phase-to-phase voltages are divided by √3 prior to comparison with the threshold value. Thus, the phase-to-ground voltage $U_N\sqrt{3}$ applies as the reference size for the parameterization.
- Exceeding the threshold is fulfilled for the set duration **`Voltage supervision time`**.

Dead-Line Check (DLC)

If after switching off a short-circuit the voltage on the switched off line does not disappear, the automatic reclosing function can be avoided with the **dead-line check (DLC)**.

The voltage measurement occurs with the 3 phase-to-ground voltages.



For the release of the close command with DLC, the following conditions apply:

- The automatic reclosing function is in the state **dead time**.
- All measured voltages for the set duration **Voltage supervision time** are below the set threshold **Volt. thres.f. live line/bus**.
- The set dead time is expired.

As soon as the voltages fall below the threshold value for the set duration, the allowance for automatic reclosing with DLC is assigned. This also applies if the values are not below the voltage threshold until the expiration of the set dead time. In this way, an automatic reclosing is executed if the automatic reclosing function is first switched to at the end of the protected line and thus, the line is exposed to voltage again.

The automatic reclosing function is blocked by the DLC under the following conditions:

- The automatic reclosing function is in the **Closure** state, the dead time has expired
- All measured voltages were not simultaneously below the set threshold values **Voltage supervision time** for the set duration**Volt.thres. f. dead line/bus** during the dead time.

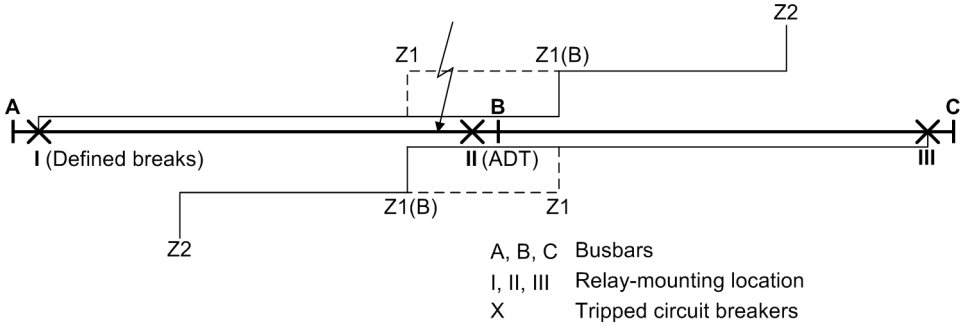
6.22.5 Automatic Reclosing Function with Adaptive Dead Time (ADT)

6.22.5.1 Description

Description

It is also possible to set the dead times only at one line end and to configure the adaptive dead time at the other end or ends. The requirements for this is that the voltage transformer aligned on the line side or a possibility to transfer a close command to a remote line end exists.

Figure 6-408 shows an example with a voltage measurement. It is assumed that device I works with defined dead times, while the adaptive dead time is configured in device II. It is important that the line is at least fed from busbar A, so from the side with the defined dead times.



With the adaptive dead time, the automatic reclosing function at the line end II decides independently if and when a reclosing is reasonable and permissible and when it is not. The criteria is the voltage of the line at the end II, which is switched through after reclosing from end I. The reclosing at end II occurs, as soon as it exists, so that the line from end I is set back under voltage. Basically, all phase-to-phase and phase-to-ground voltages are monitored.

With an implied short-circuit, the lines at the positions I, II, and III in the example are switched off. Position I is switched on again after the dead time set there. At position III the reduced dead time (RDT) can be executed with the appropriate configuration (see chapter) if an infeed is also available on busbar B.

If the short circuit has been cleared after successful reclosing, the line A-B from the busbar A will be set under voltage through the position I. Device II recognizes this voltage and switches on to warrant adequate voltage measurement time after a short delay The system incident is thus successfully cleared.

If the short circuit is not cleared after closure at position I, I will be switched to the fault again. At line end II, now no healthy voltage will appear. The device here recognizes this and does not close again.

With multiple reclosing, the process may repeat if the reclosing is unsuccessful until one of the reclosings is successful or a final disconnection occurs.

[dw_arcasp, 1, en_US]

Figure 6-408 Example for Adaptive Dead Time (ADT)

As the example shows, the adaptive dead time brings along the following advantages:

- The circuit breaker at position II does not switch off again with a remaining fault and is protected through this.
- With non-selective tripping by overreach at position III, no further disruption cycles may occur here because the short-circuit path via busbar B and the position II remains disrupted even with multiple reclosing.
- At position I, with multiple reclosing and even with a final tripping, an overlapping is allowed, because the line at position II remains open and thus, no actual overreaching can occur at position I.

The adaptive dead time also contains the reduced dead time (RDT), because the criteria are the same. A special setting of the reduced dead time (RDT) is unnecessary if the automatic reclosing function is used with adaptive dead time (ADT).

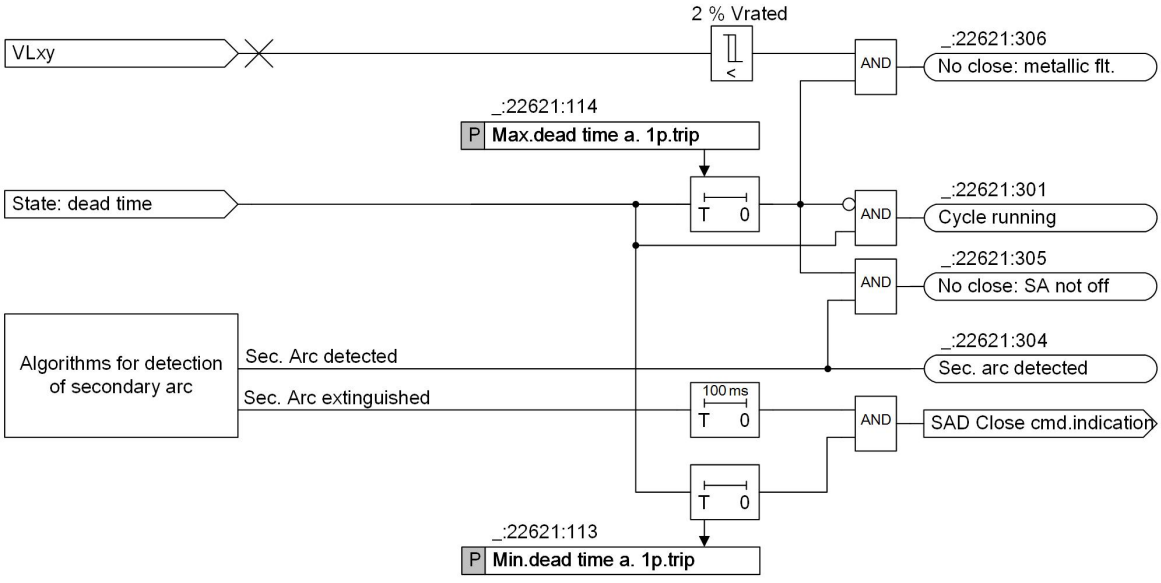
6.22.6 Automatic Reclosing Function with Secondary Arc Detection

6.22.6.1 Description

The function **Automatic reclosing function with secondary arc detection** (**SAD**[50])

- Is an adaptive automatic reclosing function based on secondary arc detection.
- Recloses after a shortened dead time in the case of 1-phase, temporary faults.
  If the secondary arc extinguishes before the end of the dead time and no metallic fault occurs, the automatic reclosing function activates sooner.
- Processes different algorithms to detect secondary arcs in parallel and weights them.
  - After a 1-pole tripping, the close command can only be issued once the minimum dead time (see the following figure) has expired.
  - When the arc is extinguished, the close command is issued only after 100 ms to prevent reignition of the arc.
  - If the secondary arc is still burning after the expiry of the maximum dead time, a 3-pole tripping occurs. This is either finally or - if instantiated - another automatic reclosing cycle is started.

50 SAD = Secondary Arc Detection



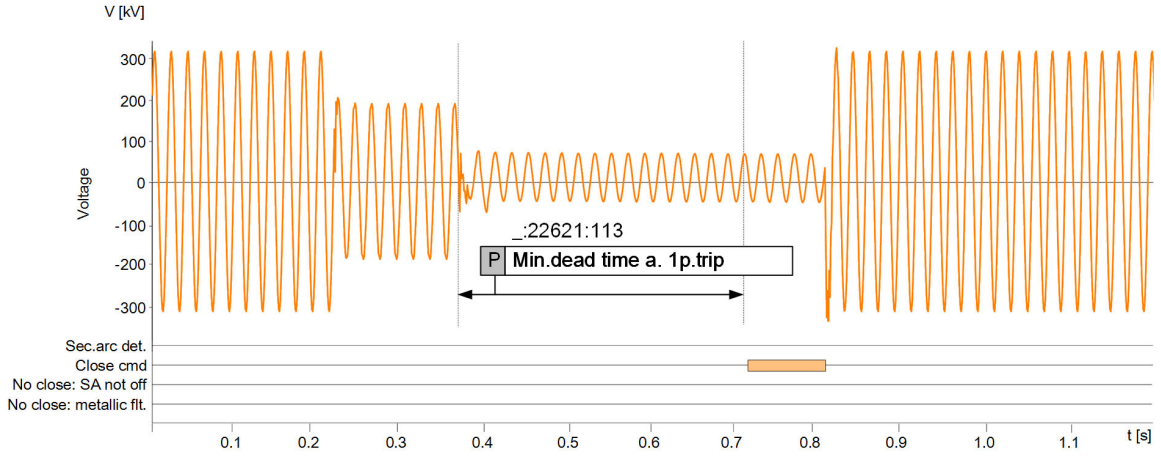
- Behaves as follows if no secondary arc is detected:
  - In case of a metallic fault, the function issues a final trip command.
  - In case of a non-metallic fault, the function issues a close command after the expiry of the minimum dead time.

This function replaces the cyclic automatic reclosing at the master end of the line. At the slave end of the line, Siemens still recommends using the automatic reclosing function with adaptive dead time (ADT).

6.22.2 Structure of the Function shows the structure of the function.

For the description of the general parameters, refer to *6.22.9 Application and Setting Notes for General Settings*.

Logic of the Stage

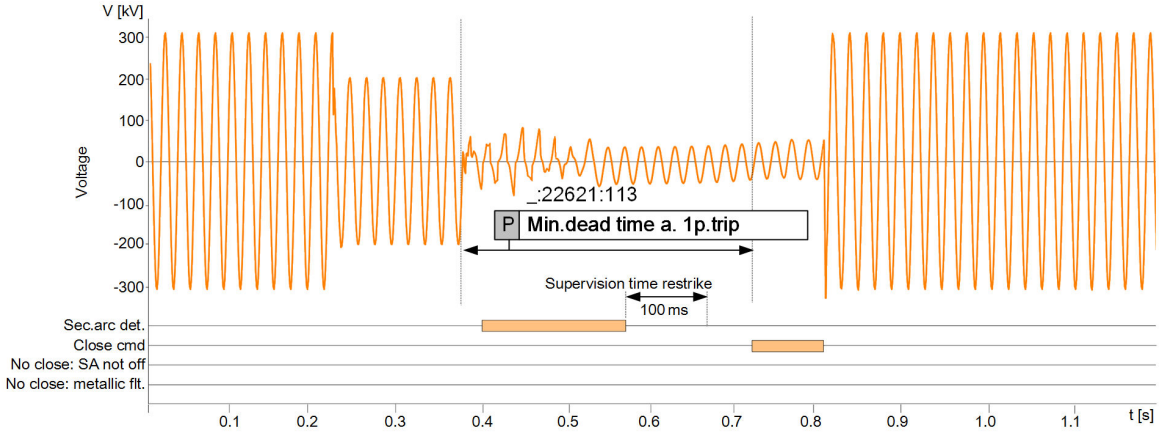


[lo_sad, 1, en_US]

Figure 6-409 Logic of the Stage SAD

VLxy Faulty-loop voltage

When the circuit breaker is open in a 1-pole way and the automatic reclosing function is ready, the dead times start (parameter: **`Min.dead time a. 1p.trip`** and **`Max.dead time a. 1p.trip`**) and the SAD cycle runs. If the maximum dead time has expired and the voltage of the faulty loop is less than 2 % V_{rated}, the indication *`(_:22621:306) No close: metallic flt.`* – no close command due to a metallic fault – is issued for a duration of 50 ms and the SAD cycle is ended. If a secondary arc is detected within the maximum dead time, the indication *`(_:22621:304) Sec. arc detected`* is issued. If the arc does not extinguish during the maximum dead time, the indication *`(_:22621:305) No close: SA not off`* is issued for 50 ms and the SAD cycle is ended.



After a 1-pole tripping, a reclosing action can only be carried out once the minimum dead time (see the following figure) has elapsed.

[dw_SAD-times_1-legend, 2, en_US]

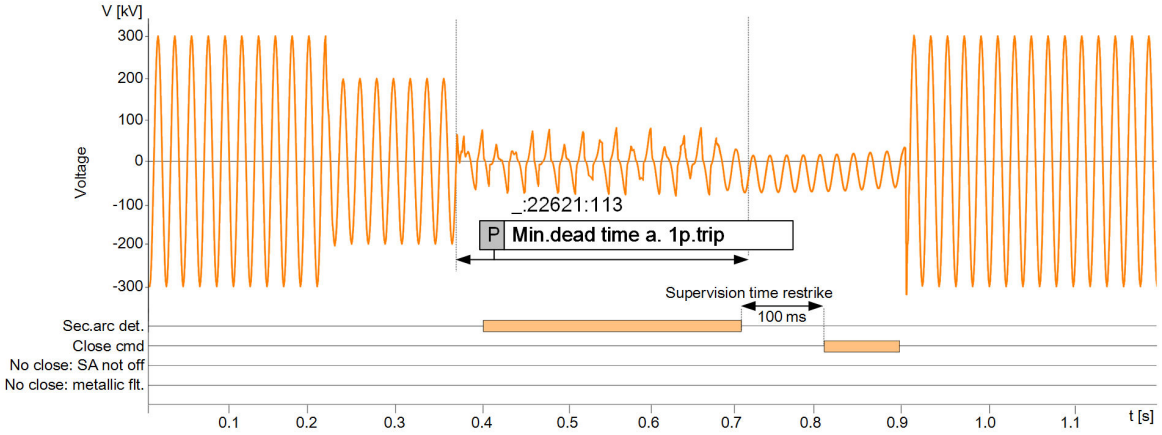


Figure 6-410 Example 1: No Secondary Arc; Close Command after Expiry of the Minimum Dead Time

If a secondary arc is detected, an additional supervision time of 100 ms takes effect after the arc is extinguished. The close command is issued only then. This prevents reclosing in case of a possible reignition of the arc. If no secondary arc is detected, this time is not relevant. If no metallic fault has been detected, the circuit breaker is reclosed after the minimum dead time has expired. The following figures show examples of when the close command is issued – depending on the burning duration of the arc.

[dw_SAD-times_2-legend, 2, en_US]

Figure 6-411 Example 2: Secondary Arc Burns Very Briefly (120 ms); Close Command after Expiry of the Minimum Dead Time

[dw_SAD-times_3-legend, 2, en_US]

Figure 6-412 Example 3: Secondary Arc Burns for 320 ms; Close Command after 420 ms (320 ms + 100 ms)

6.22.6.2 Application and Setting Notes for the Automatic Reclosing Function with Arc Detection

Parameter: Start from idle state allow.

- Default setting **(_:22621:102) Start from idle state allow.** = ***yes***

This parameter is only important and can be set if you use the automatic reclosing function in an operating mode ***with action time***.

With the parameter **Start from idle state allow.**, you can determine whether the action time of this automatic reclosing cycle is started, if the automatic reclosing function is in idle state during with incoming general pickup. Set the parameter always to ***yes***, if the automatic reclosing function is configured for only 1 cycle. If several cycles are configured, you can control the effectiveness of the automatic reclosing cycles with this parameter and various action times.

For detailed information on the functionality, refer to the chapters *6.22.4.6 Cycle Control with Operating Mode 1: with Tripping/with Action Time* and *6.22.4.7 Cycle Control with Operating Mode 2: With Pickup/With Action Time*.

Parameter: Action time

- Default setting **(_:22621:103) Action time** = ***0.20 s***

With the parameter **Action time**, you can determine, within which time frame the trip command must appear, in order to start the automatic reclosing function. If the trip command occurs only after the action time has expired, automatic reclosing does not occur within the active automatic reclosing cycle.

For detailed information on the functionality, refer to the chapters *6.22.4.6 Cycle Control with Operating Mode 1: with Tripping/with Action Time* and *6.22.4.7 Cycle Control with Operating Mode 2: With Pickup/With Action Time*.

Parameter: Dead time aft. 3-pole trip

- Default setting **(_:22621:108) Dead time aft. 3-pole trip** = ***0.50 s***

With the parameter **Dead time aft. 3-pole trip**, you can determine after which dead time the automatic reclosing function will be executed.

After a 3-pole trip of the circuit breaker, the system stability is priority. Since the switched off line cannot develop synchronizing forces, only a short dead time is permitted in most cases. The usual duration is 0.3 s to 0.6 s. A longer period can be tolerated if a synchrocheck is carried out before reclosing. Longer 3-pole dead times are also possible in radial systems.

Parameter: Dead time aft. evolv. fault

These parameters are only significant if the parameter **(_:6601:109) Response to evolv. faults** is set to ***strt. evol.flt.dead time***.

- Default setting **(_:22621:109) Dead time aft. evolv. fault** = ***1.20 s***

With the parameter **Dead time aft. evolv. fault**, you can determine after which dead time the automatic reclosing function should be executed, if based on an evolving fault during the current dead time, a 3-pole trip has occurred. For this 3-pole dead time, stability concerns for the system are also important. Often, this dead time can be set to the same value as the parameter **(_:22621:108) Dead time aft. 3-pole trip**.

For detailed information on the function in the case of evolving faults during dead time, refer to chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*.

Parameter: CB ready check bef.close

- Default setting **(_:22621:111) CB ready check bef.close** = ***no***

With the parameter **CB ready check bef.close**, you can determine if, after the expiration of the dead time (that is, directly before assigning the close command), the readiness of the circuit breaker should be queried.

Parameter Value	Description
no	With the setting ***no***, the automatic reclosing function does not check again the readiness of the circuit breaker before assigning the close demand. Siemens recommends this setting, if it is sufficient to check the readiness of the circuit breaker for the entire switching cycle once before the start of a reclosing function, consisting of tripping-reclosing-tripping. The setting for checking the readiness of the circuit breaker before the start of the automatic reclosing function is done using the parameter **(_:6601:102) CB ready check bef. start**.
yes	With the setting ***yes***, the dead time can be extended if after the expiration of the dead time the circuit breaker is not ready for the next ON-OFF cycle. The maximum delay of the dead time can be set with the parameter **(_:6601:111) Max. dead-time extension**. Siemens recommends this setting, if it can be assumed that the circuit breaker becomes available to switch on the reclosing function only after an additional waiting period.

For detailed information on the function, refer to the chapters *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition* and *6.22.4.14 Closing Indication and Close Command* .

Parameter: Synchroch. aft. 3-pole d.t.

- Default setting **(_:22621:110) Synchroch. aft. 3-pole d.t.** = ***none***

With the parameter **Synchroch. aft. 3-pole d.t.**, you can determine if a synchrocheck must be carried out for the configured automatic reclosing cycle.

If during a 3-pole interruption in the system stability problems may be a concern, Siemens recommends carrying out a synchrocheck. If only 1-pole reclosure cycles are possible or stability problems are not to be expected during the 3-pole dead time, for example, due to a highly intermeshed system or radial system, select the parameter ***none***.

Parameter Value	Description
none	During the automatic reclosing cycle a synchrocheck is not executed.
internal	In the configured automatic reclosing cycle, a synchrocheck is executed after a 3-pole dead time before the close command of the circuit breaker. For the synchrocheck a synchrocheck stage of the internal synchronization function is used, which is contained in the same function group **Circuit breaker** as the automatic reclosing function. The selection of the synchrocheck stage that is used in the automatic reclosing cycle occurs through the following described parameter **Intern. synchrocheck with**.
external	In the configured automatic reclosing cycle, a synchrocheck is executed after a 3-pole dead time before the close command of the circuit breaker. An external synchrocheck device initiates the synchrocheck. The external synchrocheck device is connected with the binary signals *Synchrocheck request* and *>Release by ext.sync.*. For detailed information about the function, refer to chapter *6.22.4.14 Closing Indication and Close Command* in the section *Synchrocheck , Page 1150*.

Parameter: Min.dead time a. 1p.trip

- Default setting **(_:22621:113) Min.dead time a. 1p.trip** = ***0.35 s***

With the parameter **Min.dead time a. 1p.trip**, you define the minimum dead time after a 1-pole tripping. Automatic reclosing is possible after expiry of the minimum dead time at the earliest.

Parameter: Max.dead time a. 1p.trip

- Default setting **(_:22621:113) Max.dead time a. 1p.trip** = ***1.20 s***

With the parameter **Max.dead time a. 1p.trip**, you define the maximum dead time after a 1-pole tripping.
If the secondary arc is still burning after the expiry of the maximum dead time, a 3-pole tripping occurs. This is either finally or - if instantiated - another automatic reclosing cycle is started.

Parameter: Intern. synchrocheck with

With the parameter **(_:22621:112) Intern. synchrocheck with**, you determine which function block of the synchronization function for the Automatic reclosing function is used after a 3-pole dead time. This selection is possible only for function blocks of the synchronization function that are included in the same **Circuit breaker** function group as the Automatic reclosing function. The setting options of the parameter are generated dynamically, according to the actual parameterization.

6.22.7 Operation with External Automatic Reclosing Function

6.22.7.1 Description

The operation of an external reclosing device with the SIPROTEC protection device occurs through the function mode **Operation with external automatic reclosing function**. In this function mode, the SIPROTEC protection functions create the trip command and the external reclosing device creates the close command.

The following figure shows the interaction of an external reclosing device with the functions of the SIPROTEC 5 device.

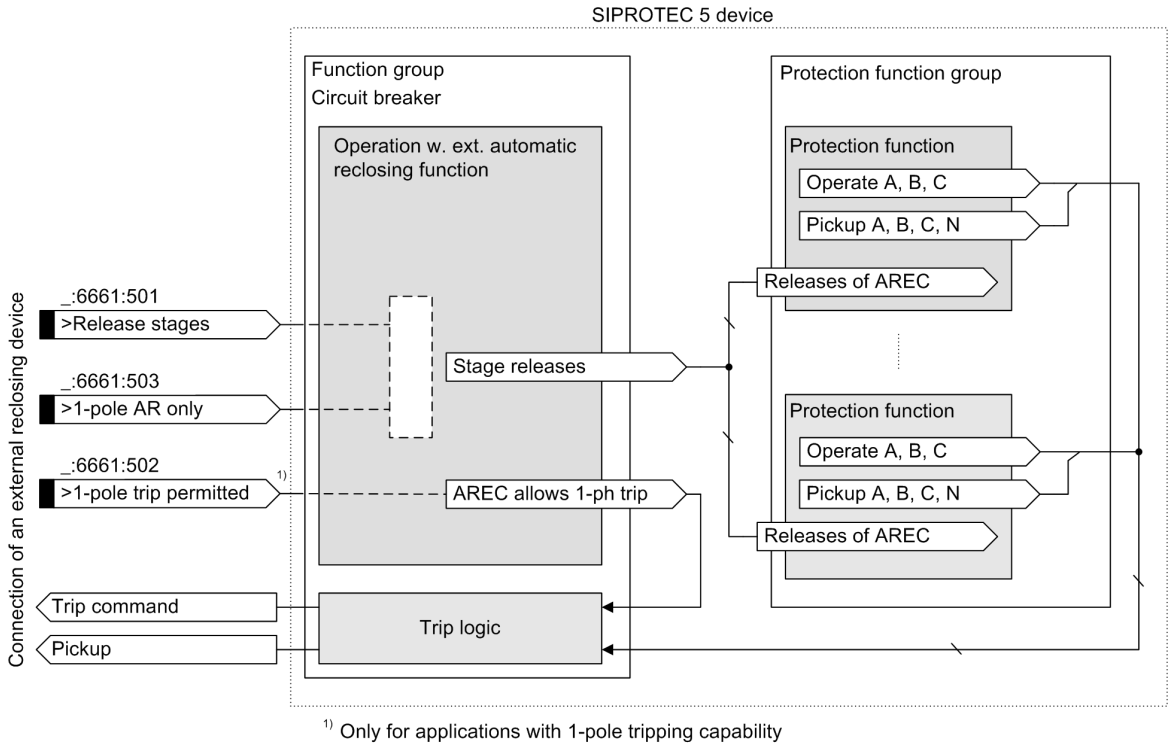

Figure 6-413 Connection of an External Automatic Reclosing Function

There are no setting parameters for operation with external automatic reclosing functions. The function provides exclusively the following described binary inputs. The external reclosing device can thus have an influence on the effects of the internal protection functions.

The following connection possibilities exist:

- From the external reclosing function, the signal *>Release stages* can be coupled so that the protection functions use special stages or zones for release. An example is the release of an overreaching zone with a distance protection or the non-delayed tripping of an overcurrent protection stage in the 1st reclosing cycle.
- For applications with 1-pole tripping, the external reclosing can provide the signal *>1-pole trip permitted*, based on which the protection functions can switch off the 1-pole circuit breaker.
- For applications with reclosing functions only with 1-pole faults and stage or zone releases through the reclosing function can the signal *>1-pole AR only* be connected. The protection functions use this information to allow the stage or zone release only affect 1-pole faults.

6.22.8 Control of the Internal Automatic Reclosing Function by an External Protection Device

The internal automatic reclosing function (AREC) can be started via the pickup indications of the phases A, B, C or via the trip command of an external protection device. The start depends on the operating mode set for the AREC, refer to *Parameter: 79 operating mode, Page 1181*.

For further information, refer to *6.22.3 Cooperation of the Automatic Reclosing Function and Protection Functions* .

Start of the Internal AREC via the Trip Command of an External Protection Device

If the internal AREC of the SIPROTEC 5 device is permitted to start via the trip command of an external protection device, Siemens recommends the following procedure for 1-pole cycles:

Route the following output signals of the external protection device to the binary inputs of the SIPROTEC 5 device:

Address	Binary Signal	Description
_:6601:513	>Gen. pickup for start	General pickup for the automatic reclosing function
_:6601:515	>Trip pole A for start	Trip command phase A for the automatic reclosing function
_:6601:516	>Trip pole B for start	Trip command phase B for the automatic reclosing function
_:6601:517	>Trip pole C for start	Trip command phase C for the automatic reclosing function

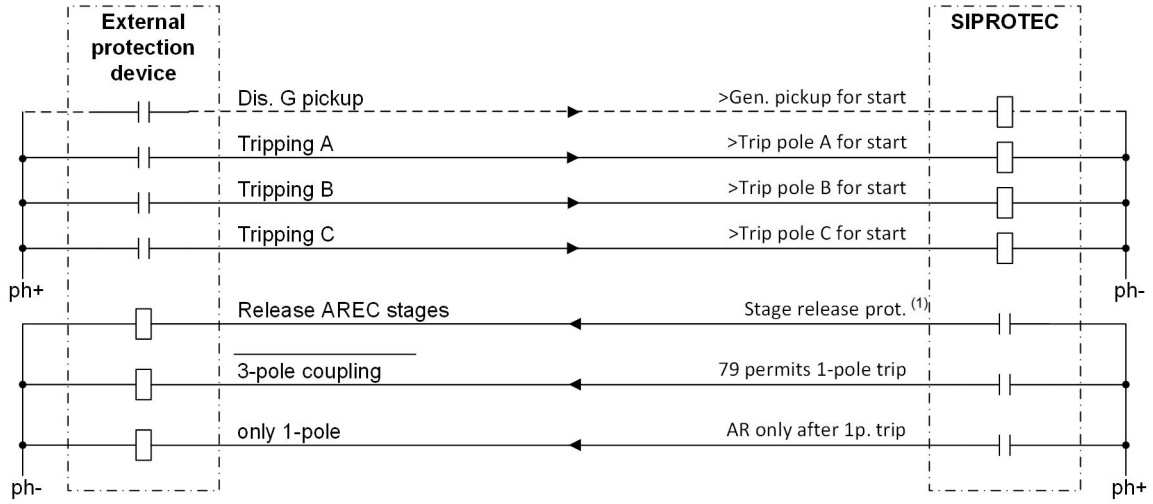
The general pickup is decisive for starting the action times. The general pickup is also necessary for the internal AREC to detect evolving faults via pickup. In other cases, the signal *>Gen. pickup for start* is not needed.

The trip commands decide whether the dead time is activated for 1-pole or 3-pole automatic reclosing cycles or whether reclosing is blocked in case of a 3-pole tripping. This depends on the parameterization of the dead times.

If 1-pole cycles are desired, *Figure 6-414* shows an example for the interconnection between the internal AREC of the SIPROTEC 5 device and an external protection device.

To achieve 3-pole coupling of the external protection and to release its accelerated stages before reclosing, you can route the following signals of the internal AREC to the binary outputs of the SIPROTEC 5 device:

Address	Binary Signal	Description
_:6601:307	79 permits 1-pole trip	The internal AREC is ready for the 1-pole automatic reclosing cycle. That is, the internal AREC permits 1-pole tripping (logic inversion of the 3-pole coupling).
_:6571:302	Stage release prot.	The cycle of the internal AREC is ready for the 1st automatic reclosing cycle and releases the stage of the external protection that is decisive for reclosing. For further cycles, corresponding output indications are available in the respective cycle. If required, route these output indications to a binary output. If the external protection does not require an overreach stage, it is not necessary to route the signal to a binary output. This is the case, for example, for the functions **Differential protection** or **Permissive overreach transfer trip with distance protection**.
_:6601:308	AR only after 1p. trip	The internal AREC function is programmed for 1-pole tripping. That is, the AREC function only recloses after 1-pole tripping. If the external protection does not require an overreach stage released by the AREC function, it is not necessary to route the signal to a binary output. This is the case, for example, for the functions **Differential protection** or **Permissive overreach transfer trip with distance protection**.

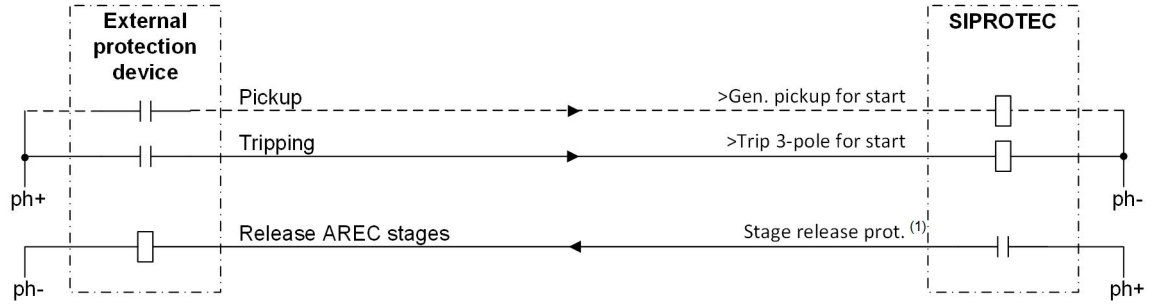


If the external protection device allows it, you can also report the 1-pole and 3-pole tripping to the internal AREC function instead of the 3 phase-selective trip commands. For this purpose, route the following signals to the binary inputs of the SIPROTEC 5 device:

Address	Binary Signal	Description
_:6601:513	>Gen. pickup for start	General pickup for the internal automatic reclosing function The general pickup is decisive for starting the action times.
_:6601:518	>Trip 1-pole for start	1-pole trip command for the internal automatic reclosing function
_:6601:519	>Trip 3-pole for start	3-pole trip command for the internal automatic reclosing function

NOTE

You must not route the phase selective signals, e.g. *>Trip pole A for start*, and the grouped signals, e.g. *>Trip 3-pole for start*, simultaneously. Decide on one variant.



[lo_connect-example_with_ext-prot_1-3pole_reclose_AR, 1, en_US]

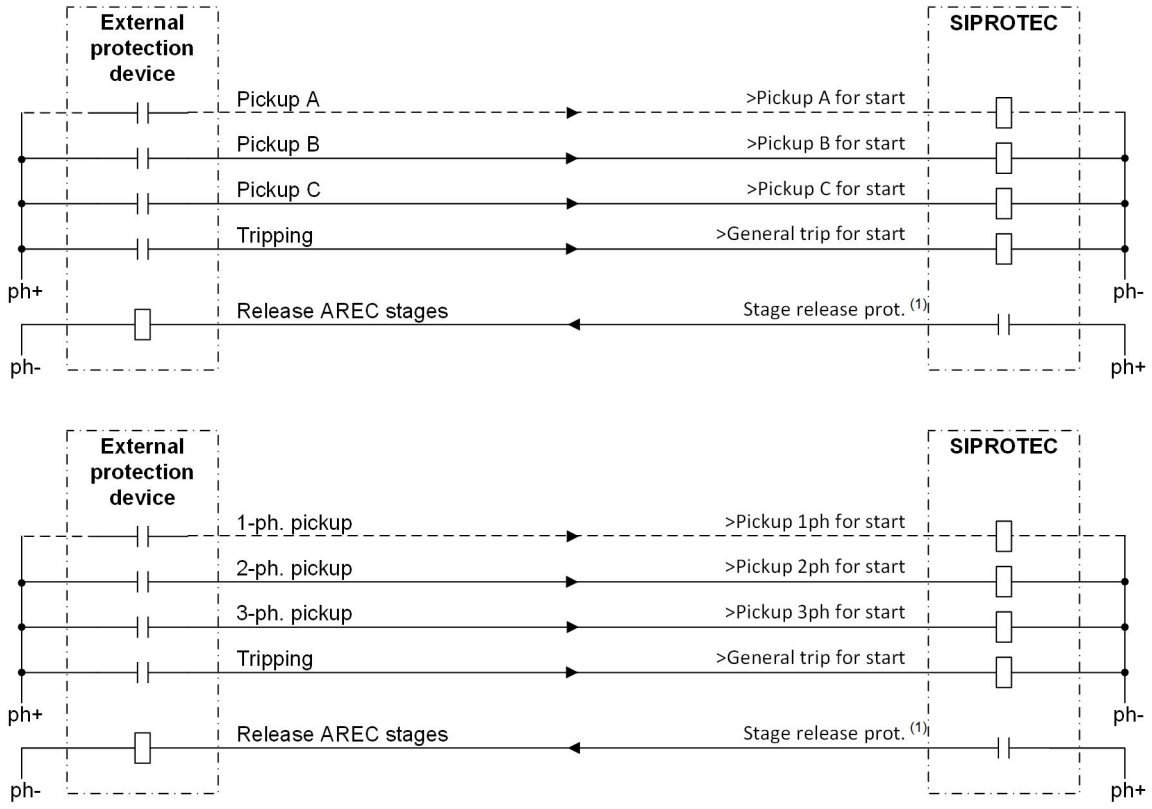
Figure 6-414 Connection Example, phase selective signals with External Protection Device for 1-/3-Pole AREC; Parameter **(_:6601:101) 79 operating mode** = ***with op., with act. time***

(1) Each AREC cycle has a dedicated release signal

For 3-pole automatic reclosing cycles, it is sufficient to route the trip command *(_:6601:519) >Trip 3-pole for start* to a binary input of the SIPROTEC 5 device. You can release overreach stages of the external protection via the signal *(_:6571:302) Stage release prot.*. Figure 6-415 shows an example.

[lo_connect-example_with_ext-prot_3pole_reclose_AR, 1, en_US]

Figure 6-415 Connection Example with External Protection Device for 3-Pole AREC; Parameter **(_:6601:101) 79 operating mode** = ***with op., with act. time***



(1) Each AREC cycle has a dedicated release signal

Start of the Internal AREC via the Pickup Indications of an External Protection Device

Starting the internal AREC function via pickup indications is explicitly only possible with 3-pole tripping. In SIPROTEC 5 devices capable of 1-/3-pole tripping, the parameter **(_:2311:113) 1-pole operate allowed** must be set to ***no***, refer to *5.9.3 Application and Setting Notes*.

If the internal automatic reclosing function is started by the pickup and you want to distinguish the AREC response, you must route the phase-selective pickup signals from the external protection to the binary inputs of the SIPROTEC 5 device.

The general trip command via the signal *(_:6601:514) >General trip for start* is sufficient for tripping. Figure 6-416 shows connection examples.

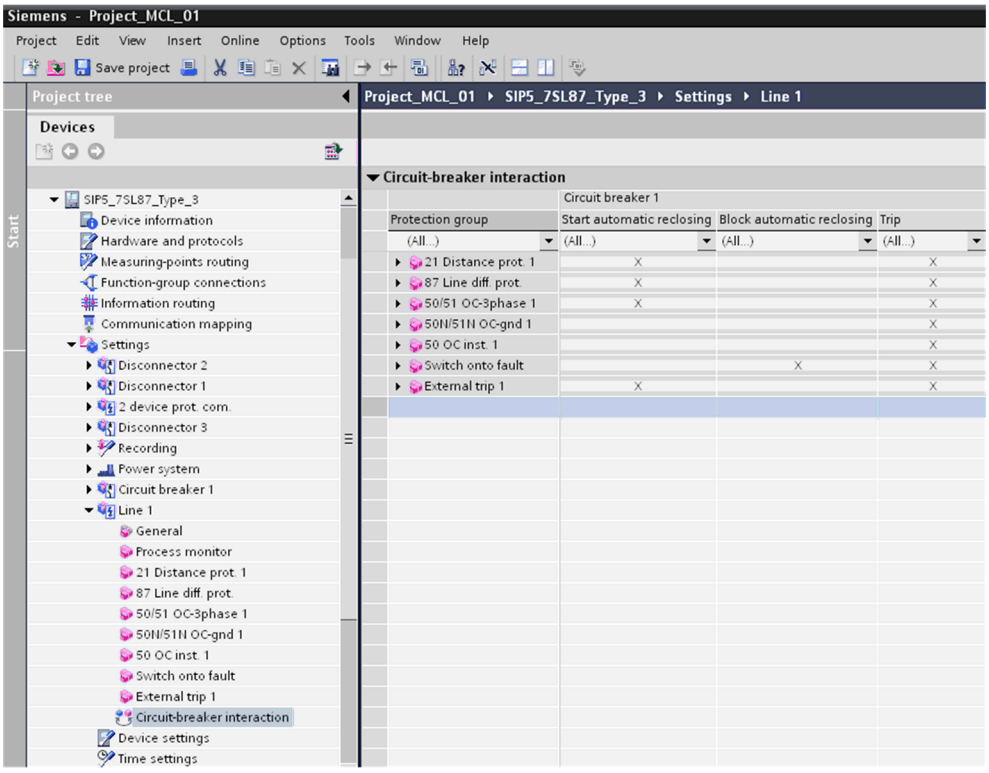
[lo_connect-example_with_ext-prot_1pole-2pole-3pole_reclose_AR, 1, en_US]

Figure 6-416 Connection Example with External Protection Device for Fault-Type Dependent Dead Time – Dead-Time Control by Pickup Signals of the Protection Device; Parameter **79 operating mode** = ***w.pickup, w. action time***

(1) Each AREC cycle has a dedicated release signal

6.22.9 Application and Setting Notes for General Settings

For the automatic reclosing function, there are 3 functions available in the function library. In each function group **Circuit breaker**, a function from the automatic reclosing function can be used.



Configure one of the following function specifications:

- Cyclic Automatic reclosing function
- Automatic reclosing function with adaptive dead time (ADT)
- Automatic reclosing function with secondary arc detection (SAD)
- Operation with External automatic reclosing function

Starting the Automatic Reclosing Function

The configuration of the interaction between internal protection functions and the automatic reclosing function can be set separately for each protection function. The configuration occurs in a matrix view in DIGSI. The Automatic reclosing function also has the corresponding binary inputs and binary outputs through which the external protection devices can be connected to the internal Automatic reclosing function.

Configure the starting and blocking condition for the automatic reclosing function at the position shown in *Figure 6-417* in DIGSI or route the corresponding binary inputs.

[scdigsia-080311-01.tif, 1, en_US]

Figure 6-417 Configuration of the Protection Functions for Starting and Blocking the Automatic Reclosing Function in DIGSI

General Settings

If you use the **Cyclic automatic reclosing function**, the **Automatic reclosing function with adaptive dead time**, or the **Automatic reclosing function with secondary arc detection (SAD)**, set the following settings under **General**.

There are no settings for the function **Operation with external automatic reclosing function**. The control occurs exclusively through binary inputs and binary outputs.

Parameter: 79 operating mode

- Default setting **(_:6601:101) 79 operating mode** = ***with op., with act. time***

You can use the parameter **79 operating mode** to determine which start criteria the automatic reclosing function works with.

Parameter Value	Description
with op., with act. time	The automatic reclosing function cycles are dependent on the operate time of the protection function(s). The start occurs with all protection function(s) or protection stages that are configured through the automatic reclosing function start matrix. Siemens generally recommends this setting for applications with 1/3-pole tripping and for applications with 3-pole tripping if a single dead time, independent of the type of connection working, is required in the automatic reclosing function cycle. For detailed information, refer to chapter *6.22.4.1 Operating Modes for Cyclic Automatic Reclosing Function* , section **Operating mode 1**.
w.pickup, w. action time	The automatic reclosing function cycles are dependent on the operate time of the protection function(s) and the type of fault. The start occurs with all protection function(s) or protection stages that are configured through the automatic reclosing function start matrix. For applications with 3-pole tripping and dead time dependent on the circuit type, Siemens recommends this setting. For detailed information, refer to chapter *6.22.4.1 Operating Modes for Cyclic Automatic Reclosing Function* , section **Operating Mode 2**.
with op., w/o act. time	Each operate indication starts the automatic reclosing function. The start occurs with all protection function(s) or protection stages that are configured through the automatic reclosing function start matrix. The automatic reclosing function start must be configured so that it only occurs from the protection stages/zones for which an automatic reclosing should occur after tripping. For detailed information, refer to chapter *6.22.4.1 Operating Modes for Cyclic Automatic Reclosing Function* , section **Operating Mode 3**.
w.pickup, w/o act. time	Each operate indication starts the automatic reclosing function. The automatic reclosing function cycles are dependent on the type of fault. The start occurs with all protection function(s) or protection stages that are configured through the automatic reclosing function start matrix. The automatic reclosing function start must be configured so that it only occurs from the protection stages/zones for which an automatic reclosing should occur after tripping. For detailed information, refer to chapter *6.22.4.1 Operating Modes for Cyclic Automatic Reclosing Function* , section **Operating Mode 4**.

Parameter: CB ready check bef. start

- Default setting **(_:6601:102) CB ready check bef. start** = ***no***

With the parameter **CB ready check bef. start**, you can determine if the readiness of the circuit breaker should be tested **before starting** the automatic reclosing function.

Additionally or alternatively, it is possible to check the readiness of the circuit breaker after the expiration of the dead time, directly before the assignment of the close command. There is another parameter described in the chapter *6.22.10 Application and Setting Notes for 1 Cycle of the Cyclic Automatic Reclosing Function* for this function.

Parameter Value	Description
yes	The automatic reclosing function checks the readiness of the circuit breaker for a switching cycle, consisting of a tripping-reclosing-switching. If the circuit breaker is ready - signaled through a binary input - the startup of the automatic reclosing function can occur. If the circuit breaker is not ready, the automatic reclosing function reports the static blocking. Siemens recommends using this setting. **Note:** The presetting of this parameter does not correspond with the recommended setting for operation. The automatic reclosing function would otherwise be blocked with a non-available circuit breaker-ready-signal. Please set the parameter as recommended.
no	The readiness of the circuit breaker is not checked before starting the automatic reclosing function. The test also does not occur if the readiness signal from the circuit breaker is connected to a binary input on the device.

Parameter: Reclai. time aft.succ.cyc.

- Default setting **(_:6601:103) Reclai. time aft.succ.cyc.** = ***3.00 s***

With the parameter **Reclai. time aft.succ.cyc.**, you set the time used to decide if the currently running reclosing cycle was successful or not. Detailed information about the function of the reclaim time can be found in the chapter *6.22.4.15 Reclaim Time*.

The presetting for the reclaim time can be frequently maintained. In regions where thunderstorms and storms often occur, a shorter reclaim time makes sense in order to minimize the danger of the final disconnection due to sequential lightning strikes or cable spark over.

Select a long reclaim time if there is no possibility for circuit-breaker supervision with multiple automatic reclosing, for example, due to missing auxiliary contacts or lacking circuit-breaker-ready-information. In this case, the reclaim time must be longer than the recovery time of the circuit breaker.

Parameter: Block. time aft. man.close

- Default setting **(_:6601:104) Block. time aft. man.close** = ***1.00 s***

With the parameter **Block. time aft. man.close**, the time is determined for which the automatic reclosing should be blocked after a manual connection.

Set the time so that the circuit breaker can be safely switched on and off during connection to a short circuit without the automatic reclosing function being automatically closed.

Parameter: Start signal supervis.time

- Default setting **(_:6601:105) Start signal supervis.time** = ***0.25 s***

With the parameter **Start signal supervis.time**, you set the maximum time after which a circuit breaker must be opened after a trip command. If the time expires, a failure of the circuit breaker is assumed and the automatic reclosing function is dynamically blocked.

For detailed information about the function of the start supervision time, refer to chapter *6.22.4.5 Start*.

NOTE

With the use of an internal or external circuit-breaker failure protection at the same line branch, observe the following:

- The start supervision time should be the same as the circuit-breaker failure protection time delay. With this, you can make sure that in the case of a circuit-breaker failure followed by the tripping of the busbar, no automatic reclosing will be executed.
  (Note: An exception to this recommendation is described below.)
- During a 1-pole trip command repeat caused by the circuit-breaker failure protection, the start supervision time must be longer than the delay time for the 1-pole trip command repeat + the **Minimum operate time** set in the circuit-breaker protection function. With this, it can be ensured that the trip command is not connected before the 1-pole trip command repeat through the circuit-breaker failure protection from the coupling of the trip command of the 3-pole automatic reclosing function.
- The start supervision time must be longer than the time delay for the tripping of the busbars if a 1-pole trip command for the line branch should not be coupled by the automatic reclosing function or the circuit-breaker failure protection 3-pole before the circuit-breaker failure protection can trip the busbars. With this case, the automatic reclosing function must be blocked with the trip command for the busbars. This helps to avoid an automatic reclosing function being executed after the tripping of the busbars for the line branch. The blocking of the automatic reclosing function can occur with a CFC link to the binary input *>Block function*.

Parameter: CB ready superv. time

The setting of this parameter is only important if the cycle-specific parameter **CB ready check bef.close** is set to ***yes***. Otherwise, this parameter has no effect.

- Default setting **(_:6601:106) CB ready superv. time** = ***3.00 s***

With the parameter **CB ready check bef. start**, you can determine after which maximum time after the tripping the circuit breaker must be ready for the reclosing function.

Set the time somewhat longer than the regeneration time of the circuit breaker after an OFF-ON-OFF cycle.

For detailed information about the function, refer to the chapters *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition* and *6.22.4.14 Closing Indication and Close Command* .

Parameter: 3-pole operate by 79

This parameter is irrelevant and cannot be set if the circuit breaker is configured exclusively for 3-pole tripping.

- Recommended setting value **(_:6601:107) 3-pole operate by 79** = ***yes***

With the parameter **3-pole operate by 79**, you can determine if the automatic reclosing function creates a 3-pole operate indication to the 3-pole coupling of the circuit-breaker pole.

Parameter Value	Description
yes	The automatic reclosing function can create a 3-pole operate indication under the following conditions: • With the blocking of the automatic reclosing function in the 1-pole dead time, for example, through an evolving fault or external blocking • If an automatic reclosing function start is signalized with **2-pole tripping**, for example, through external binary inputs • For operating modes **with tripping**, if there is a 1-pole operate indication and the automatic reclosing function does not allow for 1-pole cycles in accordance with their parameterization. • If during a 1-pole the automatic reclosing function cycle the supervision of the circuit-breaker pole recognizes an implausible condition. Siemens recommends using this setting.
no	The automatic reclosing function does not create 3-pole tripping.

For detailed information about the functionality, refer to the chapters *6.22.4.11 Dead Time for Operating Modes with Tripping*, *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition* and *6.22.4.13 Evolving-Fault Detection During the Dead Time*.

Parameter: Evolving-fault detection

This parameter is not important and cannot be set if you use the ADT function (automatic reclosing function with adaptive dead time).

- Default setting **(_:6601:108) Evolving-fault detection** = ***with trip***

With the parameter **Evolving-fault detection**, you can determine which criteria is used to recognize an evolving fault. The actual effect of the recognized evolving fault on the automatic reclosing function can be set with the parameter described below **Response to evolv. faults**.

Evolving faults are short circuits, which occur after switching off a short circuit during dead time.

For detailed information about evolving-fault detection, refer to chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*.

Parameter Value	Description
with trip	Evolving faults are recognized if an operate indication occurs during the dead time. Thus, it does not matter if the tripping-protection function is configured for the start of the automatic reclosing function or not. The pickup of a protection function without an operate indication does not lead to evolving-fault detection.
with pickup	Evolving faults are detected if during the dead time a protection function configured for the automatic reclosing function start is picked up or if an external pickup is detected through a binary input.

For applications with 1-/3-pole tripping, Siemens recommends the setting ***with trip*** if the system is adequately interconnected.

If multiple individual lines in a row form a total transmission path, the setting ***with pickup*** may be better suitable. With this setting, you can prevent 2 lines following each other from switching to 1-pole in different conductors during evolving faults. The consequence of this fault would be the remainder of a single conductor in the dead time for the overall transmission path. This is particularly important if power plants are coupled through the overall transmission path.

Parameter: Response to evolv. faults

This parameter is not important and cannot be set if you use the ADT function (automatic reclosing function with adaptive dead time).

- Default setting **(_:6601:109) Response to evolv. faults** = ***blocks 79***

With the parameter **Response to evolv. faults**, you can determine how the automatic reclosing function reacts to recognized faults.

For detailed information about the automatic reclosing function for faults, refer to chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*.

Parameter Value	Description
blocks 79	The automatic reclosing function is immediately blocked until the disconnection of the fault. For blockings through faults during the 1-pole dead times, you can force a 3-pole coupling of the trip command through the automatic reclosing function if you set the parameter **3-pole operate by 79** to ***yes***.
strt. evol.flt.dead time	After the 3-pole trip command to clear up the fault, the automatic reclosing function starts a new 3-pole automatic reclosing function cycle with the set **Dead time aft. evolv. fault**.

Parameter: Max. dead-time delay

This parameter is not important and cannot be set if you use the ADT function (automatic reclosing function with adaptive dead time).

- Default setting **(_:6601:110) Max. dead-time delay** = ***0.5 s***

With the parameter **Max. dead-time delay**, you determine at which time the starting of the dead time may be delayed before the automatic reclosing function is dynamically blocked.

The delay of the start of the dead time is possible with the binary input **>Dead time start delay**.

For detailed information about the functionality, refer to chapter *6.22.4.5 Start*.

Parameter: Max. dead-time extension

- Default setting **(_:6601:111) Max. dead-time extension** = ***1.2 s***

With the parameter **Max. dead-time extension**, you determine the time by which the dead time may be extended before the automatic reclosing function is dynamically blocked.

With the setting ***oo (invalid)***, the extension is unlimited.

An extension of the dead time can be required under the following conditions:

- Waiting for the readiness of the circuit breaker
- Inquiry of a synchronous test
- Delay through binary input in order, for example, to give the leading automatic reclosing function priority in a system with 1 1/2 circuit breaker layout.

Remember that longer dead times after 3-pole disconnection are only permissible if no stability problems occur or if a synchronous test occurs before the reclosing.

For detailed information about the functionality, refer to chapter *6.22.4.14 Closing Indication and Close Command* .

Parameter: Voltage supervision time

This parameter is only important if you use the subfunctions RDT, DLC, or the ADT function. If you do not use any of these functions, the setting of this parameter is free to select.

- Default setting **(_:6601:114) Voltage supervision time** = ***0.1 s***

With the parameter **Voltage supervision time**, you can determine the measuring time that is available as a criteria for the voltage decision. It should be longer than all transient oscillations through switching operations.

For the subfunctions **Reduced dead time** and **Reclosing function with adaptive dead time**, this measuring time applies for the determination of the surpassing of a voltage threshold. For the subfunction **Dead-line check**, the surpassing of a voltage threshold is checked.

Siemens recommends the setting 0.10 s.

For detailed information about the functionality, refer to the following parameters and to the chapters *6.22.4.19 Dead-Line Check (DLC) and Reduced Dead Time (RDT)* and *6.22.5.1 Description*.

Parameter: Volt. thres.f. live line/bus

This parameter is only important if you use the subfunction **RDT** or the function **ADT**. If you do not use any of these functions, the setting of this parameter is free to select.

- Default setting **(_:6601:115) Volt. thres.f. live line/bus** = ***48 V***

With the parameter **Volt. thres.f. live line/bus**, you can determine the limit voltage above which the line should be seen as fault-free. It must be lower than the smallest expected operating voltage. The phase-to-ground voltage applies as the reference value.

For detailed information about the functionality, refer to the following parameters and to the chapters *6.22.4.19 Dead-Line Check (DLC) and Reduced Dead Time (RDT)* and *6.22.5.1 Description*.

Parameter: Dead-line check/reduc.d.t

This parameter is not important and cannot be set if you use the ADT function (automatic reclosing function with adaptive dead time).

- Default setting **(_:6601:113) Dead-line check/reduc.d.t** = ***without***

With the parameter **Dead-line check/reduc.d.t**, you can determine if the automatic reclosing function should work with one of the additional functions ***Dead-line check DLC*** or ***Reduced dead t. RDT***.

Parameter Value	Description
without	The automatic reclosing function occurs after the expiration of the parameterized dead times. DLC or RDT are not activated.
Reduced dead t. RDT	The automatic reclosing function works with a reduced dead time (RDT).
Dead-line check DLC	The automatic reclosing functions work with dead-line check. The closing indication is only assigned if the line was really de-energized during the dead time.

For detailed information about the functionality, refer to chapter *6.22.4.19 Dead-Line Check (DLC) and Reduced Dead Time (RDT)* .

NOTE

Use RDT or DLC only if the voltages of the line can be correctly measured with an open circuit breaker. This is only possible if the voltage transformer is aligned on the line-side - seen from the circuit breaker.

Parameter: Volt.thres. f. dead line/bus

This parameter is only important if you use the Dead-line check subfunction. If you do not use any of this subfunction, the setting of this parameter is free to select.

- Default setting **(_:6601:116) Volt.thres. f. dead line/bus** = ***30 V***

With the parameter **Volt.thres. f. dead line/bus**, you can determine the limit voltage below which the line should be seen with certainty as dead or turned off. The threshold value is used by the Dead-line check subfunction (dead-line check). The reference size is the phase-to-ground voltage.

For detailed information about the functionality, refer to chapter *6.22.4.19 Dead-Line Check (DLC) and Reduced Dead Time (RDT)* .

Parameter: Send delay f. remot. close

With the parameter **Send delay f. remot. close**, you can determine after which time after the automatic reclosing function the information is sent to the remote closing.

- Default setting **(_:6601:112) Send delay f. remot. close** = ***oo (invalid)***

The transmission delay prevents the device operating in the adaptive dead time mode on the opposite side from closing unnecessarily if the local reclosing function remains unsuccessful. On the other hand, it must be remembered that the line is not available for transporting energy as long as the opposite end is also closed. Thus, the **Send delay f. remot. close** must be added to the dead time in order to determine the system stability.

For detailed information about this functionality, refer to chapter *6.22.4.14 Closing Indication and Close Command* .

6.22.10 Application and Setting Notes for 1 Cycle of the Cyclic Automatic Reclosing Function

For the function of the cyclic automatic reclosing function, 1 cycle is preset. The preset cycle cannot be deleted. You can add and delete more cycles from the function library in **DIGSI 5**.

Parameter: Start from idle state allow.

This parameter is only important and can be set if you use the automatic reclosing function in an operating mode ***with action time***.

- Default setting **(_:6571:102) Start from idle state allow.** = ***yes***

With the parameter **Start from idle state allow.** you can determine whether the action time of this automatic reclosing cycle is started, if the automatic reclosing function is in idle state during with incoming general pickup. Please set the parameter always to ***yes***, if the automatic reclosing function is configured for only 1 cycle. If several cycles are configured, you can control the effectiveness of the automatic reclosing cycles with this parameter and various action times.

Detailed information about the functionality can be found in Chapters *6.22.4.6 Cycle Control with Operating Mode 1: with Tripping/with Action Time* und *6.22.4.7 Cycle Control with Operating Mode 2: With Pickup/With Action Time*.

Parameter: Action time

This parameter is only important and can be set if you use the automatic reclosing function in an operating mode ***with action time***.

- Default setting **(_:6571:103) Action time** = ***0.2 s***

With this parameter **Action time** you can determine, within which time frame the trip command must appear, in order to start the automatic reclosing function. If the trip command occurs only after the action time has expired, automatic reclosing does not occur within the active automatic reclosing cycle.

You can find detailed information about the functionality in

Chapters *6.22.4.6 Cycle Control with Operating Mode 1: with Tripping/with Action Time* and *6.22.4.7 Cycle Control with Operating Mode 2: With Pickup/With Action Time*.

Parameter: Dead time aft. 3-pole trip, Dead time aft. 1-pole trip

This parameter is only important and can be set if you use the automatic reclosing function in an operating mode ***with tripping***.

- Default setting **(_:6571:108) Dead time aft. 3-pole trip** = ***0.5 s***
- Default setting **(_:6571:107) Dead time aft. 1-pole trip** = ***1.2 s***

With this parameter **Dead time aft. 3-pole trip** and **Dead time aft. 1-pole trip**, you can determine after which dead time the automatic reclosing function will be executed. You can set different dead times for 1-pole and 3-pole reclosing cycles. Whether a trip occurs for 1-pole or 3-pole depends on the type of the protection function, and if the tripping protection function for the start of the automatic reclosing function has been configured.

NOTE

If you would like to permit the automatic reclosing function only after a 1-pole tripping of the circuit breaker, set the dead time after the 3-pole trip (parameter dead time after 3-pole OFF) to ∞. If the automatic reclosing function should only occur after a 3-pole trip, set the dead time after the 1-pole trip (parameter **Dead time aft. 1-pole trip**) to ∞. Therefore, all protection functions will be tripped as 3-pole after each type of fault.

After a 3-pole trip of the circuit breaker, the system stability is priority. Since the switched off line cannot develop synchronizing forces, only a short dead time is permitted in most cases. The usual duration is 0.3 s to 0.6 s. A longer period can be tolerated if a synchrocheck is carried out prior to reclosing. Even in radial systems longer 3-pole dead times are possible. The dead time after a 1-pole trip of the circuit breaker must be long enough to ensure the short circuit arc has extinguished and the ambient air is deionized. It is only then that the automatic reclosing function can be successful. Due to the charge reversal of the conducted capacity, this time is longer, depending on the length of the line. Standard durations are between 0.9 s and 1.5 s.

Parameter: Dead time aft.1ph. pickup, Dead time aft.2ph. pickup, Dead time aft.3ph. pickup

This parameter is only important and can be set if you use the automatic reclosing function in an operating mode ***with pickup***.

- Default setting **(_:6571:104) Dead time aft.1ph. pickup** = ***1.2 s***
- Default setting **(_:6571:105) Dead time aft.2ph. pickup** = ***1.2 s***
- Default setting **(_:6571:106) Dead time aft.3ph. pickup** = ***0.5 s***

With the 3 dead-time parameters, you can determine after which dead time the automatic reclosing function will be executed. Please set the times as desired for the respective type of short circuit.

- The parameter **Dead time aft.1ph. pickup** applies to dead times after 1-phase short circuits and the following protection tripping: A, B, C, or A-Gnd, B-Gnd, C-Gnd
- The parameter **Dead time aft.2ph. pickup** applies to dead times after 2-phase short circuits and the following protection tripping: A-B, B-C, C-A, or A-B-gnd, B-C-gnd, C-A-gnd
- The parameter **Dead time aft.3ph. pickup** applies to dead times after 3-phase short circuits and the following protection tripping: A-B-C or A-B-C-Gnd

NOTE

If you would like to avoid automatic reclosing during individual short-circuit types, please set the respective dead times to ***oo (invalid)***.

Example:

After 1-phase short-circuits, the automatic reclosing function should occur after 1.2 sec. The automatic reclosing function should not occur for 2-phase and 3-phase short circuits.
For this application, the parameters should be set as follows:

- **Dead time aft.1ph. pickup** = ***1.2 s***
- **Dead time aft.2ph. pickup** = ***oo (invalid)***
- **Dead time aft.3ph. pickup** = ***oo (invalid)***

Parameter: Dead time aft. evolv. fault

These parameters are only significant if the parameter **(_:6601:109) Response to evolv. faults** is set to ***strt. evol.flt.dead time***.

- Default setting **(_:6571:109) Dead time aft. evolv. fault** = ***1.2 s***

With the parameter **Dead time aft. evolv. fault**, you can determine after which dead time the automatic reclosing function should be executed, if based on an evolving fault during the current dead time, a 3-pole trip has occurred. For this 3-pole dead time, stability concerns for the system are also important. Often, this dead time as well as the parameter **(_:6571:108) Dead time aft. 3-pole trip** can be set.

Detailed information about the function during evolving faults during dead time are described in Chapter *6.22.4.13 Evolving-Fault Detection During the Dead Time*.

Parameter: CB ready check bef.close

- Default setting **(_:6571:111) CB ready check bef.close** = ***no***

With the parameter **CB ready check bef.close** you can determine if after the expiration of the dead time (meaning, directly prior to assigning the close command) readiness of the circuit breaker should be queried.

Parameter Value	Description
no	With the setting ***no***, the automatic reclosing function does not check again the readiness of the circuit breaker prior to assigning the close demand. Siemens recommends this setting, if it is sufficient to check the readiness of the circuit breaker for the entire switching cycle once before the start of a reclosing function, consisting of tripping-reclosing-tripping. The setting for checking the readiness of the circuit breaker prior to the start of the automatic reclosing function is done using the parameter **(_:6601:102) CB ready check bef. start**.
yes	With the setting ***yes***, the dead time can be extended if after the expiration of the dead time the circuit breaker is not ready for the next ON-OFF cycle. The maximum delay of the dead time can be set with the parameter **(_:6601:111) Max. dead-time extension**. Siemens recommends this setting, if it can be assumed that the circuit breaker becomes available to switch on the reclosing function only after an additional waiting period.

Detailed information about the function can be found in Chapters *6.22.4.16 Circuit-Breaker Readiness and Circuit-Breaker Condition* and *6.22.4.14 Closing Indication and Close Command* .

Parameter: Synchroch. aft. 3-pole d.t.

- Default setting **(_:6571:110) Synchroch. aft. 3-pole d.t.** = ***none***

With the parameter **Synchroch. aft. 3-pole d.t.** you can determine if a synchrocheck must be carried out for the configured automatic reclosing cycle.

If during a 3-pole interruption in the system stability problems may be a concern, the synchrocheck should be carried out. If only 1-pole reclosure cycles are possible or stability problems are not to be expected during the 3-pole dead time, for example, due to a highly intermeshed system or radial system, please select the parameter ***none***.

Parameter Value	Description
none	During the automatic reclosing cycle a synchrocheck is not executed.
internal	In the configured automatic reclosing cycle, a synchrocheck is executed after a 3-pole dead time prior to the close command of the circuit breaker. For the synchrocheck a synchrocheck stage of the internal synchronization function is used, which is contained in the same function group as the circuit breaker and the automatic reclosing function. The selection of the synchrocheck stage that is used in the automatic reclosing cycle occurs through the following described parameter **Internal synchrocheck**.
external	In the configured automatic reclosing cycle, a synchrocheck is executed after a 3-pole dead time prior to the close command of the circuit breaker. An external synchrocheck device initiates the synchrocheck. The external synchrocheck device is connected with the binary signals *Synchrocheck request* and *>Release by ext.sync.*. Detailed information about the function can be found in Chapter *6.22.4.14 Closing Indication and Close Command* under the section **Synchrocheck**.

Parameter: Internal synchrocheck

These parameters are only significant if the previously described parameter **(_:6571:110) Synchroch. aft. 3-pole d.t.** is set to ***internal***.

With the parameter **Internal Synchrocheck**, you can determine which function block of the synchronization function for the automatic reclosing function is used after a 3-pole dead time. This selection is only possible for function blocks of the synchronization function, and which are included in the same circuit-breaker function group as the automatic reclosing function. The setting options of the parameter will be generated dynamically, according to the actual parameterization.

6.23 Overcurrent Protection, Phases

6.23.1 Overview of Functions

The **Overcurrent protection, phases** function (ANSI 50/51):

- Detects short circuits in electrical equipment
- Can be used as backup overcurrent protection in addition to the main protection

6.23.2 Structure of the Function

The **Overcurrent protection, phases** function is used in protection function groups. 2 kinds of functions are available for the 3-phase overcurrent protection:

- **Overcurrent protection, phases – advanced** (50/51 OC-3ph-A)
- **Overcurrent protection, phases – basic** (50/51 OC-3ph-B)

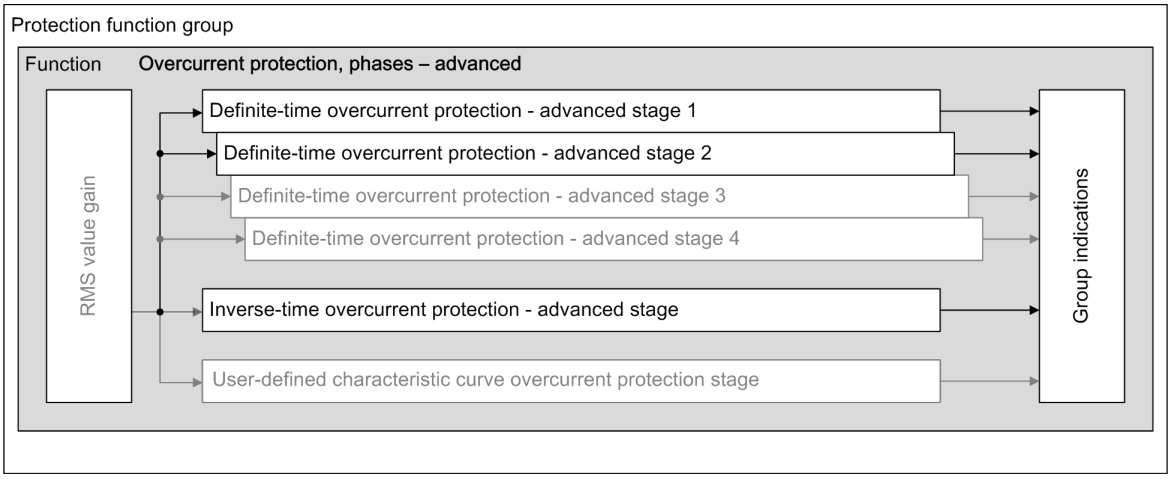
The Basic function type is provided for standard applications. The Advanced function type offers more functionality and is provided for more complex applications.

Both function types are preconfigured by the manufacturer with 2 **Definite-time overcurrent protection** stages and with 1 **Inverse-time overcurrent protection** stage.

In the **Overcurrent protection, phase – advanced** function type, the following stages can be operated simultaneously:

- Maximum of 4 stages **Definite-time overcurrent protection – advanced**
- 1 stage **Inverse-time overcurrent protection – advanced**
- 1 stage **User-defined overcurrent protection characteristic curve**

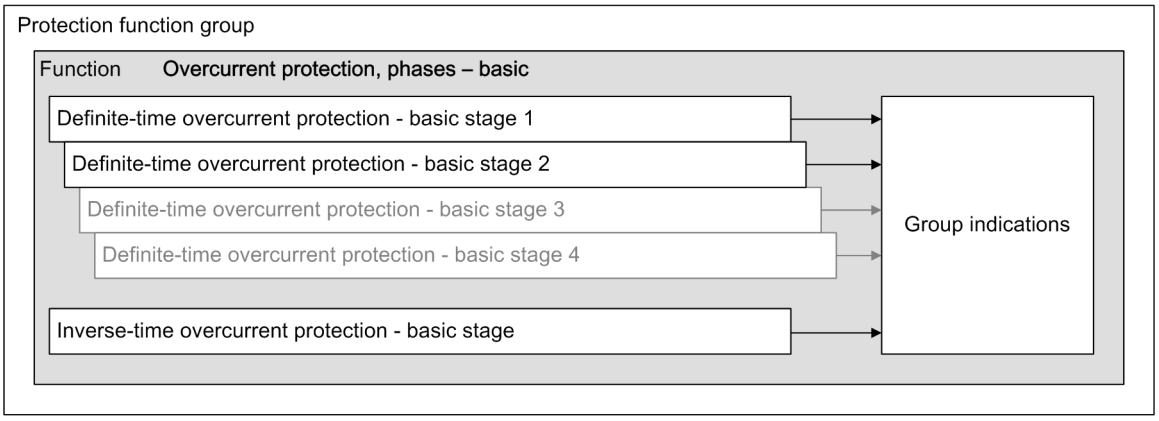
In the **Overcurrent protection, phases – basic** function type, the following stages can be operated simultaneously:



- Maximum of 4 stages **Definite-time overcurrent protection – basic**
- 1 stage **Inverse-time overcurrent protection – basic**

Stages that are not preconfigured are shown in gray in the following figures. Apart from the tripping delay characteristic, the stages are identical in structure.

The optional function block **Filter** offered in the advanced function allows to gain harmonics or to compensate the amplitude attenuation for the RMS value.



The group-indication output logic generates the following group indications of the protection function by the logical OR of the stage-selective indications:

- **`Pickup`**
- **`Operate`**

[dw_ocp_ad with filter2, 1, en_US]

Figure 6-418 Structure/Embedding of the Function Overcurrent Protection, Phases – Advanced

[dw_ocp_bp_1, 3, en_US]

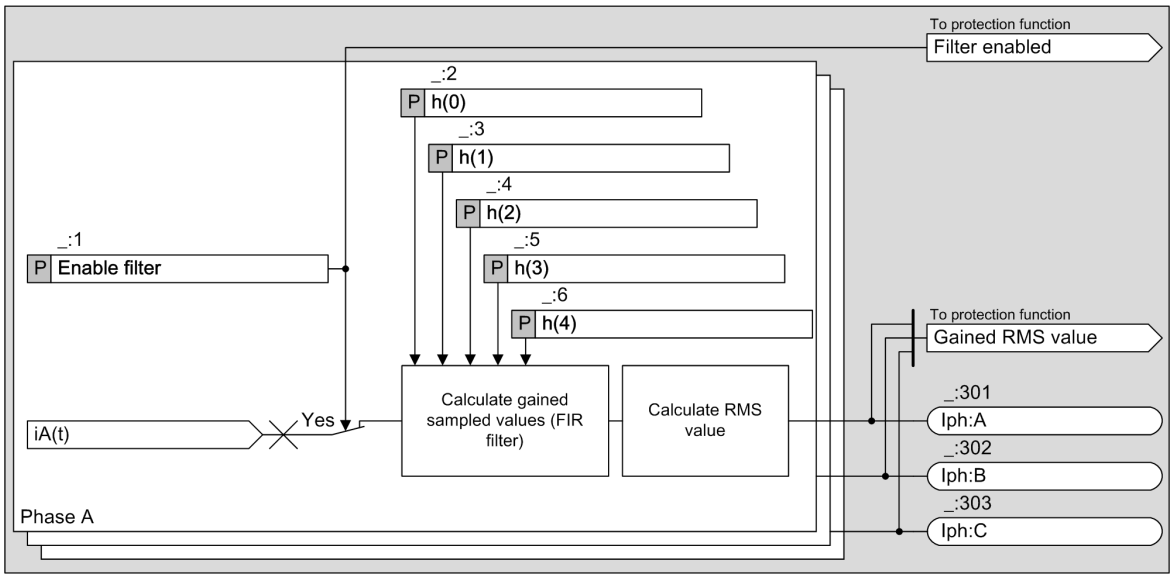
Figure 6-419 Structure/Embedding of the Function Overcurrent Protection, Phases – Basic

If the device-internal functions listed in the following are present in the device, these functions can influence the pickup values and time delays of the stages or block the stages. The stage can also be affected by an external source via a binary input signal. This functionality is only available in the Advanced function type.

- Cold-load pickup detection
- Binary input signal

If the device is equipped with the **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer-inrush currents.

6.23.3 Filter for RMS Value Gain



6.23.3.1 Description

The function block **Filter** can be used to adapt the RMS value for 2 means:

- To gain harmonics in a defined way. Higher harmonics can stress the protected object thermally more than lower harmonics. This is the case for reactors applied in AC filters. In addition, the amplitude attenuation of higher frequencies due to the anti-aliasing filter of the device is automatically compensated by the filter
- To only compensate the amplitude attenuation of higher frequencies due to the anti-aliasing filter

The filter gain (amplitude response) is realized by a 9-order FIR filter.

Logic

[lo_tolp_filter_stage, 1, en_US]

Figure 6-420 Logic Diagram of the Function Block Filter

The FIR filter gains the 8-kHz sampled values according to the set filter coefficients. Afterwards, the RMS value is calculated. The symmetrical 9-order filter coefficients are set via the values of the respective parameters **h(0)**, **h(1)**, **h(2)**, **h(3)**, and **h(4)**.

NOTE

A FIR-filter configuration tool is provided as an auxiliary PC tool. With this PC tool, the coefficients h(0), h(1), h(2), h(3), h(4) of the FIR filter are generated according to the required gain factors (amplitude response).

If you require the tool, contact the local Siemens representative to download it via the Intranet of Siemens Industry Online Support (SIOS). The tool is available on SIOS under **Protection** > **Engineering tools for protection** > **Further Tools**.

The gained RMS value is delivered to the protection stages only when the function block **Filter** is instantiated and the parameter **Enable filter** is set as ***yes***. Otherwise, the normal RMS value is used.

Functional Measured Values

Values	Description	Primary	Secondary	% Referenced to
Iph:A	Gained RMS measured value of current A	kA	A	Parameter **Rated current**
Iph:B	Gained RMS measured value of current B	kA	A	Parameter **Rated current**
Iph:C	Gained RMS measured value of current C	kA	A	Parameter **Rated current**

You can find the parameter **Rated current** in the **FB General** of function groups where the **Overcurrent protection, phases – advanced** function is used.

If the parameter **Enable filter** is set to ***no***, the functional measured values are shown as ---.

6.23.3.2 Application and Setting Notes

Parameter: `Enable filter`

- Default setting **`(_:1) Enable filter`** = ***`no`***.

With the parameter **`Enable filter`**, you set whether the **Filter** is enabled.

Parameter Value	Description
`yes`	If gained RMS values should be used in one of the protection stages, set parameter **`Enable filter`** = ***`yes`***.
`no`	If no gained RMS values are needed, set the parameter **`Enable filter`** = ***`no`***.

Parameter: `h(0),h(1),h(2),h(3),h(4)`

- Default setting **`(_:2) h(0)`** = ***`0.000`***
- Default setting **`(_:3) h(1)`** = ***`0.000`***
- Default setting **`(_:4) h(2)`** = ***`0.000`***
- Default setting **`(_:5) h(3)`** = ***`0.000`***
- Default setting **`(_:6) h(4)`** = ***`1.000`***

With the default value of the coefficients, the filter has no effect and no gain is applied.

If the filter shall be applied to adapt the RMS value calculation to a specific protection object such as a reactor, the reactor manufacturer has to provide the required amplitude response (gain factors) for the reactor. To determine the coefficients h(0) to h(4) for the FIR filter, you must enter the gain factors into the auxiliary PC tool which is available in the SIPROTEC download area. The 5 required coefficients are generated by the tool. They have to be entered manually as settings to configure the filter. The amplitude attenuation of higher frequencies due to the anti aliasing filter of the device is automatically taken into account and compensated by the filter.

To only compensate the attenuation of higher frequencies by the device, set the following coefficients in the filter.

Rated Frequency	Filter Coefficients for Only Compensating the Device Amplitude Attenuation
50 Hz	h(0) = -0.002 h(1) = -0.012 h(2) = 0.045 h(3) = -0.110 h(4) = 1.151
60 Hz	h(0) = -0.005 h(1) = -0.020 h(2) = 0.058 h(3) = -0.128 h(4) = 1.170

6.23.3.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
`Filter`				
_:1	Filter:Enable filter		• no • yes	no
_:2	Filter:h(0)		-100.000 to 100.000	0.000

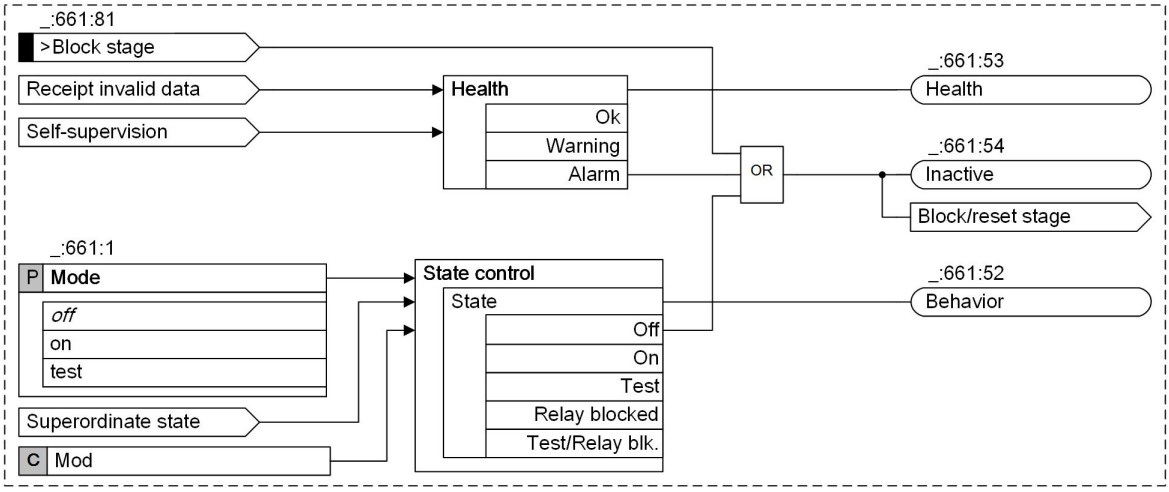
6.23.4 Stage with Definite-Time Characteristic Curve

6.23.4.1 Description



Logic of the Basic Stage

[lo_ocp_3b1, 4, en_US]

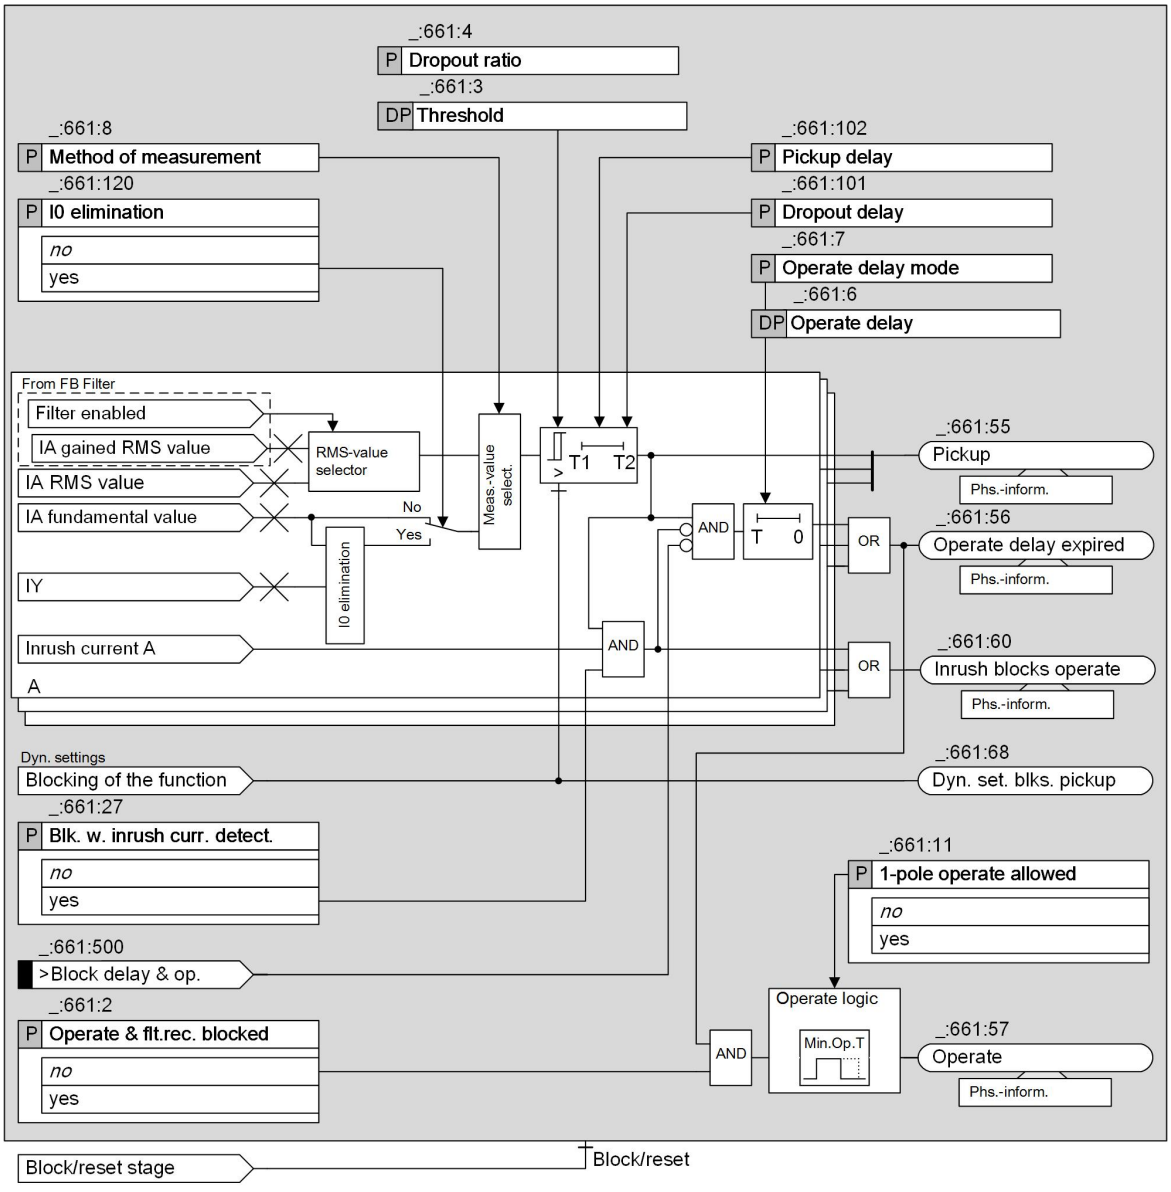


Figure 6-421 Logic Diagram of the Definite-Time Overcurrent Protection (Phases) – Basic

Logic of the Advanced Stage

[lo_ocp_advanced_umz_stage_control, 2, en_US]

Figure 6-422 Logic Diagram of the Stage Control

[lo_ocp_3p1, 5, en_US]

Figure 6-423 Logic Diagram of the Definite-Time Overcurrent Protection (Phases) – Advanced

Method of measurement (Basic and Advanced Stage)

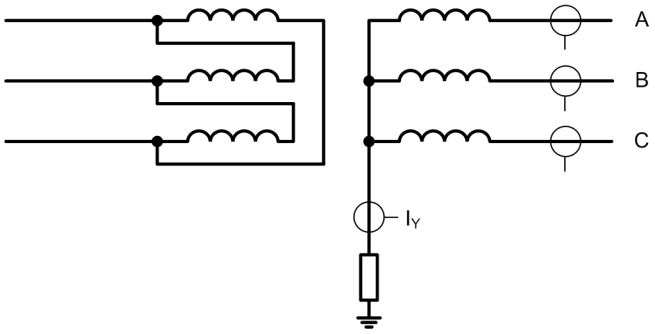
You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

RMS-Value Selection (Advanced Stage)

If ***RMS value*** is selected as the method of measurement, the protection function supports 2 kinds of RMS measurement.

- Normal RMS value
- Gained RMS value from the function block **Filter**



If the function block **Filter** is configured and if you have enabled the filter, the gained RMS value is automatically used.

NOTE

When the function block **Filter** is applied, only one 3-phase current measuring point is allowed to be connected to the 3-phase current interface of the function group.

I0 Elimination (Advanced Stage)

In order to increase the sensitivity for the 2-phase short circuit on the transformer low-voltage side, use the I0 elimination of the phase currents for the overcurrent-protection application on one transformer.
In order to determine the I0 elimination of the phase currents, the transformer neutral point current I_Y must be measured.

[dw_sgaocp, 1, en_US]

Figure 6-424 I0 Elimination Principle

The transformer neutral point current I_Y is measured via a 1-phase current measuring point that is connected to the **Transformer neutral point** function group. Connect the function group **Transformer neutral point** to the function group **Transformer side**. In the function **Overcurrent protection, phases** operates with in the **Transformer side** function group.

Connect protection-function group to protection-function group

	Transformer side 1	Transformer side 2	Transformer diff. 1
Protection group	neutral point	neutral point	side
(All)	(All)	(All)	(All)
Transformer side 1			X
Transformer side 2			X
Transform. neut.p 1		X	

[sc_cpfoiut, 1, en_US]

Figure 6-425 Connection of the Transformer Neutral Point Function Group with the Neutral Point Input of the Transformer Side Function Group.

In case of an I0 elimination, the following calculations result:

$\underline{I}_{A\text{-elim.}} = \underline{I}_A - 1/3\ \underline{I}_Y$

$\underline{I}_{B\text{-elim.}} = \underline{I}_B - 1/3\ \underline{I}_Y$

$\underline{I}_{C\text{-elim.}} = \underline{I}_C - 1/3\ \underline{I}_Y$

The phase current $\underline{I}_{phx\text{-elim.}}$ is necessary for the following protection process.

If the **Method of measurement** parameter is set to ***fundamental comp.***, the I0 elimination is applied.

The currents $\underline{I}_{phx\text{-elim.}}$ are available as functional values.

Pickup Delay (Advanced Stage)

If the current exceeds the threshold value, the pickup delay is generated. If the threshold remains exceeded during the pickup delay time, the pickup signal is generated.

Dropout Delay (Advanced Stage)

If the current falls below the dropout threshold, the dropout can be delayed for the time specified by the parameter **Dropout delay**. During the dropout delay, the pickup is maintained. Meanwhile, the operate delay continues to run (parameter **Operate delay mode** = ***Running dur. DO-delay***) or is frozen (parameter **Operate delay mode** = ***Frozen dur. DO-delay***). If the operate delay expires while the pickup is still maintained, the stage operates.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Via the binary input signal **>Block stage** from an external or internal source
- Via the functionality of the **dynamic settings** (only available in the Advanced function type, see **Influence of other functions via dynamic settings** and *6.23.8.1 Description*).

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in *6.23.7.1 Description* .

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in *6.23.8.1 Description* .

6.23.4.2 Application and Setting Notes

Parameter: Method of measurement

- Default setting **(_:661:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Operate delay mode

- Default setting **(_:661:7) Operate delay mode** = ***Running dur. DO-delay***

This parameter is not visible in the basic stage.

With the parameter **Operate delay mode**, you specify whether the operate delay continues to run or is frozen during the dropout delay.

This setting is only valid if the parameter **Dropout delay** is not ***0***.

Parameter Value	Description
Running dur. DO-delay	During the dropout delay, the operate delay continues to run.
Frozen dur. DO-delay	During the dropout delay, the operate delay is frozen. If the current exceeds the threshold value again, the operate delay continues to run.

Parameter: Threshold, Operate delay

- Default setting **(_:661:3) Threshold** = ***1.500 A*** (for the 1st stage)
- Default setting **(_:661:6) Operate delay** = ***0.30 s*** (for the 1st stage)

Set the **Threshold** and **Operate delay** parameters for the specific application.

The following details apply to a 2-stage characteristic curve (1st stage = definite-time overcurrent protection stage and 2nd stage = high-current stage).

1st stage (overcurrent stage):

The setting depends on the maximum occurring operating current. Pickup by overload must be excluded since overcurrent protection operates with short tripping times as short-circuit protection and not as overload protection. Therefore, set the **Threshold** parameter for lines to approx. 10 %, for transformers and motors to approx. 20 % above the maximum load that is expected.

EXAMPLE

Overcurrent-protection stage: 110-kV overhead line, 150 mm² cross-section

Maximum transmittable power	
P_{max}	= 120 MVA
Correspondingly	
I_{max}	= 630 A
Current transformer	= 600 A/5 A
Safety factor	= 1.1

Settings in primary and secondary measurands result in the setting values:

Threshold value 1st stage (primary) = $1.1 \cdot 630\ \text{A} = 693\ \text{A}$

Threshold value 1st stage (secondary) = $1.1 \cdot \frac{630\ \text{A}}{600\ \text{A}} \cdot 5\ \text{A} = 5.8\ \text{A}$

[fo_ocp_ph1, 2, en_US]

The **Operate delay** to be set is derived from the time-grading schedule that has been prepared for the system.

2nd Stage (High-Current Stage):

This tripping stage can also be used for current grading. This applies in the case of very long lines with low source impedance or ahead of high reactances (for example, transformers, shunt reactors). Set the **Threshold** parameter to ensure that the stage does not pick up in case of a short circuit at the end of the line.

Set the **Operate delay** parameter to ***0*** or to a low value.

Siemens recommends that the threshold values be determined with a system analysis. The following example illustrates the principle of grading with a current threshold on a long line.

EXAMPLE

High-current stage: 110-kV overhead line, 150 mm² cross-section

s (length) = 60 km

Z_L/s = 0.46 Ω/km

Ratio of zero-sequence impedance and positive-sequence impedance of the line: $Z_{L0}/Z_{L1} = 4$

Short-circuit power at the beginning of the line:

S_{sc}' = 2.5 GVA

Ratio of zero-sequence impedance and positive-sequence impedance of the source impedance at the beginning of the line: $Z_{P0}/Z_{P1} = 2$

Current transformer = 600 A/5 A

Resulting in the following values for the line impedance Z_L and the source impedance Z_P:

$$Z_L = 0.46\ \Omega/\text{km} \cdot 60\text{km} = 27.6\ \Omega$$

[fo_ocp_002, 1, en_US]

$$Z_P = \frac{110\ \text{kV}^2}{2500\ \text{MVA}} = 4.84\ \Omega$$

[fo_ocp_003, 1, en_US]

The 3-phase short-circuit current at the end of the line is $I_{sc\ end}$:

$$I_{sc\ end} = \frac{1.1 \cdot V_{rated}}{\sqrt{3} \cdot (Z_P + Z_L)} = \frac{1.1 \cdot 110\ \text{kV}}{\sqrt{3} \cdot (4.84\ \Omega + 27.6\ \Omega)} = 2150\ \text{A}$$

[fo_ocp_ph4, 1, en_US]

The settings in primary and secondary values result in the following setting values which include a safety margin of 10 %:

Threshold value 2nd stage (primary) = $1.1 \cdot 2150\ \text{A} = 2365\ \text{A}$

Threshold value 2nd stage (secondary) = $1.1 \cdot \frac{2150\ \text{A}}{600\ \text{A}} \cdot 5\ \text{A} = 19.7\ \text{A}$

[fo_ocp_004, 2, en_US]

If short-circuit currents exceed 2365 A (primary) or 19.7 A (secondary), there is a short circuit on the line to be protected. The overcurrent protection can cut off this short circuit immediately.

Note: The amounts in the calculation example are accurate enough for overhead lines. If the source impedance and line impedance have different angles, you have to use complex numbers to calculate the **Threshold** .

Parameter: I0 elimination

- Default setting **(_:661:120) I0 elimination** = ***no***

This parameter is not visible in the basic stage.

The I0 elimination in phase currents for overcurrent-protection applications can be used in a transformer. This increases the sensitivity for the 2-phase short circuit on the transformer low-voltage side. The following conditions must be fulfilled:

- The transformer neutral point current I_Y is measured and is available for the protection function group.
- The parameter **Method of measurement** is set to ***fundamental comp.***.

With the **I0 elimination** parameter, you can switch the I0 elimination function on or off.

Parameter: Pickup delay

- Default setting **(_:661:102) Pickup delay** = ***0.00 s***

This parameter is not visible in the basic stage.

For special applications, it is desirable that a short exceeding of the current threshold does not lead to the pickup of the stage and start fault logging and recording. If this stage is used as a thermal overload function, that is considered a special application.

When using the **Pickup delay** parameter, a time interval is defined during which a pickup is not triggered if the current threshold is exceeded.

For all short-circuit protection applications, this value is 0.00 s as a default.

Parameter: Dropout delay

- Default setting **(_:661:101) Dropout delay** = ***0.00 s***

This parameter is not visible in the basic stage.

Siemens recommends using the default setting ***0*** since the dropout of a protection stage must be done as fast as possible.

You can use the **Dropout delay** parameter ≠ ***0*** to obtain a uniform dropout behavior if you use it together with an electromechanical relay. This is required for time grading. The dropout time of the electromechanical relay must be known for this purpose. Subtract the dropout time of your own device (see Technical Data) and set the result.

Parameter: Dropout ratio

- Default setting **(_:661:4) Dropout ratio** = ***0.95***

This parameter is not visible in the basic stage.

The recommended set value of ***0.95*** is appropriate for most applications.

To achieve high-precision measurements, the setting value of the parameter **Dropout ratio** can be reduced, for example, to ***0.98***. If you expect highly fluctuating measurands at the response threshold, you can increase the setting value of the parameter **Dropout ratio**. This avoids chattering of the tripping stage.

Parameter: 1-pole operate allowed

- Default setting **(_:661:11) 1-pole operate allowed** = ***no***

The parameter must be set for the specific application.

Parameter Value	Description
no	The stage always operates 3-pole.
yes	The stage operates phase-selectively. However, tripping by the device (generated in the trip logic of the **Circuit-breaker** function group) is always 3-pole because the device does not support phase-selective tripping.

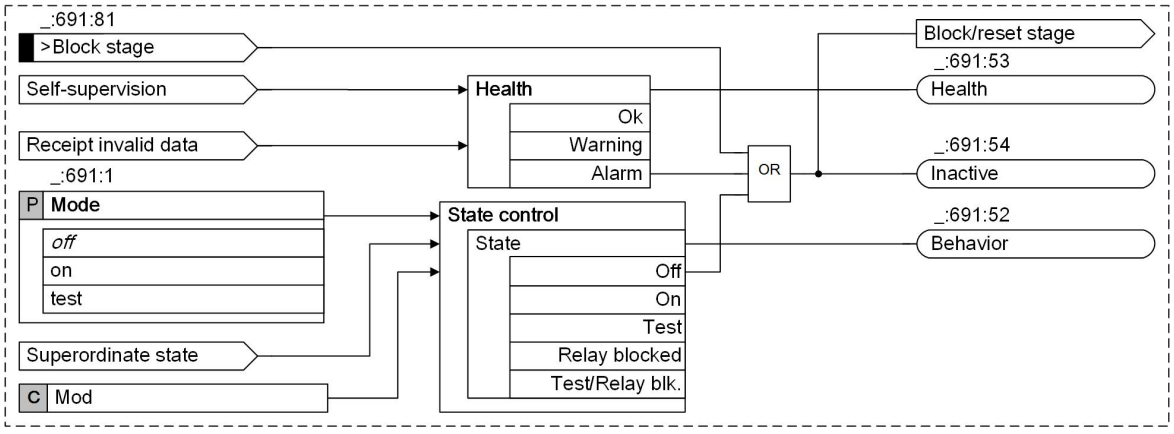
6.23.5 Stage with Inverse-Time Characteristic Curve

6.23.5.1 Description



Logic of the Basic Stage

[lo_ocp3b2_3_en_US]

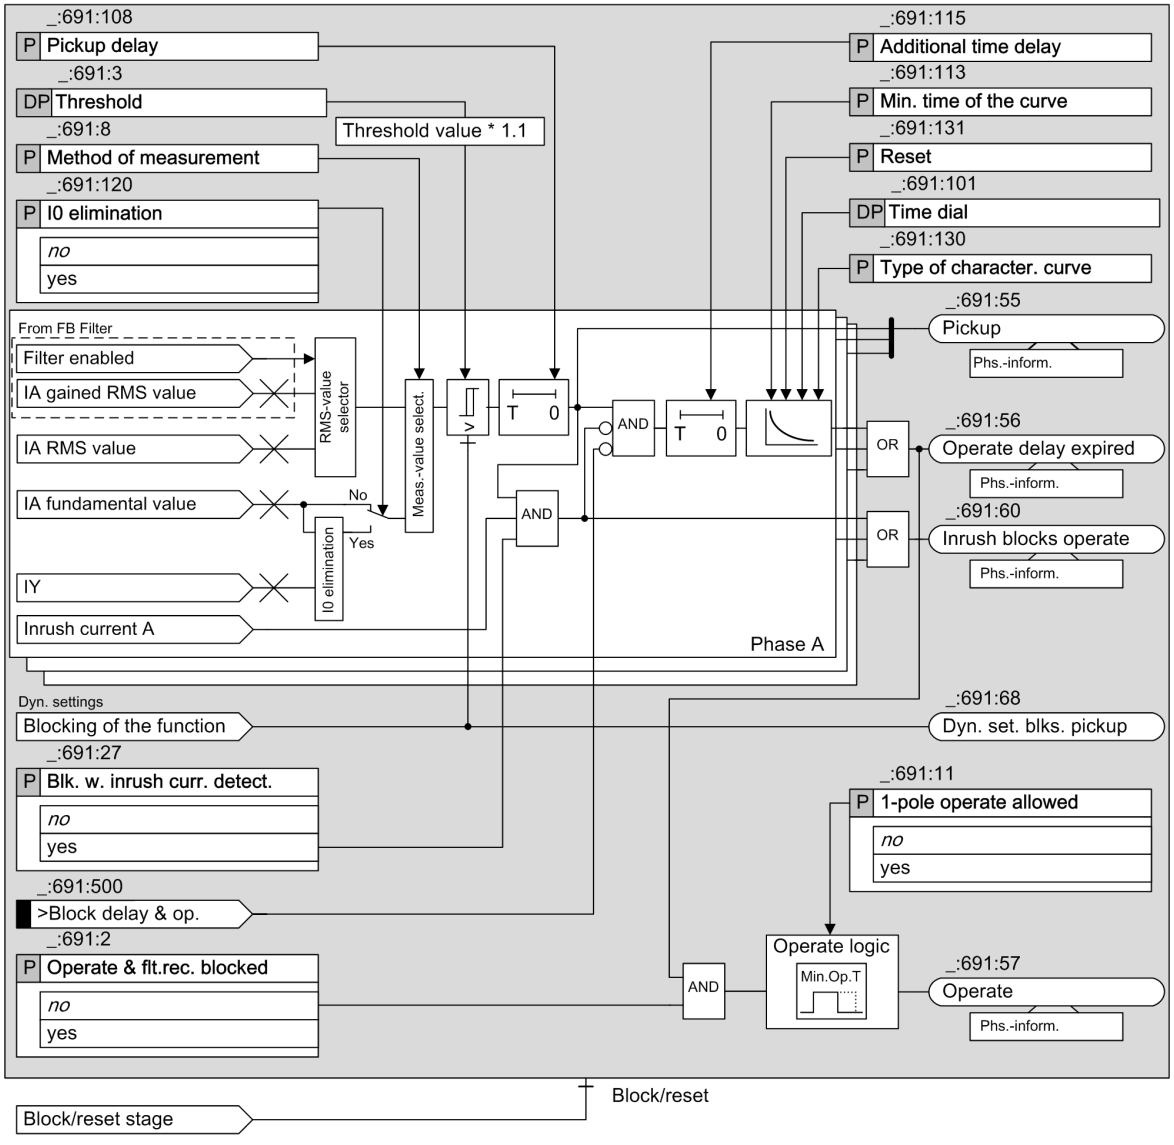


Figure 6-426 Logic Diagram Inverse-Time Overcurrent Protection (Phases) – Basic

Logic of the Advanced Stage

[lo_stage_control_OCP, 2, en_US]

Figure 6-427 Logic Diagram Stage Control

[lo_ocp_3p2, 4, en_US]

Figure 6-428 Logic Diagram Inverse-Time Overcurrent Protection (Phases) – Advanced

RMS-Value Selection (Advanced Stage)

If ***RMS value*** is selected as the method of measurement, the protection function supports 2 kinds of RMS measurement.

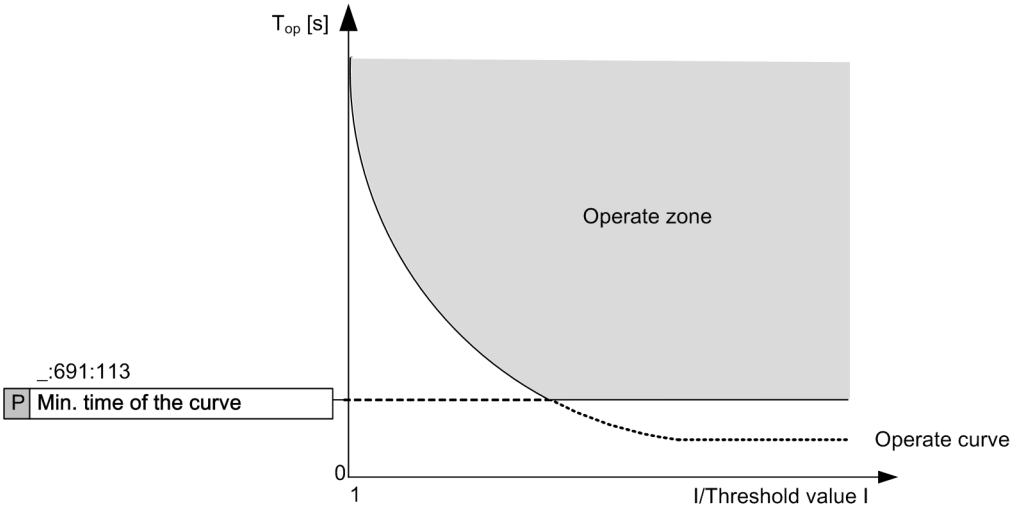
- Normal RMS value
- Gained RMS value from the function block **Filter**

If the function block **Filter** is configured and if you have enabled the filter, the gained RMS value is automatically used.

NOTE

When the function block **Filter** is applied, only one 3-phase current measuring point is allowed to be connected to the 3-phase current interface of the function group.

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve according to IEC and ANSI (Basic and Advanced Stage)



When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Minimum Time of the Curve (Advanced Stage)

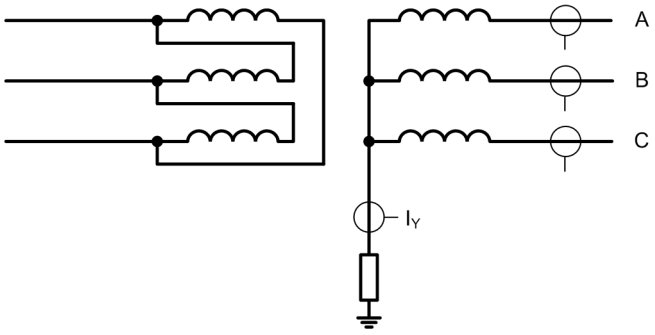
With the parameter **`Min. time of the curve`**, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time.

[dw_ocp_3_mi, 1, en_US]

Figure 6-429 Minimum Operating Time of the Curve

Additional Time Delay (Advanced Stage)

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay. With this setting, the whole curve is shifted on the time axis by this additional definite time.



Method of Measurement (Basic and Advanced Stage)

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

I0 Elimination (Advanced Stage)

In order to increase the sensitivity for the 2-phase short circuit on the transformer low-voltage side, use the I0 elimination of the phase currents for the overcurrent-protection applications on one transformer.
In order to determine the I0 elimination of the phase currents, the transformer neutral point current I_Y must be measured.

[dw_sgaocp, 1, en_US]

Figure 6-430 I0 Elimination Principle

The transformer neutral point current I_Y is measured via a 1-phase current measuring point that is connected to the **Transformer neutral point** function group. Connect the function group **Transformer neutral point** to the function group **Transformer side**. In the function **Overcurrent protection, phases** operates with in the **Transformer side** function group.

Connect protection-function group to protection-function group

	Transformer side 1	Transformer side 2	Transformer diff. 1
Protection group	neutral point	neutral point	side
(All)	(All)	(All)	(All)
Transformer side 1			X
Transformer side 2			X
Transform. neut.p 1		X	

[sc_cpfoiut, 1, en_US]

Figure 6-431 Connection of the Transformer Neutral Point Function Group with the Neutral Point Input of the Transformer Side Function Group.

In case of an I0 elimination, the following calculations must be considered:

$\underline{I}_{A\text{-elim.}} = \underline{I}_A - 1/3\ \underline{I}_Y$

$\underline{I}_{B\text{-elim.}} = \underline{I}_B - 1/3\ \underline{I}_Y$

$\underline{I}_{C\text{-elim.}} = \underline{I}_C - 1/3\ \underline{I}_Y$

The phase current $\underline{I}_{phx\text{-elim.}}$ is necessary for the following protection process.

If the **Method of measurement** parameter is set to ***fundamental comp.***, the I0 elimination is operating.

The currents $\underline{I}_{phx\text{-elim.}}$ are available as functional values.

Pickup Delay (Advanced Stage)

If the current exceeds the threshold value, the pickup delay starts. If the threshold is exceeded during the pickup delay time, the pickup signal is generated.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Via the binary input signal **>Block stage** from an external or internal source
- Via the functionality of the **dynamic settings** (only available in the Advanced function type, see **Influence of other functions via dynamic settings** and *6.23.8.1 Description*).

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in *6.23.7.1 Description* .

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in *6.23.8.1 Description* .

6.23.5.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:691:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Type of character. curve

- Default setting **(_:691:130) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application. For more information about the parameter **Type of character. curve**, refer to chapter *12.18.2 Stage with Inverse-Time Characteristic Curve*.

Parameter: Min. time of the curve

- Default setting **(_:691:113) Min. time of the curve** = ***0.00 s***

This parameter is only available in the advanced stage.

With the **Min. time of the curve** parameter, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time. If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

NOTE

If the set value is smaller than the smallest possible time delay of the inverse-time characteristic curve, the parameter has no influence on the delay time.

Parameter: Additional time delay

- Default setting **(_:691:115) Additional time delay** = ***0.00 s***

With the **Additional time delay** parameter, you define a definite-time delay in addition to the inverse-time delay.

If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic time.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

Parameter: Threshold

- Default setting **(_:691:3) Threshold** = ***1.500 A***

Set the **Threshold** and **Type of character. curve** parameters for the specific application.

The setting depends on the maximum occurring operating current. Pickup by overload must be excluded since overcurrent protection operates with short tripping times as short-circuit protection and not as overload protection. Set the **Threshold** parameter for lines to approx. 10 %, for transformers and motors to approx. 20 % above the maximum expected load.

Note that a safety margin is set between pickup value and threshold value. The stage only picks up at approx. 10 % above the **Threshold**.

EXAMPLE

Overcurrent-protection stage: 110-kV overhead line, 150 mm² cross-section

Maximum transmittable power
P_{max} = 120 MVA
Correspondingly
I_{max} = 630 A
Current transformer = 600 A/5 A

Settings in primary and secondary measurands result in the setting values:

Threshold value I> (primary) = 630 A

$$\text{Threshold value I> (secondary)} = \frac{630\ \text{A}}{600\ \text{A}} \cdot 5\ \text{A} = 5.25\ \text{A}$$

[fo_ocp_005, 2, en_US]

Parameter: I0 elimination

- Default setting **(_:661:120) I0 elimination** = ***no***

This parameter is not visible in the basic stage.

The I0 elimination in phase currents for overcurrent-protection applications can be used in a transformer. This increases the sensitivity for the 2-phase short circuit on the low-voltage side of the transformer. The following conditions must be fulfilled:

- The transformer neutral point current I_Y is measured and is available for the protection function group.
- The parameter **Method of measurement** is set to ***fundamental comp.***.

With the **I0 elimination** setting, you can switch the I0 elimination function on or off.

Parameter: Pickup delay

- Default setting **(_:661:102) Pickup delay** = ***0.00 s***

This parameter is not visible in the basic stage.

For special applications it is desirable if the current threshold is briefly exceeded, that this will not lead to the pickup of the stage and starts fault logging or recording. If this stage is used as a thermal overload function, that is considered a special application.

When using the **Pickup delay** parameter, a time interval is defined during which a pickup is not trigger if the current threshold is exceeded.

For all short-circuit protection applications, this value is 0.00 s and is considered as a default.

Parameter: Time dial

- Default setting **(_:691:101) Time dial** = ***1.00***

With the **Time dial** parameter, you displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading schedule that has been prepared for the electrical power system.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the parameter **Time dial** at ***1*** (default setting).

Parameter: `Reset`

- Default setting **`(_:691:131) Reset`** = ***`disk emulation`***

With the **`Reset`** parameter, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Select this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

Parameter: `1-pole operate allowed`

- Default setting **`(_:691:11) 1-pole operate allowed`** = ***`no`***

The parameter must be set for the specific application.

Parameter Value	Description
`no`	The stage always operates 3-pole.
`yes`	The stage operates phase-selectively. However, tripping by the device (generated in the trip logic of the **Circuit-breaker** function group) is always 3-pole because the device does not support phase-selective tripping.

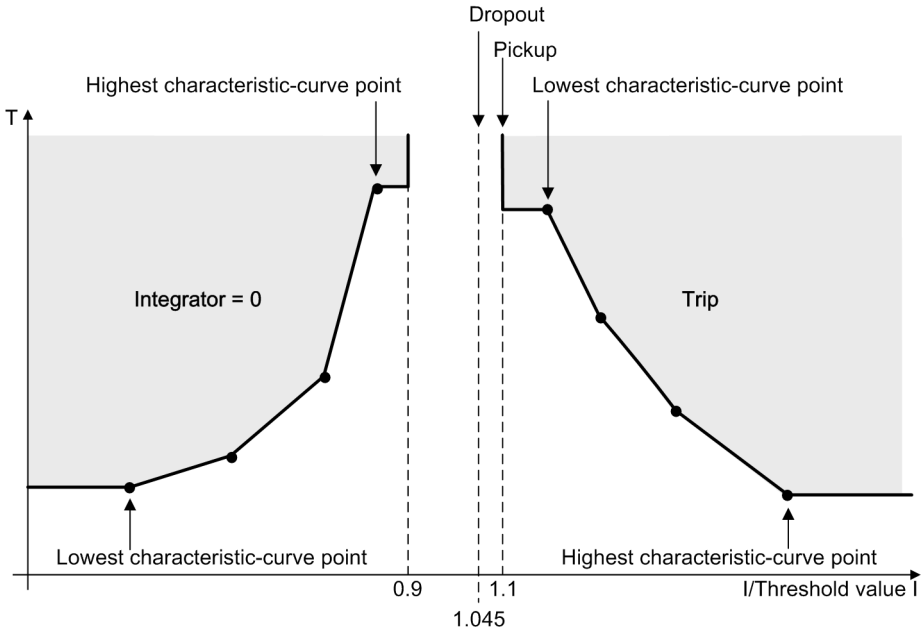
6.23.6 Stage with User-Defined Characteristic Curve

6.23.6.1 Description

This stage is only available in the advanced function type.

This stage is structured the same way as the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.23.5.1 Description*). The only differences are as follows:

- You can define the characteristic curve as desired.
- The pickup and dropout behaviors of this stage are determined by the standard parameter **Threshold** and, if necessary, by an additional parameter **Threshold (absolute)** .



User-Defined Characteristic Curve

With the user-defined characteristic curve, you can define the operate curve point by point using up to 30 value pairs of current and time. The device uses linear interpolation to calculate the characteristic curve from these values. You can also define a dropout characteristic curve if you wish.

Pickup and Dropout Behaviors with the User-Defined Characteristic Curve

When the input variable exceeds the **Threshold** value by 1.1 times, the characteristic curve is processed. An integrating method of measurement totalizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls short of the pickup value by a factor of 1.045 (0.95 x 1.1 x **Threshold** value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

[dw_ocp_ken_02, 2, en_US]

Figure 6-432 Pickup Behavior and Dropout Behavior when Using a User-Defined Characteristic Curve

NOTE

The currents that are lower than the current value of the smallest characteristic-curve point do not extend the operate time. The pickup characteristic runs in parallel to the current axis up to the smallest characteristic-curve point. Currents that are larger than the current value of the largest characteristic-curve point do not reduce the operate time. The pickup characteristic runs in parallel to the current axis from the largest characteristic-curve point.

If you want to change the pickup threshold of the stage without changing all points of the characteristic curve, you can use the additional **Threshold (absolute)** parameter.

You can set the **Threshold (absolute)** parameter to be greater than 1.1 times the **Threshold** value. Then the stage behaviors are as follows:

- The stage picks up when the measured current value exceeds the **Threshold (absolute)** value.
- The stage starts dropout when the measured current value falls short of the **Threshold (absolute)** value by 0.95 times.
- For measured current values lower than the **Threshold (absolute)** value, no pickup takes place and consequently the characteristic curve is not processed.

If you set the **Threshold (absolute)** parameter to be less than 1.1 times the **Threshold** value, the pickup and dropout behaviors are not affected by the **Threshold (absolute)** parameter.

6.23.6.2 Application and Setting Notes

This stage is structured the same way as the **Inverse-time overcurrent protection – advanced** stage. The only differences are described in chapter *6.23.6.1 Description* . This chapter provides only the application and setting notes for setting characteristic curves and for setting the **Threshold (absolute)** parameter. You can find more information on the other parameters of the stage in chapter *6.23.5.2 Application and Setting Notes* .

Parameter: Current/time value pairs (from the operate curve)

With these settings, you define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **Threshold** parameter to ***1.00*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to shift the characteristic curve.

Set the time value in seconds. The characteristic curve is shifted via the **Time dial** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: Time dial

- Default setting **(_:101) Time dial** = ***1***

With the **Time dial** parameter, you displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading schedule that has been prepared for the electrical power system. Where no time grading and therefore no displacement of the characteristic curve is required, leave the **Time dial** parameter at ***1***.

Parameter: Reset

- Default setting **(_:110) Reset** = ***disk emulation***

With the **Reset** parameter, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
disk emulation	In the case of this setting, a dropout characteristic curve has to be set in addition to the operate curve. Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Select this setting if the dropout is not to be performed after disk emulation but an instantaneous dropout is desired.

Parameter: Current/time value pairs (of the dropout characteristic curve)

With these settings, you define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **Threshold** parameter to ***1.00*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to shift the characteristic curve.

Set the time value in seconds. The characteristic curve is shifted via the **Time dial** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: `1-pole operate allowed`

- Default setting **`(_:11) 1-pole operate allowed`** = ***`no`***

The parameter must be set for the specific application.

Parameter Value	Description
`no`	The stage always operates 3-pole.
`yes`	The stage operates phase-selectively. However, tripping by the device (generated in the trip logic of the **Circuit-breaker** function group) is always 3-pole because the device does not support phase-selective tripping.

Parameter: `Threshold (absolute)`

- Default setting **`(_:113) Threshold (absolute)`** = ***`0.000 A`***

With the **`Threshold (absolute)`** parameter, you define and change the absolute pickup threshold of the stage without changing all points of the characteristic curve.

The parameter is only used for special applications. With the default setting, this functionality is disabled.

You can find more information in *Pickup and Dropout Behaviors with the User-Defined Characteristic Curve , Page 1220*.

6.23.7 Blocking of the Tripping by Device-Internal Inrush-Current Detection

6.23.7.1 Description

The **`Blk. w. inrush curr. detect.`** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

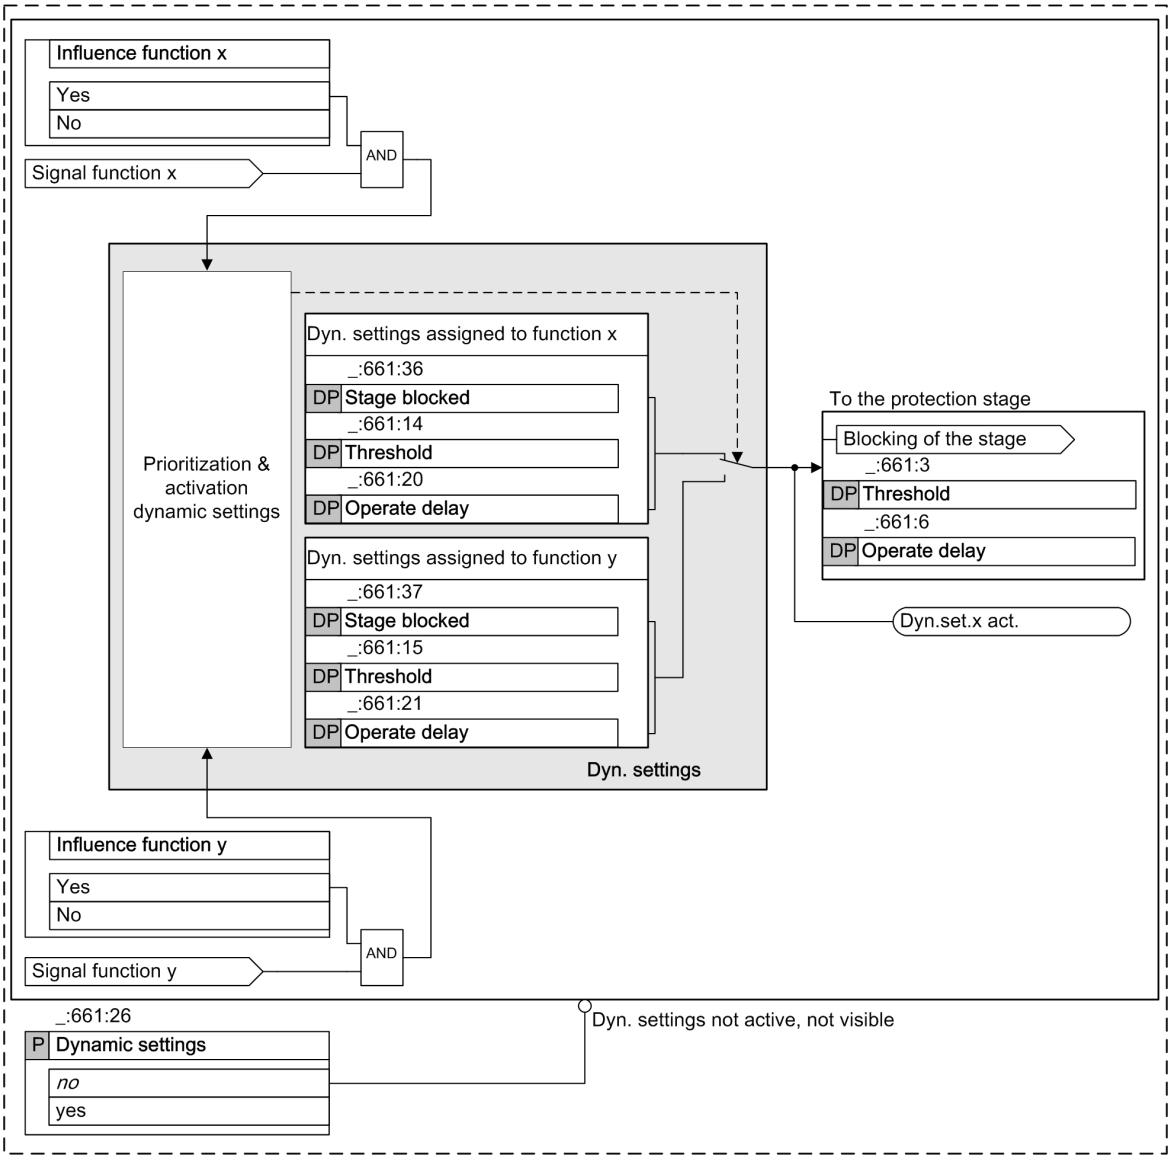
The following figure only shows the part of the stage (exemplified by definite-time overcurrent protection stage 1) that illustrates the influence of the blocking. Only if the central function **Inrush-current detection** (see chapter *12.62 Inrush-Current Detection*) is in effect can the blocking be set.

[lo_ocp3pha, 1, en_US]

Figure 6-433 Part-Logic Diagram on the Influence of Inrush-Current Detection Exemplified by the 1st Definite-Time Overcurrent Protection Stage

6.23.7.2 Application and Setting Notes

Parameter: **`Blk. w. inrush curr. detect.`**



- Default setting **`(_:661:27) Blk. w. inrush curr. detect.`** = ***`no`***

Parameter Value	Description
`no`	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This, for example, applies to the high-current stage that is set such according to the short-circuit voltage V_{sc} of the transformer that it only picks up on faults from the high-voltage side. The transformer inrush current cannot become larger than the maximum transmittable short-circuit current.
`yes`	When the transformer inrush current detection detects an inrush current that would lead to a tripping of the stage, the start of the time delay and tripping of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

6.23.8 Influence of Other Functions via Dynamic Settings

6.23.8.1 Description

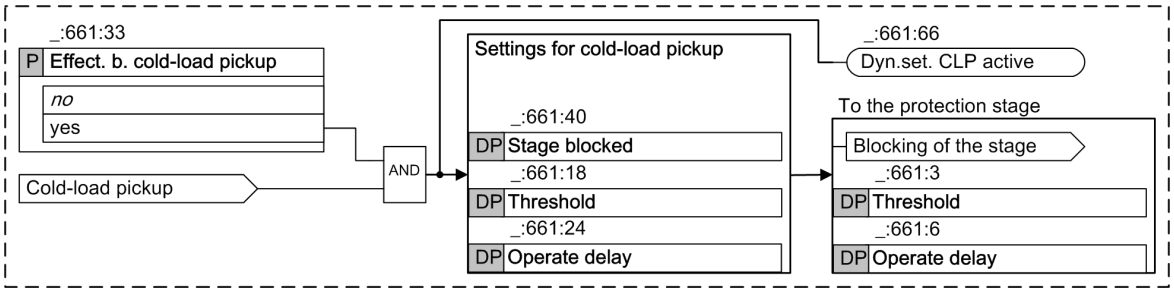
The parameters **Threshold** and **Operate delay** used for tripping are so-called **dynamic settings**. Depending on other functions, the settings of these parameters can be changed dynamically (see *Figure 6-434*). Depending on other functions, the stage can also be blocked dynamically. This functionality is only available in function type Advanced.

[lo_ocp_3dpa, 2, en_US]

Figure 6-434 Principle of the Dynamic Settings Exemplified by 1st Definite-Time Overcurrent Protection Stage

If available in the device, the following functionalities can affect the overcurrent-protection stages:

Functionalities	Priority
Cold-load pickup detection	Priority 1
Binary input signal	Priority 2



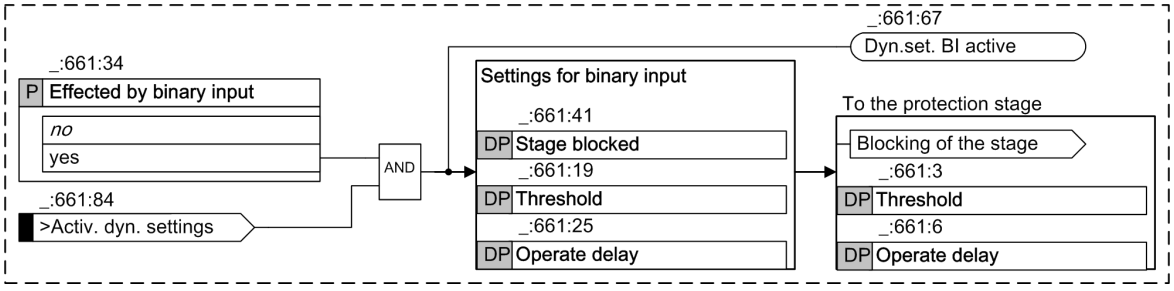
These functionalities generate signals that change the settings of the dynamic settings of the overcurrent-protection stage or block it, if required. In the latter case, the settings of the **Threshold** and **Operate**

delay parameters are of no relevance. Within the overcurrent-protection stage, each of these signals is provided with a configuration parameter **Influence of function ...** and its own dynamic settings (**Operate delay** and **Threshold**). The configuration settings are used to set whether the signal shall be active or not, this means whether the dynamic settings shall be activated or not. If one of these signals (for example, signal function x) becomes active and is to take effect, these settings become dynamic, that is, instantly active. This means that the setting assigned to the signal replaces the standard setting. If the signal becomes inactive, the standard settings apply again. The activation of the dynamic settings is reported.

Where several signals are active in parallel, the priority specified above shall apply. This means that a signal with priority 1 precedes that of priority 2. The settings assigned to signal 1 become active.

The functionality of the dynamic settings can be disabled. In this case, the settings assigned to the signals are not visible and are without effect.

Link to the Device-Internal Function *Cold-Load Pickup Detection (Advanced Stage)*



[lo_ocp3kal, 1, en_US]

Figure 6-435 Influence of the Cold-Load Pickup Detection on the Overcurrent-Protection Stage

In the case of cold-load pickup, you have the option to change the settings for the **Threshold** and **Operate delay** parameters of the protection stage. You can also block the stage. To do so, you must activate the influence of the cold-load pickup. You also have to set the **Threshold** and **Operate delay** or assign settings to **Stage blocked**, which take effect when the signal is active.

The way signals are generated **Cold-load pickup** is described in *5.5.4.1 Overview of Functions*.

Link to an External *Function via a Binary Input Signal (Advanced Stage)*

[lo_ocp3bin, 1, en_US]

Figure 6-436 Influence of the Binary Input on the Overcurrent-Protection Stage

You can use the binary input signal **>Activ. dyn. settings** to change the settings for the **Threshold** and the **Operate delay** parameters of the protection stage. You can also block the stage. To do so, you must activate the influence of the binary input. You also have to set the **Threshold** and **Operate delay** or assign settings to **Stage blocked**, which take effect when the signal is active.

6.23.8.2 Application and Setting Notes (Advanced Stage)

Parameter: Dynamic settings

- Default setting **(_:661:26) Dynamic settings** = *no*

Parameter Value	Description
no	The influence on the overcurrent-protection stage by device-internal or external functions is not necessary.
yes	If a device-internal function (cold-load pickup detection) or an external function should affect the overcurrent-protection stage (such as changing the setting of the threshold value or time delay, blocking of the stage), the setting must be changed to ***yes***. This makes the configuration parameters **Influence of function...** as well as the dynamic settings **Threshold**, **Operate delay** and **Stage blocked** of the stage visible and enables the settings to be set for the specific influence.

Influence of External Devices

The influence of an external device can also be configured.

To realize the application, the configuration setting **Effected by binary input** must be changed to ***yes*** (= influenced). This activates the **>Activ. dyn. settings** input signal within the stage. When the input signal becomes active, it switches to the assigned dynamic settings.

6.24 Overcurrent Protection, Ground

6.24.1 Overview of Functions

The **Overcurrent protection, ground** function (ANSI 50N/51N):

- Detects short circuits in electrical equipment
- Can be used as backup overcurrent protection in addition to the main protection

6.24.2 Structure of the Function

The **Overcurrent protection, ground** function is used in protection function groups. 2 kinds of functions are available for the 3-phase overcurrent protection:

- **Overcurrent protection, ground – advanced** (50N/51N OC-gnd-A)
- **Overcurrent protection, ground – basic** (50N/51N OC-gnd-B)

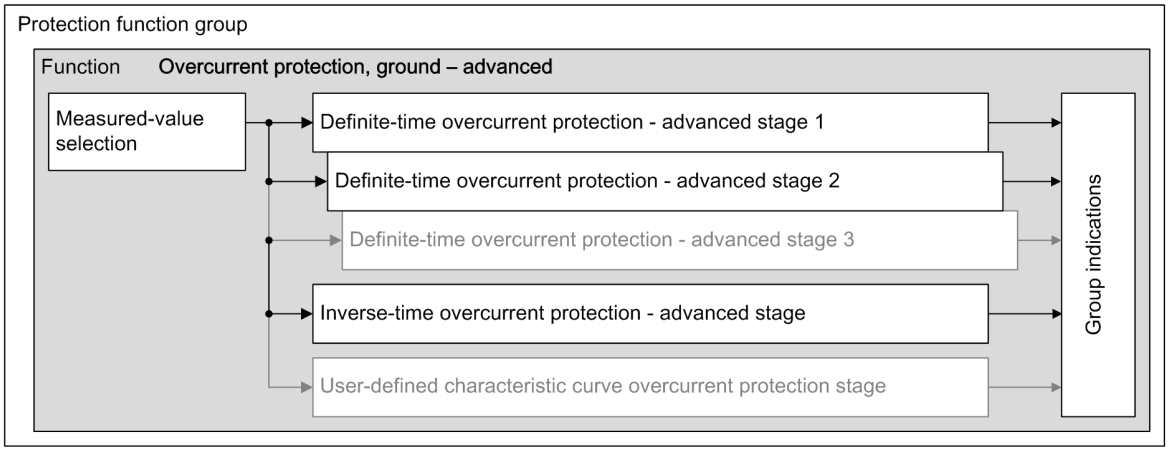
The function type Basic is provided for standard applications. The function type Advanced offers more functionality and is provided for more complex applications.

Both function types are pre-configured by the manufacturer with 2 **Definite-time overcurrent protection** stages and with 1 **Inverse-time overcurrent protection** stage.

In the function type **Overcurrent protection, ground – advanced** the following stages can be operated simultaneously:

- Maximum of 3 stages **Definite-time overcurrent protection – advanced**
- 1 stage **Inverse-time overcurrent protection – advanced**
- 1 stage **User-defined characteristic curve overcurrent protection**

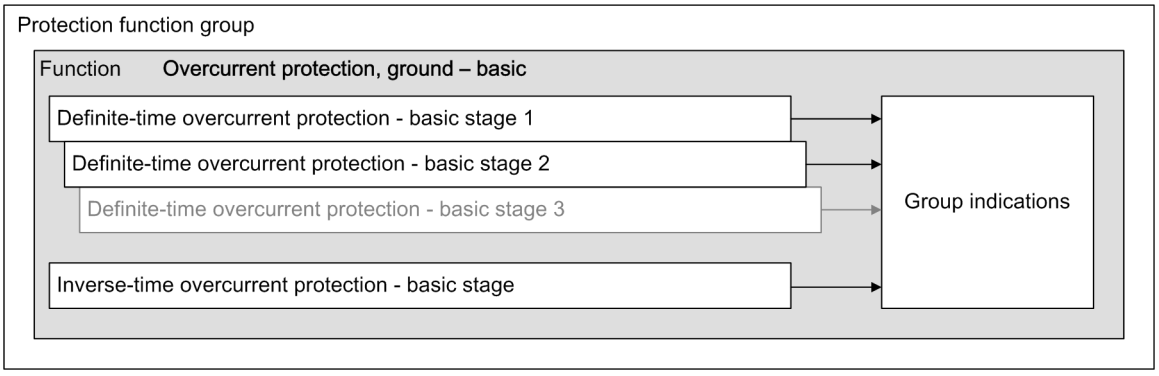
In the function type **Overcurrent protection, ground – basic** the following stages can be operated simultaneously:



- Maximum of 3 stages **Definite-time overcurrent protection – basic**
- 1 stage **Inverse-time overcurrent protection – basic**

The non-preconfigured stages are shown in gray in the following figures. Apart from the tripping delay characteristic, the stages are identical in structure.

The measured-value selection (only advanced stage) is general functionality and has a uniform effect on the stages (see *Figure 6-437* and *6.24.3.1 Description*). This ensures that all stages of the function receive the same measured current value.



The group-indication output logic generates the following group indications of the protection function by the logical OR of the stage-selective indications:

- **`Pickup`**
- **`Operate`**

[dw_ocp_ga2, 5, en_US]

Figure 6-437 Structure/Embedding of the Function Overcurrent Protection, Ground – Advanced

[dw_ocp_gb1, 4, en_US]

Figure 6-438 Structure/Embedding of the Function Overcurrent Protection, Ground – Basic

If the following listed, device-internal functions are present in the device, these functions can influence the pickup values and tripping delays of the stages or block the stages. The stage can also be affected by an external source via a binary input signal.

- Cold-load pickup detection
- Binary input signal

If the device is equipped with an **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer-inrush currents (available in both function types).

6.24.3 General Functionality

6.24.3.1 Description

Measured-Value Selection

The function provides the option to select between the values ***IN measured*** or ***3I0 calculated***.

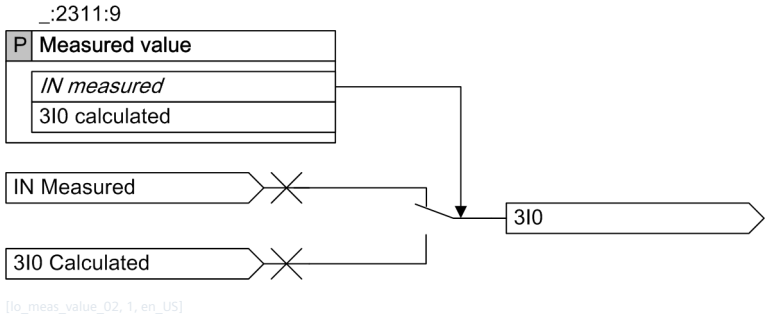


Figure 6-439 Logic Diagram of Measured-Value Selection

Both options are only available for the current-transformer connection types ***3-phase + IN*** and ***3-phase + IN-separate***. For other connection types respectively, only one option is possible. If you select an option that is not allowed, an inconsistency message is given.

Depending on the CT secondary rated current, the CT connection type, and the selected setting, the secondary threshold setting range varies according to the following table.

Table 6-10 Threshold Setting Range

Connection Type	Measured Value	CT Terminal Type	Threshold Setting Range (rated I-sec.: ph = 1 A, IN = 1 A)	Threshold Setting Range (rated I-sec.: ph = 1 A, IN = 5 A)	Threshold Setting Range (rated I-sec.: ph = 5 A, IN = 1 A)	Threshold Setting Range (rated I-sec.: ph = 5 A, IN = 5 A)
3ph + IN	3I0 calculated	4 * Protection	0.010 A to 40.000 A	N/A	N/A	0.050 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	N/A	N/A	0.002 A to 8.000 A
	IN measured	4 * Protection	0.010 A to 40.000 A	N/A	N/A	0.050 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	N/A	N/A	0.002 A to 8.000 A
3ph + IN-separate	3I0 calculated	4 * Protection	0.010 A to 40.000 A	0.010 A to 40.000 A	0.050 A to 200.00 A	0.050 A to 200.00 A
		3 * Protection, 1 * sen.	0.010 A to 40.000 A	0.010 A to 40.000 A	0.050 A to 200.00 A	0.050 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	0.001 A to 1.600 A	0.002 A to 8.000 A	0.002 A to 8.000 A
	IN measured	4 * Protection	0.010 A to 40.000 A	0.050 A to 200.00 A	0.010 A to 40.000 A	0.050 A to 200.00 A
		3 * Protection, 1 * sen.	0.001 A to 1.600 A	0.002 A to 8.000 A	0.001 A to 1.600 A	0.002 A to 8.000 A
		4 * Measurement	0.001 A to 1.600 A	0.002 A to 8.000 A	0.001 A to 1.600 A	0.002 A to 8.000 A

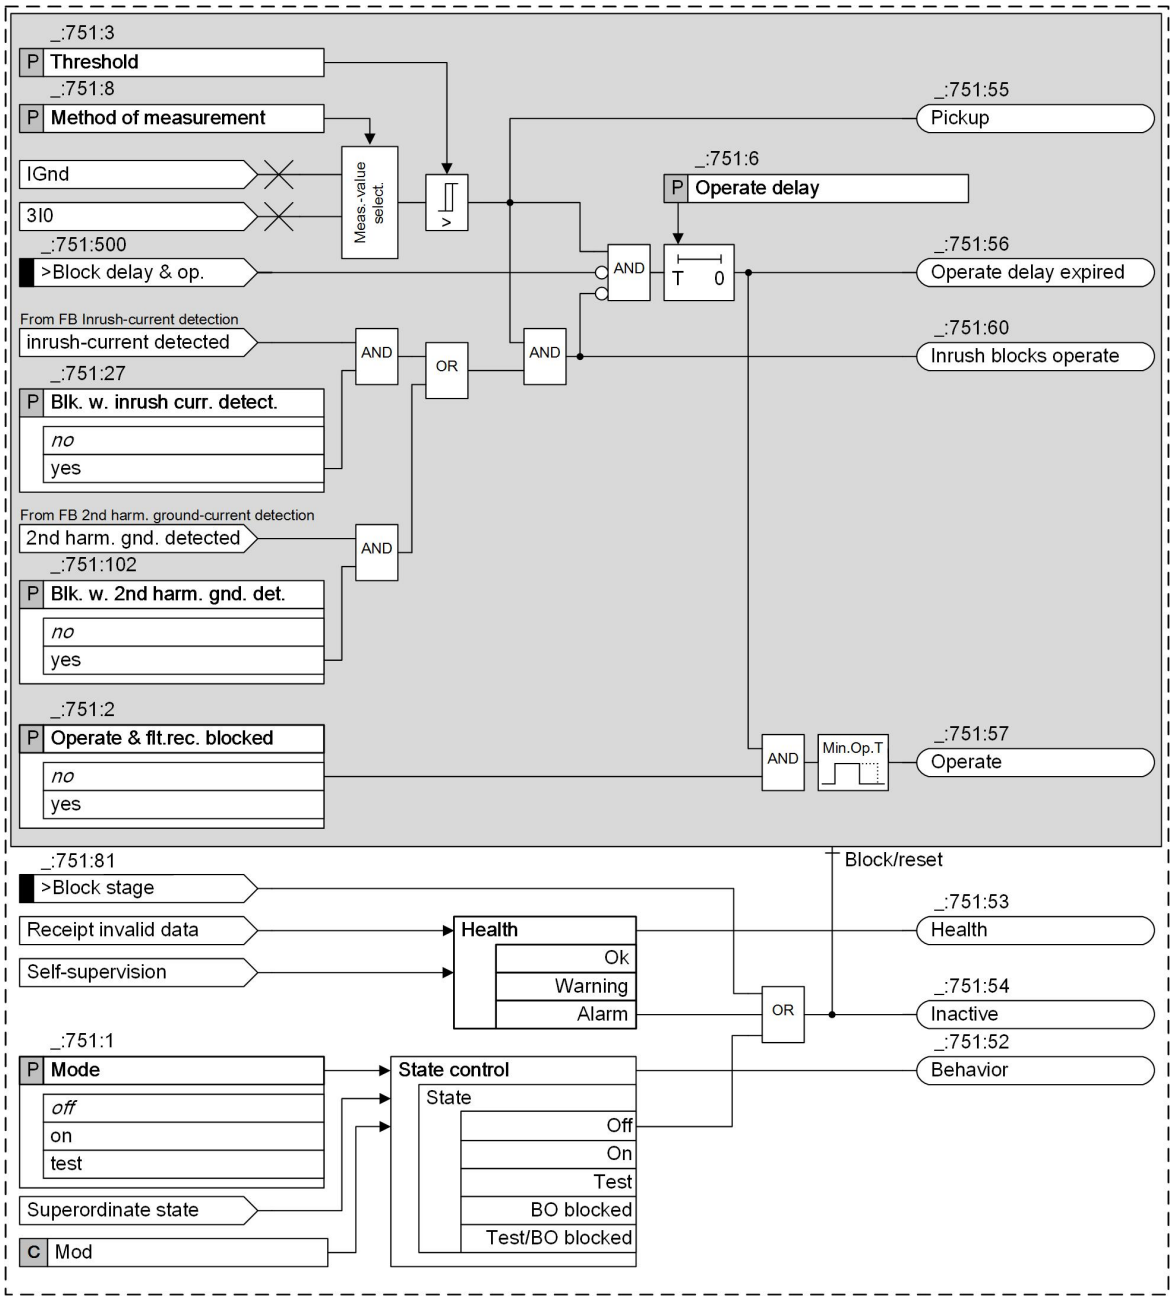
6.24.3.2 Application and Setting Notes

Parameter: `Measured value`

- Recommended setting value **`Measured value`** = ***`IN Measured`***

This parameter is not available in the basic function.

Parameter Value	Description
IN Measured	The function operates with the measured ground current IN. This is the recommended setting unless there is a specific reason to use the calculated zero-sequence current 3I0.
3I0 Calculated	The function operates with the calculated zero sequence current 3I0. This setting option can be used when applying a redundant 50N/51N function for safety reasons.

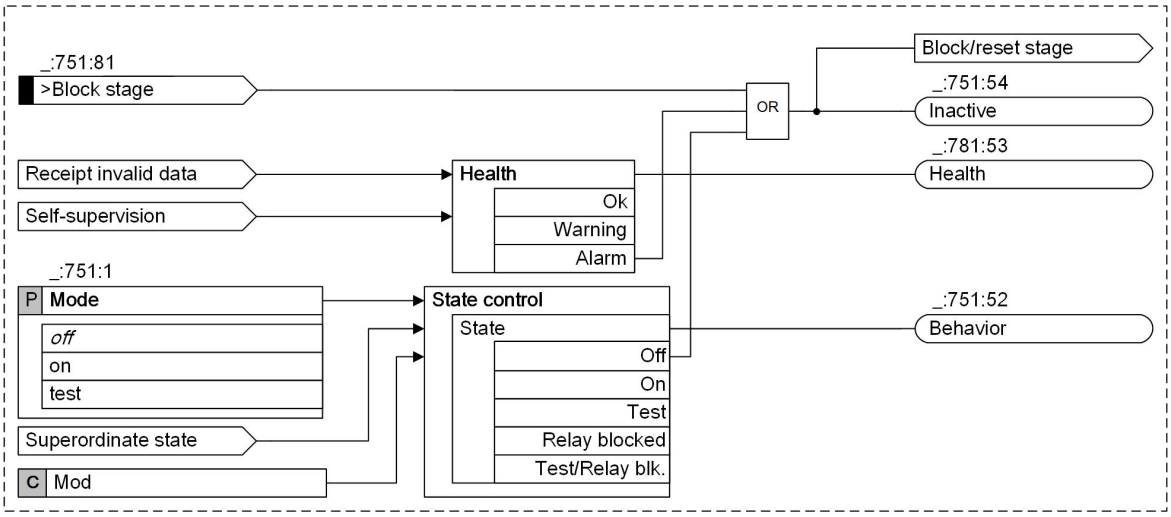


6.24.3.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General				
_:2311:9	General:Measured value		• 3I0 calculated • IN measured	IN measured

6.24.4 Stage with Definite-Time Characteristic Curve

6.24.4.1 Description



Logic of the Basic Stage

[lo_ocp_gb1, 4, en_US]

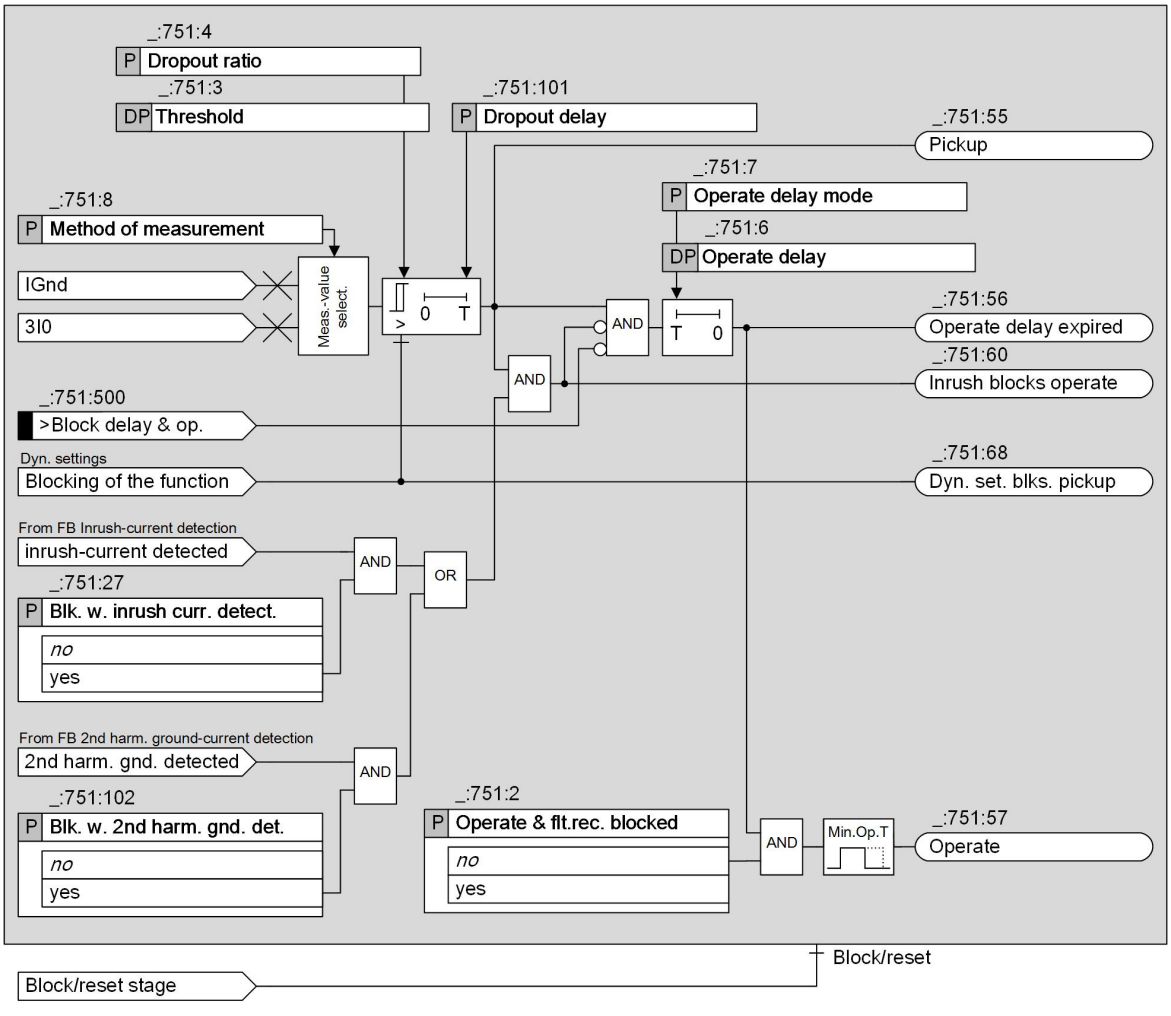


Figure 6-440 Logic Diagram Definite-Time Overcurrent Protection (Ground) – Basic

Logic of the Advanced Stage

[lo_ocp_gnd_umz_adv_stage_control, 2, en_US]

Figure 6-441 Logic Diagram Stage Control

[lo_ocp_gn1, 5, en_US]

Figure 6-442 Logic Diagram Definite-Time Overcurrent Protection (Ground) – Advanced

Method of Measurement (Basic and Advanced Stage)

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Dropout Delay (Advanced Stage)

If the current falls below the dropout threshold, the dropout can be delayed for the time specified by the parameter **Dropout delay**. During the dropout delay, the pickup is maintained. Meanwhile, the operate delay continues to run (parameter **Operate delay mode** = ***Running dur. DO-delay***) or is frozen (parameter **Operate delay mode** = ***Frozen dur. DO-delay***). If the operate delay expires while the pickup is still maintained, the stage operates.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Via the binary input signal **>Block stage** from an external or internal source
- Via the functionality of the **dynamic settings** (see **Influence of other functions via dynamic settings** and *6.24.8.1 Description*).

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in *6.24.7.1 Description*.

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in *6.24.8.1 Description* .

6.24.4.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:751:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Operate delay mode

- Default setting **(_:661:7) Operate delay mode** = ***Running dur. DO-delay***

This parameter is not visible in the basic stage.

With the parameter **Operate delay mode**, you specify whether the operate delay continues to run or is frozen during the dropout delay.

This setting is only valid if the parameter **Dropout delay** is not ***0***.

Parameter Value	Description
Running dur. DO-delay	During the dropout delay, the operate delay continues to run.
Frozen dur. DO-delay	During the dropout delay, the operate delay is frozen. If the current exceeds the threshold value again, the operate delay continues to run.

Parameter: Threshold, Operate delay

- Default setting **(_:751:3) Threshold** = ***1.20 A*** (for the first stage)
- Default setting **(_:751:6) Operate delay** = ***0.300 s*** (for the first stage)

Set the **Threshold** and **Operate delay** parameters for the specific application.

The following details apply to a 2-stage characteristic curve (1st stage = definite-time overcurrent protection stage and 2nd stage = high-current stage).

1st stage (overcurrent stage):

The setting depends on the minimal occurring ground-fault current. This must be determined.

For very small ground-fault currents, Siemens recommends using the **Ground-fault protection against high-resistance ground faults in grounded systems** function.

The **Operate delay** to be set is derived from the time-grading schedule that has been prepared for the system. Where overcurrent protection is used in emergency mode, shorter time delays might be reasonable (one grading time above fast tripping), since the emergency mode only operates if the main protection function fails.

2nd stage (high-current stage):

This tripping stage can also be used for current grading. This applies in the case of very long lines with low source impedance or ahead of high reactances (for example, transformers, shunt reactors). Set the **Threshold** parameter to ensure that the stage does not pick up in case of a short-circuit at the end of the line.

Set the **Operate delay** parameter to ***0*** or to a low value.

Siemens recommends that the threshold values be determined with a system analysis. The following example illustrates the principle of grading with a current threshold on a long line.

EXAMPLE

High-current stage: 110-kV overhead line, 150 mm² cross-section

s (length) = 60 km

Z_L/s = 0.46 Ω/km

Ratio of zero-sequence impedance and positive-sequence impedance of the line: $Z_{L0}/Z_{L1} = 4$

Short-circuit power at the beginning of the line:

S_{sc}' = 2.5 GVA

Ratio of zero-sequence impedance and positive-sequence impedance of the source impedance at the beginning of the line: $Z_{P0}/Z_{P1} = 2$

Current transformer = 600 A/5 A

Resulting in the following values for the line impedance Z_L and the source impedance Z_P:

$$Z_L = 0.46\ \Omega/\mathrm{km} \cdot 60\mathrm{km} = 27.6\ \Omega$$

[fo_ocp_002, 1, en_US]

$$Z_P = \frac{110\ \mathrm{kV}^2}{2500\ \mathrm{MVA}} = 4.84\ \Omega$$

[fo_ocp_003, 1, en_US]

The 1-pole short-circuit current at the end of the line is $I_{scG\ end}$:

$$I_{sc\ gnd\ end} = \frac{1.1 \cdot V_N \cdot 3}{\sqrt{3} \cdot \left[Z_P \cdot \left(2 + \frac{Z_{P0}}{Z_{P1}}\right) + Z_L \cdot (2 + \frac{Z_{L0}}{Z_{L1}})\right]} = \frac{1.1 \cdot 110\mathrm{kV} \cdot 3}{\sqrt{3} \cdot [4.84\ \Omega \cdot (2+2) + 27.6\ \Omega \cdot (2+4)]} = 1133\ \mathrm{A}$$

[fo_ocp_005, 1, en_US]

The settings in primary and secondary values result in the following setting values which include a safety margin of 10 %:

Threshold value 2nd stage (primary) $= 1.1 \cdot 1133\ \mathrm{A} = 1246.3\ \mathrm{A}$

Threshold value 2nd stage (secondary) $= 1.1 \cdot \frac{1133\ \mathrm{A}}{600\ \mathrm{A}} \cdot 5\ \mathrm{A} = 10.39\ \mathrm{A}$

[fo_ocp_gr4, 3, en_US]

In case of short-circuit currents exceeding 1246 A (primary) or 10.39 A (secondary) there is a short-circuit on the line to be protected. The overcurrent protection can cut off this short circuit immediately.

Note: The amounts in the calculation example are accurate enough for overhead lines. If the source impedance, line impedance and zero-sequence impedance have very different angles, you have use complex numbers to calculate the **Threshold**.

Parameter: Dropout delay

- Recommended setting value **(_:751:101) Dropout delay** = ***0***

This parameter is not visible in the basic stage.

Siemens recommends using the default setting ***0*** since the dropout of a protection stage must be done as fast as possible.

You can use the **Dropout delay** parameter ≠ ***0*** to obtain a uniform dropout behavior if you use it together with an electromechanical relay. This is required for time grading. The dropout time of the electromechanical relay must be known for this purpose. Subtract the dropout time of your own device (see Technical Data) and set the result.

Parameter: `Dropout ratio`

- Recommended setting value **`(_:751:4) Dropout ratio`** = ***`0.95`***

This parameter is not visible in the basic stage.

The recommended set value of ***`0.95`*** is appropriate for most applications.

To achieve high-precision measurements, the setting value of the parameter **`Dropout ratio`** can be reduced, for example, to ***`0.98`***. If you expect highly fluctuating measurands at the response threshold, you can increase the setting value of the parameter **`Dropout ratio`**. This avoids chattering of the stage.

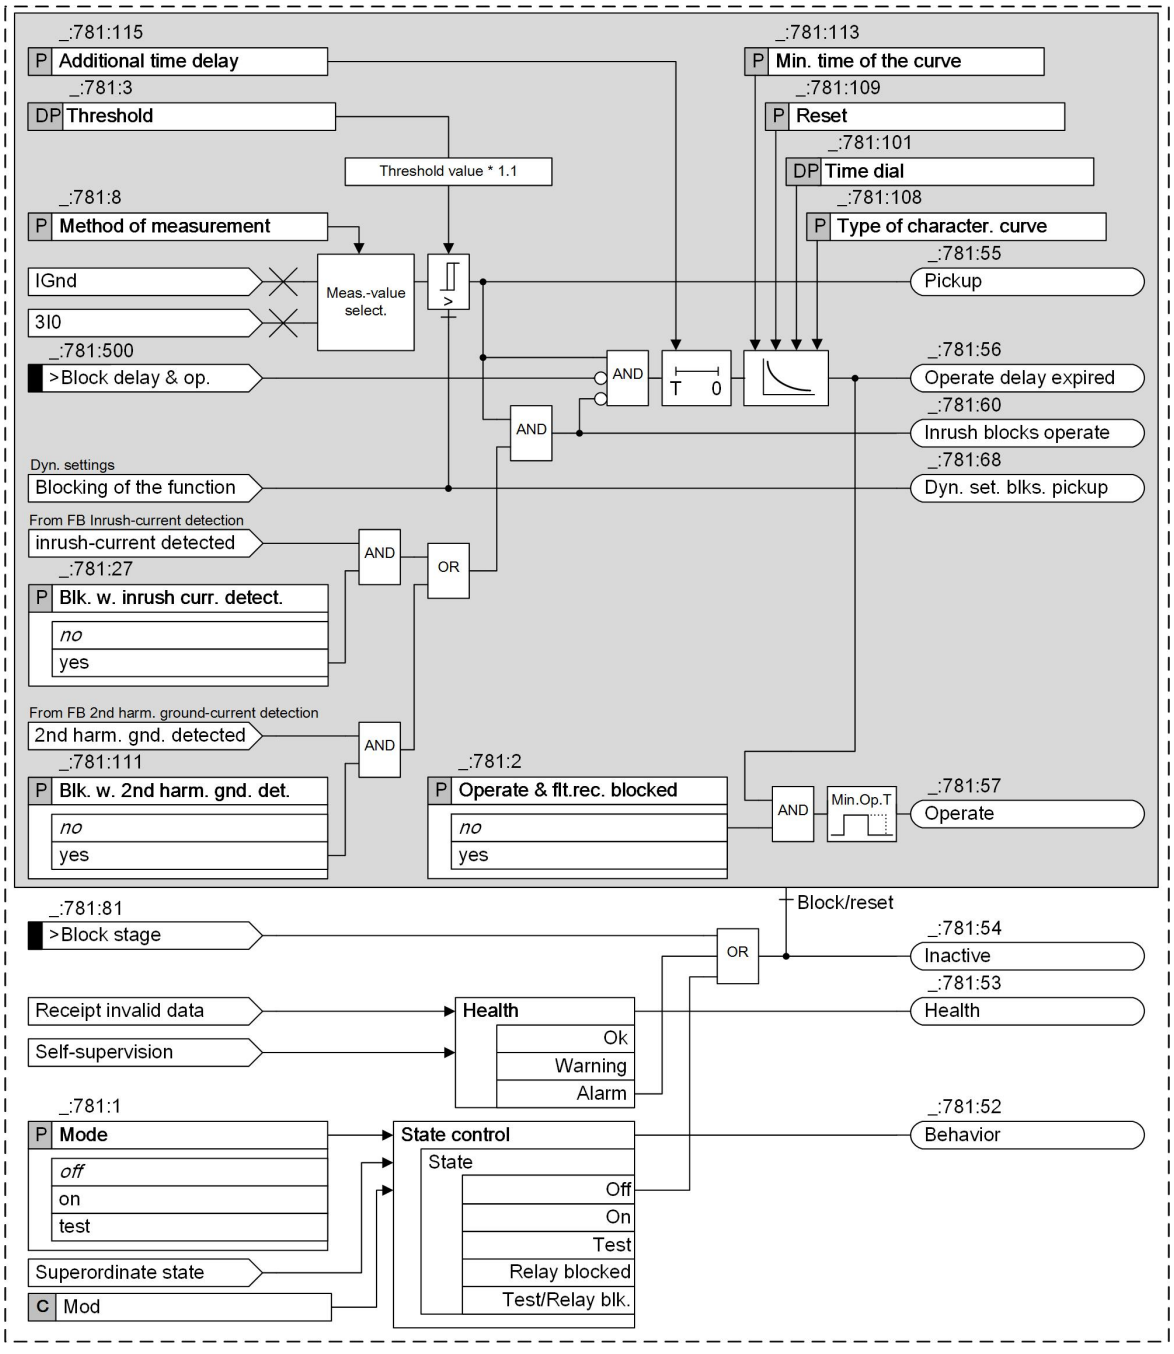
6.24.5 Stage with Inverse-Time Characteristic Curve

6.24.5.1 Description



Logic of the Basic Stage

[lo_ocp_gr2, 6, en_US]

Figure 6-443 Logic Diagram Inverse-Time Overcurrent Protection (Ground) – Basic

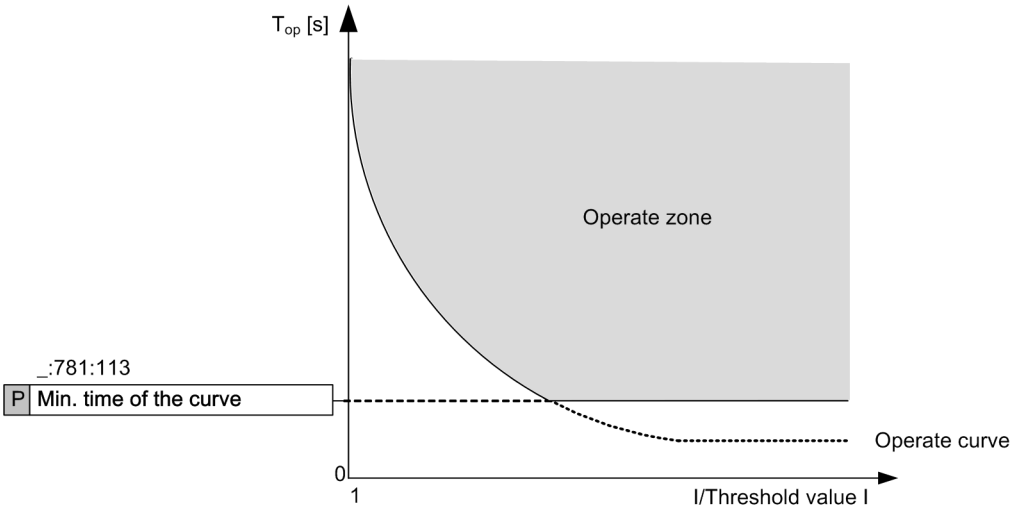
Logic of the Advanced Stage

[lo_ocp_gn2, 5, en_US]

Figure 6-444 Logic Diagram Inverse-Time Overcurrent Protection (Ground) – Advanced

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI (Basic and Advanced Stage)

When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.



When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting

parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Minimum Time of the Curve (Advanced Stage)

With the parameter **`Min. time of the curve`**, you define the minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time.

[dw_ocp_gr3_mi, 1, en_US]

Figure 6-445 Minimum Operating Time of the Curve

Additional Time Delay (Advanced Stage)

With the parameter **`Additional time delay`**, you define a definite-time delay in addition to the inverse-time delay. With this setting, the whole curve is shifted on the time axis by this additional definite time.

Method of Measurement (Basic and Advanced Stage)

You use the **`Method of measurement`** parameter to define whether the stage uses the ***`fundamental comp.`*** or the calculated ***`RMS value`***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Via the binary input signal **`>Block stage`** from an external or internal source
- Via the functionality of the **`dynamic settings`** (see **Influence of other functions via dynamic settings** and *6.24.8.1 Description*).

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in *6.24.7.1 Description*.

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in *6.24.8.1 Description* .

6.24.5.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:781:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Type of character. curve

- Default setting **(_:781:108) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application. For more information about the parameter **Type of character. curve**, refer to chapter*12.19.2 Stage with Inverse-Time Characteristic Curve*.

Parameter: Min. time of the curve

- Default setting **(_:781:113) Min. time of the curve** = ***0.00 s***

This parameter is only available in the advanced stage.
With the **Min. time of the curve** parameter, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time. If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

NOTE

If the set value is smaller than the smallest possible time delay of the inverse-time characteristic curve, the parameter has no influence on the delay time.

Parameter: `Additional time delay`

- Recommended setting value **`(_:781:115) Additional time delay`** = ***`0.00 s`***

With the **`Additional time delay`** parameter, you define a definite-time delay in addition to the inverse-time delay.
If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.
This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommend keeping the default setting of 0 s.

Parameter: `Threshold`

- Default setting **`(_:781:3) Threshold`** = ***`1.20 A`***

The setting depends on the minimal occurring ground-fault current. This must be determined.

Parameter: `Time dial`

- Default setting **`(_:781:101) Time dial`** = ***`1`***

With the **`Time dial`** parameter, you displace the characteristic curve in the time direction.
The set value for the **`Time dial`** parameter is derived from the time-grading schedule that has been prepared for the electrical power system. Where overcurrent protection is used in emergency mode, shorter time delays might be reasonable (one grading time above fast tripping), since the emergency mode only operates if the main protection function fails.
Where no time grading and therefore no displacement of the characteristic curve is required, leave the **`Time dial`** parameter at ***`1`***.

Parameter: `Reset`

- Default setting **`(_:781:109) Reset`** = ***`disk emulation`***

With the **`Reset`** parameter, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Select this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

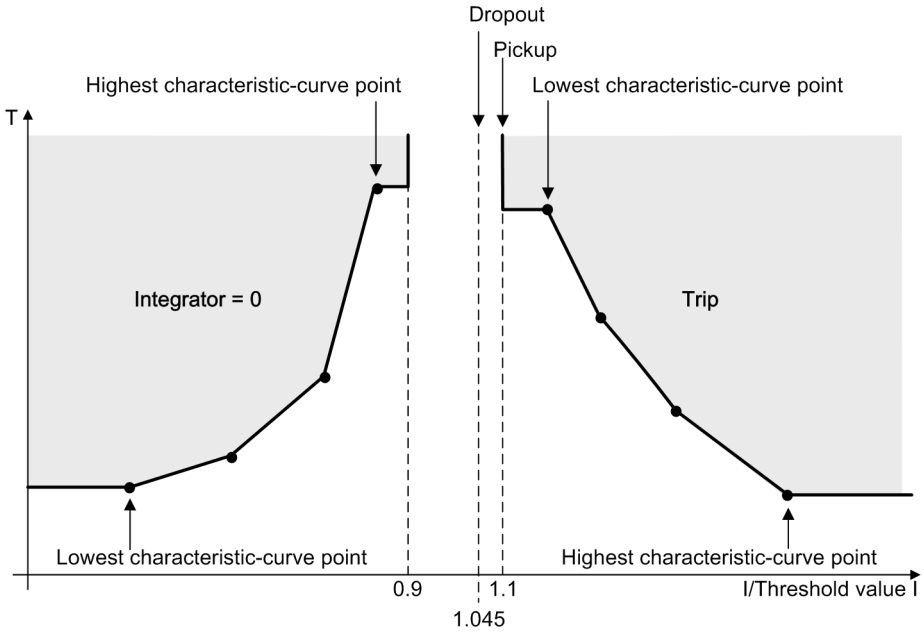
6.24.6 Stage with User-Defined Characteristic Curve

6.24.6.1 Description

This stage is only available in the advanced function type.

This stage is structured the same way as the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.24.5.1 Description*). The only differences are as follows:

- You can define the characteristic curve as desired.
- The pickup and dropout behaviors of this stage are determined by the standard parameter **Threshold** and, if necessary, by an additional parameter **Threshold (absolute)**.



User-Defined Characteristic Curve

With the user-defined characteristic curve, you can define the operate curve point by point using up to 30 value pairs of current and time. The device uses linear interpolation to calculate the characteristic curve from these values. You can also define a dropout characteristic curve if you wish.

Pickup and Dropout Behaviors with the User-Defined Characteristic Curve

When the input variable exceeds the **Threshold** value by 1.1 times, the characteristic curve is processed. An integrating method of measurement totalizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls short of the pickup value by a factor of 1.045 (0.95 x 1.1 x **Threshold** value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve).
The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

[dw_ocp_ken_02, 2, en_US]

Figure 6-446 Pickup Behavior and Dropout Behavior when Using a User-Defined Characteristic Curve

NOTE

The currents that are lower than the current value of the smallest characteristic-curve point do not extend the operate time. The pickup characteristic runs in parallel to the current axis up to the smallest characteristic-curve point. Currents that are larger than the current value of the largest characteristic-curve point do not reduce the operate time. The pickup characteristic runs in parallel to the current axis from the largest characteristic-curve point.

If you want to change the pickup threshold of the stage without changing all points of the characteristic curve, you can use the additional **`Threshold (absolute)`** parameter.

You can set the **`Threshold (absolute)`** parameter to be greater than 1.1 times the **`Threshold`** value. Then the stage behaviors are as follows:

- The stage picks up when the measured current value exceeds the **`Threshold (absolute)`** value.
- The stage starts dropout when the measured current value falls short of the **`Threshold (absolute)`** value by 0.95 times.
- For measured current values lower than the **`Threshold (absolute)`** value, no pickup takes place and consequently the characteristic curve is not processed.

If you set the **`Threshold (absolute)`** parameter to be less than 1.1 times the **`Threshold`** value, the pickup and dropout behaviors are not affected by the **`Threshold (absolute)`** parameter.

6.24.6.2 Application and Setting Notes

This stage is structured the same way as the **Inverse-time overcurrent protection – advanced** stage. The only differences are described in chapter *6.24.6.1 Description* . This chapter provides only the application and setting notes for setting characteristic curves and for setting the **`Threshold (absolute)`** parameter. You can find more information on the other parameters of the stage in chapter *6.24.5.2 Application and Setting Notes* .

Parameter: `Current/time value pairs` (from the operate curve)

With these settings, you define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **Threshold** parameter to ***1.00*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to shift the characteristic curve.

Set the time value in seconds. The characteristic curve is shifted via the **Time dial** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: Time dial

- Default setting **(_:101) Time dial** = ***1***

With the **Time dial** parameter, you displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading schedule that has been prepared for the electrical power system. Where no time grading and therefore no displacement of the characteristic curve is required, leave the **Time dial** parameter at ***1***.

Parameter: Reset

- Default setting **(_:110) Reset** = ***disk emulation***

With the **Reset** parameter, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
disk emulation	In the case of this setting, a dropout characteristic curve has to be set in addition to the operate curve. Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Select this setting if the dropout is not to be performed after disk emulation but an instantaneous dropout is desired.

Parameter: Current/time value pairs (of the dropout characteristic curve)

With these settings, you define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **Threshold** parameter to ***1.00*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to shift the characteristic curve.

Set the time value in seconds. The characteristic curve is shifted via the **Time dial** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: Threshold (absolute)

- Default setting **(_:113) Threshold (absolute)** = ***0.000 A***

With the **Threshold (absolute)** parameter, you define and change the absolute pickup threshold of the stage without changing all points of the characteristic curve.

The parameter is only used for special applications. With the default setting, this functionality is disabled. You can find more information in *Pickup and Dropout Behaviors with the User-Defined Characteristic Curve , Page 1253*.

6.24.7 Blocking of the Tripping by Device-Internal Inrush-Current Detection

6.24.7.1 Description

The **Blk. w. inrush curr. detect.** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

The **Blk. w. 2nd harm. gnd. det.** parameter allows you to define whether the operate indication of the stage should be blocked when the detected 2nd harmonic component of the ground current exceeds a threshold value. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

The following figure only shows the part of the stage (exemplified by definite-time overcurrent protection stage 1) that illustrates the influence of the inrush-current detection. Only if the central function **Inrush-current detection** (see section *12.62 Inrush-Current Detection*) is in effect can the blocking be set.

[lo_ocp_grd, 2, en_US]

Figure 6-447 Part-Logic Diagram on the Influence of Inrush-Current Detection Exemplified by the 1st Definite-Time Overcurrent Protection Stage

(1) From FB **Inrush-current detection**

(2) From FB **2nd harmonic ground-current detection**

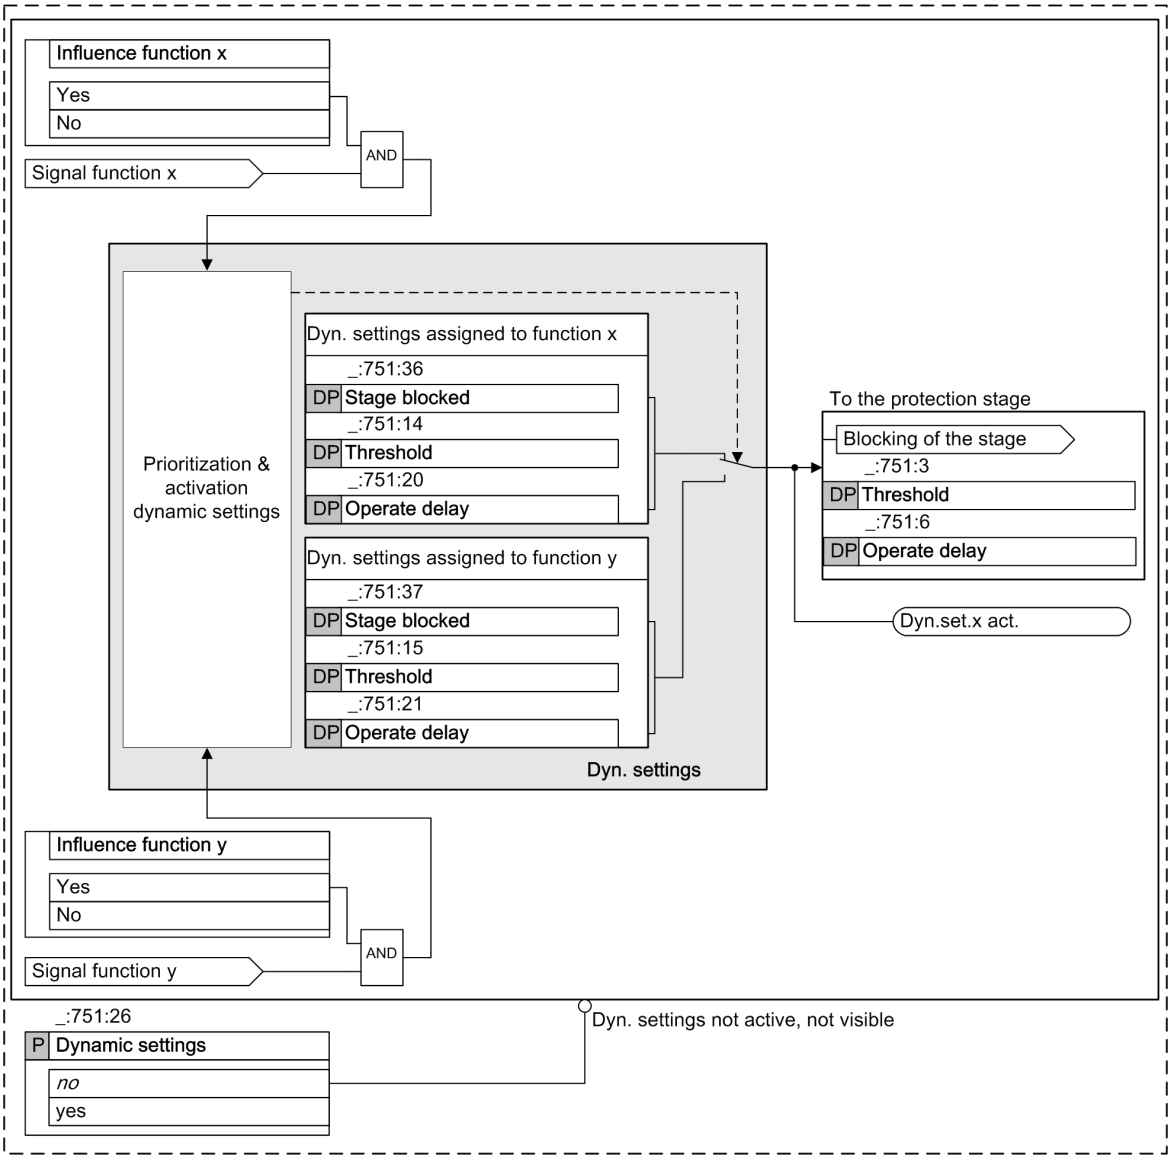
6.24.7.2 Application and Setting Notes

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:751:27) Blk. w. inrush curr. detect.** = ***no***

Parameter Value	Description
no	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This, for example, applies to the high-current stage that is set such according to the short-circuit voltage V_{sc} of the transformer that it only picks up on faults from the high-voltage side. The transformer inrush current cannot become larger than the maximum transmittable short-circuit current.
yes	When the transformer inrush-current detection detects an inrush current that would lead to a tripping of the stage, the start of the time delay and tripping of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

Parameter: **`Blk. w. 2nd harm. gnd. det.`**



- Default setting **`(_:751:102) Blk. w. 2nd harm. gnd. det.`** = ***no***

Parameter Value	Description
no	If no 3I0/IN current flow due to CT saturation with a level above the pickup threshold is expected, select this setting.
yes	If 3I0/IN current flow due to CT saturation with a level above the pickup threshold is expected, the blocking must be activated. This provides stability for the following conditions: • CT saturation without inrush current since a saturated signal also contains 2nd-harmonic content • Phase inrush current that leads to CT saturation and therefore causes 2nd-harmonic inrush current being present also in the parasitic 3I0 current

6.24.8 Influence of Other Functions via Dynamic Settings

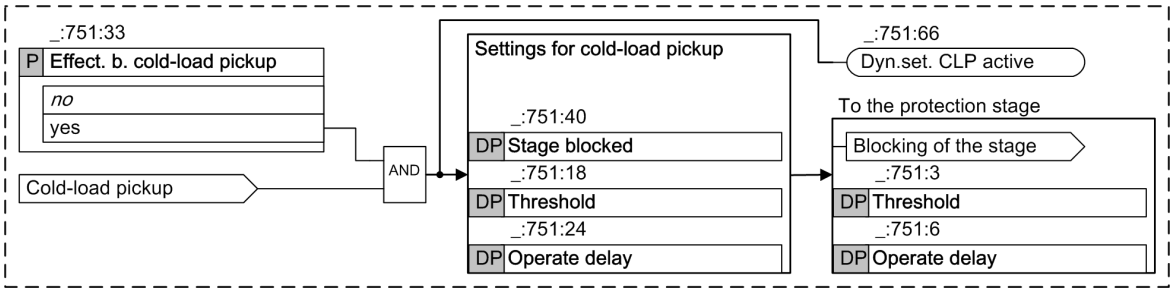
6.24.8.1 Description

The **`Threshold`** and **`Operate delay`** settings used for tripping are so-called **`dynamic settings`**. Depending on other functions, the settings of these parameters can be changed dynamically. Depending on other functions, the stage can also be blocked dynamically. This functionality is only available in function type Advanced.

[lo_ocp_gnd, 2, en_US]

Figure 6-448 Principle of the Dynamic Settings in the Example of 1st Definite-Time Overcurrent Protection Stage

If available in the device, the following functionalities can affect the overcurrent-protection stages:



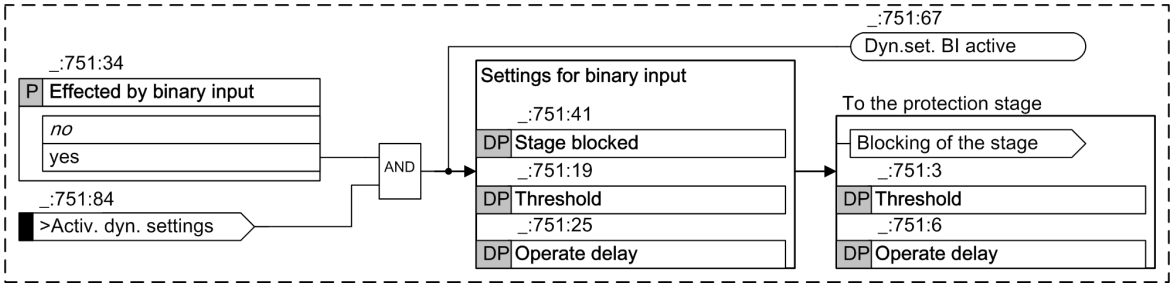
Functionalities	Priority
Cold-load pickup detection	Priority 1
Binary input signal	Priority 2

These functionalities generate signals that change the settings of the dynamic settings of the overcurrent-protection stage or block it, if required. In the latter case, the settings for the **Threshold** and the **Operate delay** are of no relevance. Within the overcurrent-protection stage, each of these signals is provided with a configuration parameter **Influence of function ...** and its own dynamic settings (**Operate delay** and **Threshold**). The configuration settings are used to set whether the signal shall be active or not, this means whether the dynamic settings shall be activated or not. If one of these signals (for example, signal function x) becomes active and is to take effect, these parameter settings become dynamic, that is, instantly active. This means that the setting assigned to the signal replaces the standard setting. If the signal becomes inactive, the standard settings apply again. The activation of the dynamic settings is reported.

Where several signals are active in parallel, the priority specified above shall apply. This means that a signal with priority 1 precedes that of priority 2. The settings assigned to signal 1 become active.

The functionality of the dynamic settings can be disabled. In this case, the settings assigned to the signals are not visible and are without effect.

Link to the Device-Internal Function *Cold-Load Pickup Detection (Advanced Stage)*



[lo_ocp_kal_gnd, 1, en_US]

Figure 6-449 Influence of the Cold-Load Pickup Detection on the Overcurrent-Protection Stage

You have the option of changing the settings for the **Threshold** and the **Operate delay** of the protection stage for a cold-load pickup. You can also block the stage. To do so, you must activate the influence of the cold-load pickup. You also have to set the **Threshold** and **Operate delay** or assign settings to **Stage blocked**, which take effect when the signal is active.

The way signals are generated **Cold-load pickup** is described in chapter *5.5.4.13 Cold-Load Pickup Detection (Optional)*.

Link to an External *Function via a Binary Input Signal (Advanced Stage)*

[lo_ocp_bin_gnd, 1, en_US]

Figure 6-450 Influence of the Binary Input on the Overcurrent-Protection Stage

You can use the binary input signal **>Activ. dyn. settings** to change the settings for the **Threshold** and the **Operate delay** of the protection stage. You can also block the stage. To do so, you must activate the influence of the binary input. You also have to set the **Threshold** and **Operate delay** or assign settings to **Stage blocked**, which take effect when the signal is active.

6.24.8.2 Application and Setting Notes (Advanced Stage)

Binary Input Signal: **Dynamic settings**

- Default setting **(_:751:26) Dynamic settings** = *no*

Parameter Value	Description
no	The influence on the overcurrent-protection stage by device-internal or external functions is not necessary.
yes	If a device-internal function (cold-load pickup detection) or an external function should affect the overcurrent-protection stage (such as changing the setting of the threshold value or time delay, blocking of the stage), the setting must be changed to ***yes***. This makes the configuration parameters **Influence of function...** as well as the dynamic settings **Threshold**, **Operate delay** and **Stage blocked** of the stage visible and enables the settings to be set for the specific influence.

Influence of External Devices

The influence of an external device can also be configured.

To realize the application, the configuration setting **Effected by binary input** must be changed to ***yes*** (= influenced). This activates the **>Activ. dyn. settings** input signal within the stage. When the input signal becomes active, it switches to the assigned dynamic settings.

6.25 Overcurrent Protection, 1-Phase

6.25.1 Function Overview

The **Overcurrent protection, 1-phase** function (ANSI 50N/51N):

- Detects and monitors the current measured in a transformer neutral point grounding
- Can operate as sensitive tank leakage protection
- Detects and monitors the circulating current between the neutral points of 2 capacitor banks
- Switches off high-current faults instantaneously

6.25.2 Structure of the Function

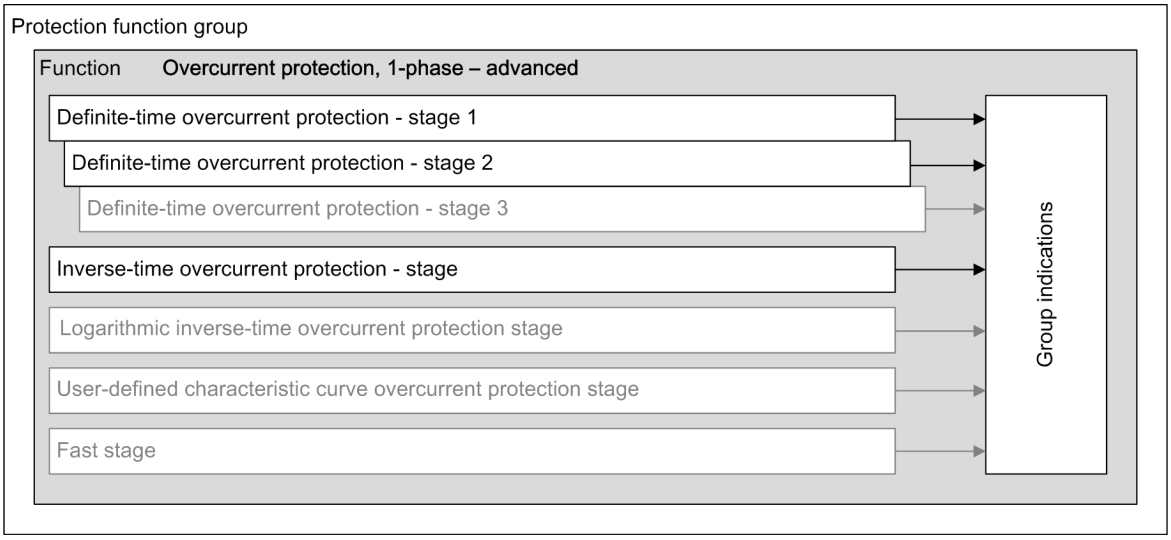
The **Overcurrent protection, 1-phase** function is used in protection function groups with 1-phase current measurement. 2 function types are available:

- **Overcurrent protection, 1-phase – advanced** (50N/51N OC-1ph-A)
- **Overcurrent protection, 1-phase – basic** (50N/51N OC-1ph-B)

The function type Basic is provided for standard applications. The function type Advanced offers more functionality and is provided for more complex applications.

Both function types are pre-configured by the manufacturer with 2 **Definite-time overcurrent protection** stages and with 1 **Inverse-time overcurrent protection** stage.

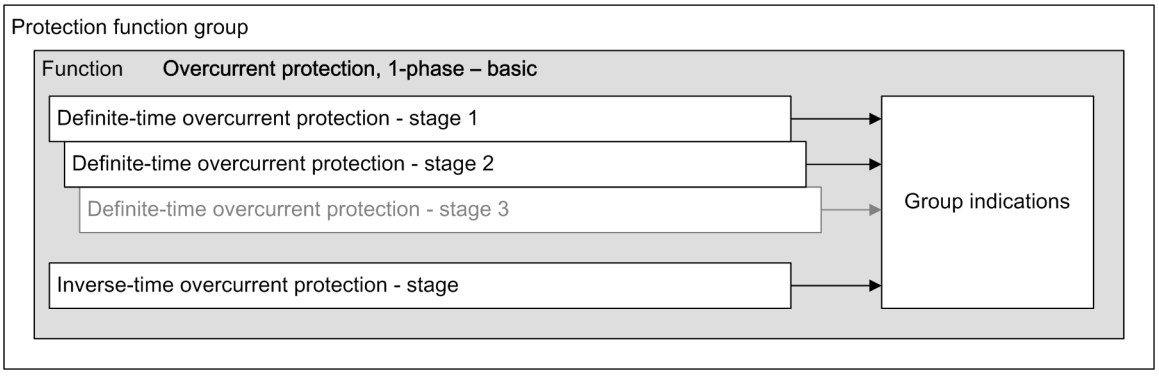
In the function type **Overcurrent protection, 1-phase – advanced** the following stages can be operated simultaneously:



- Maximum of 3 stages **Definite-time overcurrent protection** (UMZ)
- 1 stage **Inverse-time overcurrent protection** (AMZ)
- 1 stage **Logarithmic inverse-time overcurrent protection**
- 1 stage **User-defined characteristic curve overcurrent protection**
- 1 **Fast stage**

In the function type **Overcurrent protection, 1-phase – basic**, the following stages can operate simultaneously:

- Maximum of 3 stages **Definite-time overcurrent protection**
- 1 stage **Inverse-time overcurrent protection**



The non-preconfigured stages in *Figure 6-451* and *Figure 6-452* are shown in gray. Apart from the operate-delay characteristic curve, the **Definite-time overcurrent protection** stage, the **Inverse-time overcurrent protection** stage, the **Logarithmic inverse-time overcurrent protection** stage, and the **User-defined characteristic curve-time overcurrent protection** stage are structured identically.

The **Fast stage** uses a fast tripping algorithm. It is therefore suited in particular for sensitive ground-fault detection according to the high-impedance principle.

[dw_ocp_1pa, 4, en_US]

Figure 6-451 Structure/Embedding the Function Overcurrent Protection, 1-Phase – Advanced

[dw_ocp_1pb, 3, en_US]

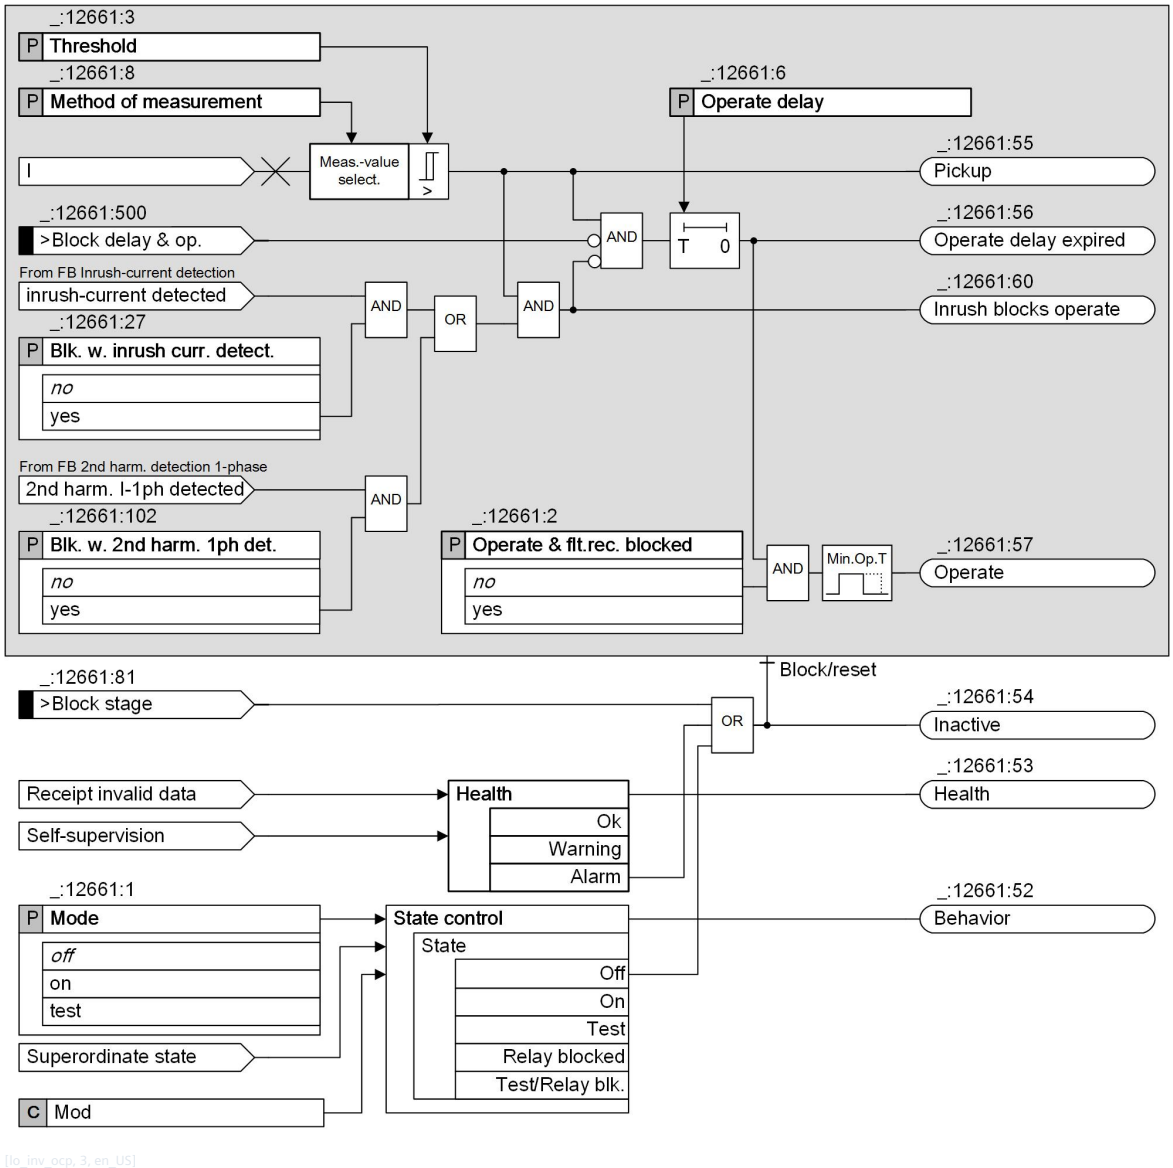


Figure 6-452 Structure/Embedding the Function Overcurrent Protection, 1-Phase – Basic

If the device is equipped with the **Inrush-current detection** function, you can stabilize the stages against issuing of the operate indication due to transformer inrush-currents.

6.25.3 Stage with Definite-Time Characteristic Curve

6.25.3.1 Description

Logic of a Stage

[lo_inv_ocp, 3, en_US]

Figure 6-453 Logic Diagram of the Definite-Time Overcurrent Protection, 1-Phase

Method of measurement

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Blocking of the Stage

The picked up stage can reset completely via the binary input signal *>Block stage*.

Blocking of the Time Delay

You can use the binary input signal *>Block delay & op.* to prevent the start of the time delay and thus also tripping. A running time delay is reset. The pickup is reported and a fault is opened.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.9.11 Blocking of the Tripping by Device-Internal Inrush-Current Detection*.

6.25.3.2 Application and Setting Notes

Parameter: `Method of measurement`

- Recommended setting value **`(_:12661:8) Method of measurement`** = ***`fundamental comp.`***

With the **`Method of measurement`** parameter, you define whether the stage uses the ***`fundamental comp.`*** (standard method) or the calculated ***`RMS value`***.

Parameter Value	Description
`fundamental comp.`	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
`RMS value`	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **`threshold value`** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: `Threshold`, `Operate delay`

- Default setting **`(_:12661:3) Threshold`** = ***`1.200 A`*** (for the first stage)
- Default setting **`(_:12661:6) Operate delay`** = ***`0.300 s`*** (for the first stage)

Set the **`Threshold`** and **`Operate delay`** parameters for the specific application.

6.25.4 Stage with Inverse-Time Characteristic Curve

6.25.4.1 Description

Logic of the Stage

[lo_def_ocp, 3, en_US]

Figure 6-454 Logic Diagram of the Inverse-Time Overcurrent Protection (1-Phase)

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI

When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout

according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Method of Measurement

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Blocking of the Stage

The picked up stage can reset completely via the binary input signal *>Block stage*.

Blocking of the Time Delay

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also tripping. A running time delay is reset. The pickup is reported and a fault is opened.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.9.11 Blocking of the Tripping by Device-Internal Inrush-Current Detection*.

6.25.4.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:12691:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Type of character. curve

- Default setting **(_:12691:108) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application.

Parameter: `Threshold`

- Default setting **`(_:12691:3) Threshold`** = ***`1.200 A`***

Set the **`Threshold`** and **`Type of character. curve`** parameters for the specific application.

Note that a safety margin is set between pickup value and threshold value. The stage only picks up at approx. 10 % above the **`Threshold`**.

Parameter: `Time dial`

- Default setting **`(_:12691:101) Time dial`** = ***`1`***

Use the **`Time dial`** parameter to displace the characteristic curve in the time direction.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the parameter **`Time dial`** at ***`1`*** (default setting).

Parameter: `Reset`

- Default setting **`(_:12691:109) Reset`** = ***`disk emulation`***

You use the **`Reset`** parameter to define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Use this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

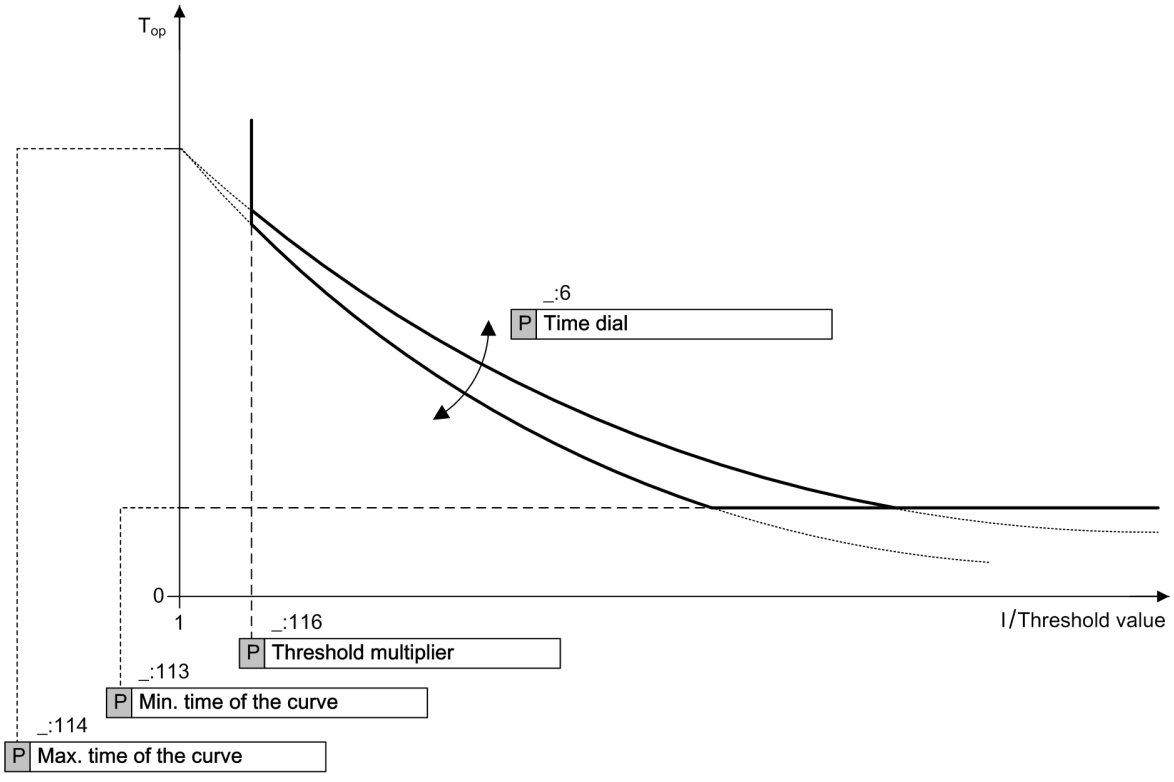
6.25.5 Stage with Inverse-Time Overcurrent Protection with Logarithmic-Inverse Characteristic Curve

6.25.5.1 Description

Logic of the Stage

[lo_ocp 1phase logarithmic, 3, en_US]

Figure 6-455 Logic Diagram of the Logarithmic Inverse-Time Overcurrent Protection (1-Phase)



Apart from the operate curve, this type of stage is identical to the **Inverse-time overcurrent protection** stage (see chapter *6.25.4.1 Description*).

This section will only discuss the nature of the operate curve. For further functionality, refer to chapter *6.25.4.1 Description* .

Operate Curve

If the function picks up, the logarithmic inverse-time characteristic curve is processed. A time value T_{op} is calculated for every input value exceeding 95 % of the pickup value. An integrator accumulates the value $1/T_{op}$. If the accumulated integral reaches the fixed value 1, the stage operates.

The curve used to calculate the time value T_{op} is shown in the following figure. The **Threshold multiplier** parameter defines the beginning of the characteristic curve. The **Max. time of the curve** determines the initial value of the characteristic curve. The **Time dial** parameter changes the slope of the characteristic curve. At high currents, the **Min. time of the curve** parameter indicates the lower time limit.

[dw_ocp 1phase logarithmic, 1, en_US]

Figure 6-456 Operate Curve of Logarithmic Inverse-Time Characteristic

The time to operate is calculated with the following formula:

$$T_{op} = T_{max} - T_d \ In\left(\frac{I}{I_{thresh} \cdot I_{mul}}\right)$$

[fo_ocp 1phase logarithmic, 1, en_US]

Where

T_{max}	Maximum time of the curve (parameter **Max. time of the curve**)
T_d	Time dial (parameter **Time dial**)
T_{op}	Operate time
I	1-phase current
I_{thresh}	Threshold value (parameter **Threshold**)
I_{mul}	Threshold multiplier (parameter **Threshold multiplier**)

If the calculated time is less than T_{min} (parameter **Min. time of the curve**), T_{min} is used.

6.25.5.2 Application and Setting Notes

Apart from the operate curve, this type of stage is identical to the ground-fault protection type with inverse-time delay according to IEC and ANSI (see chapter *6.25.4.1 Description*).

This section only discusses the nature of the operate curve. For further functionality, refer to chapter *6.25.4.2 Application and Setting Notes* .

Stage Type Selection

If the operate delay is to be dependent on the current level according to a logarithmic characteristic curve, select this stage type.

Parameter: `Threshold`

- Default setting **`(_:3) Threshold`** = ***`1.20 A`***

With the parameter **`Threshold`**, you define the pickup value corresponding to the application. In doing so, for the time-graded stages, the setting for the superordinate and subordinate stages must be taken into account in the grading chart.

Parameter: `Threshold multiplier`

- Default setting **`(_:116) Threshold multiplier`** = ***`1.1`***

With the parameter **`Threshold multiplier`**, you define the beginning of the characteristic curve on the current axis (in relation to the threshold value).

General information cannot be provided. Define the value corresponding to the application.

EXAMPLE

`Threshold` (Secondary current)	I_{thresh} = 1.2 A
`Threshold multiplier`	I_{mul} = 1.1
Pickup value (Secondary current)	I_{PU} = 1.2 A ×1.1 = 1.32 A

Parameter: `Time dial`

- Default setting **`(_:6) Time dial`** = ***`1.250 s`***

With the parameter **`Time dial`**, you change the slope of the characteristic curve.

General information cannot be provided. Define the value corresponding to the application.

Parameter: `Max. time of the curve`

- Default setting **`(_:114) Max. time of the curve`** = ***`5.800 s`***

The parameter **`Max. time of the curve`** determines the initial value of the characteristic curve (for I = **`Threshold`**).

General information cannot be provided. Define the value corresponding to the application.

Parameter: `Min. time of the curve`

- Default setting **`(_:113) Min. time of the curve`** = ***`1.200 s`***

The parameter **`Min. time of the curve`** determines the lower time limit (at high currents).

General information cannot be provided. Define the value corresponding to the application.

Parameter: `Additional time delay`

- Default setting **`(_:115) Additional time delay`** = ***`0 s`***

With the parameter **Additional time delay**, you set an additional current-independent time delay. This additional delay is intended for special applications.
Siemens recommends setting this time to ***0 s*** so that it has no effect.

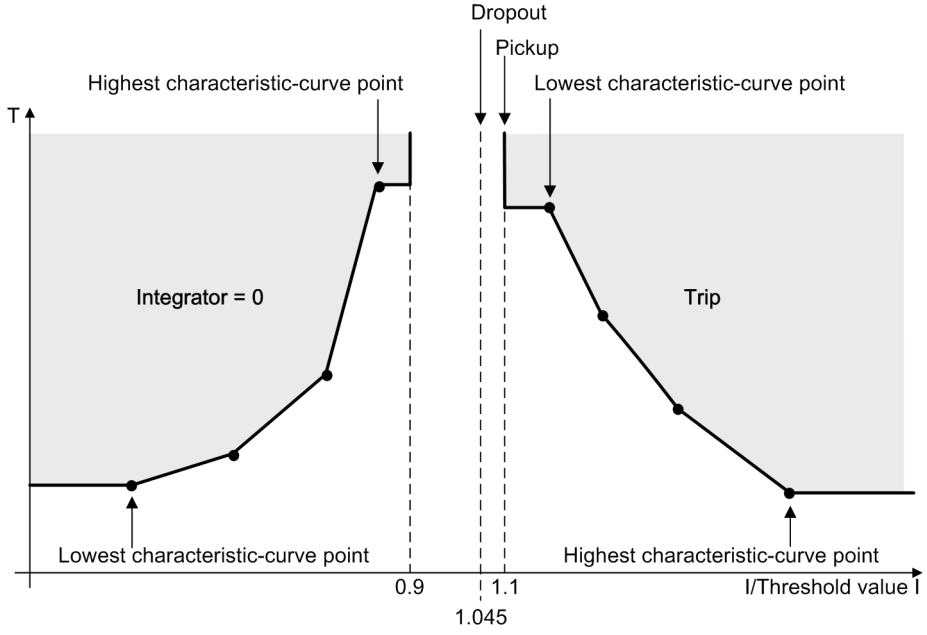
6.25.6 Stage with User-Defined Characteristic Curve

6.25.6.1 Description

The **User-defined characteristic curve overcurrent protection** stage is only available in the advanced function type.

This stage is structured the same way as the stage with the inverse-time characteristic curve. The only difference is that you can define the characteristic curve as desired.

User-Defined Characteristic Curve



With the user-defined characteristic curve, you can define the operate curve point by point using up to 30 value pairs of current and time. The device uses linear interpolation to calculate the characteristic curve from these values. You can also define a dropout characteristic curve if you wish.

Pickup and Dropout Behaviors with the User-Defined Characteristic Curve

When the input variable exceeds the threshold value by 1.1 times, the characteristic curve is processed.

An integrating method of measurement totalizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls short of the pickup value by a factor of 1.045 (0.95 x 1.1 x threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

[dw_ocp_ken_02, 2, en_US]

Figure 6-457 Pickup Behavior and Dropout Behavior when Using a User-Defined Characteristic Curve

NOTE

Note that the currents that are lower than the current value of the smallest characteristic-curve point do not extend the operate time. The pickup characteristic runs in parallel to the current axis up to the smallest characteristic-curve point. Currents that are larger than the current value of the largest characteristic-curve point do not reduce the operate time. The pickup characteristic runs in parallel to the current axis from the largest characteristic-curve point.

6.25.6.2 Application and Setting Notes

This stage is structured the same way as the stage with the inverse-time characteristic curve. The only difference is that you can define the characteristic curve as desired. This chapter only provides application and setting notes for setting characteristic curves.

Parameter: `Current/time value pairs` (from the operate curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **`Threshold`** parameter to ***`1.00`*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to displace the characteristic curve.

Set the time value in seconds. The characteristic curve is displaced using the **`Time dial`** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: `Time dial`

- Default setting **`(_:101) Time dial`** = ***`1`***

Use the **`Time dial`** parameter to displace the characteristic curve in the time direction.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the **`Time dial`** parameter at ***`1`***.

Parameter: `Reset`

- Default setting **`Reset`** = ***`disk emulation`***

You use the **`Reset`** parameter to define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	In the case of this setting, a dropout characteristic curve has to be set in addition to the operate curve. Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Use this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

Parameter: `Current/time value pairs` (of the dropout characteristic curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **`Threshold`** parameter to ***`1.00`*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to displace the characteristic curve.

Set the time value in seconds. The characteristic curve is displaced using the **`Time dial`** parameter.

NOTE

The value pairs must be entered in continuous order.

6.25.7 Fast Stage

6.25.7.1 Description

Logic of a Stage

The fast stage is only available in function type Advanced.

[lo_ocp_1phs, 3, en_US]

Figure 6-458 Logic Diagram of the Fast Stage, 1-Phase

Method of Measurement, Pickup and Dropout Behaviors of the Fast Stage

This stage evaluates the unfiltered measurands. Thus, very short response times are possible. When the absolute values of 2 consecutive sampled values of the last half period exceed the **Threshold**, the stage picks up. When all sampled values of the previous period are less than the dropout threshold, the stage drops out.

Blocking of the Stage

The picked up stage can reset completely via the binary input signal *>Block stage*.

6.25.7.2 Application and Setting Notes

Parameter: Threshold, Operate delay

- Default setting **(_:3) Threshold** = ***10.00 A***
- Default setting **(_:6) Operate delay** = ***0.00 s***

Set the **Threshold** and **Operate delay** parameters for the specific application.

Ensure that the sampled values are compared directly without an additional factor with the set threshold value.

Parameter: `Dropout ratio`

- Recommended setting value **`(_:4) Dropout ratio`** = ***`0.90`***

The recommended setting value of ***`0.90`*** is sufficient for many applications. To obtain high-precision measurements, the **`Dropout ratio`** can be reduced. If you expect highly fluctuating measurands at the pickup threshold, you can increase the **`Dropout ratio`** setting. This avoids chattering of the tripping stage.

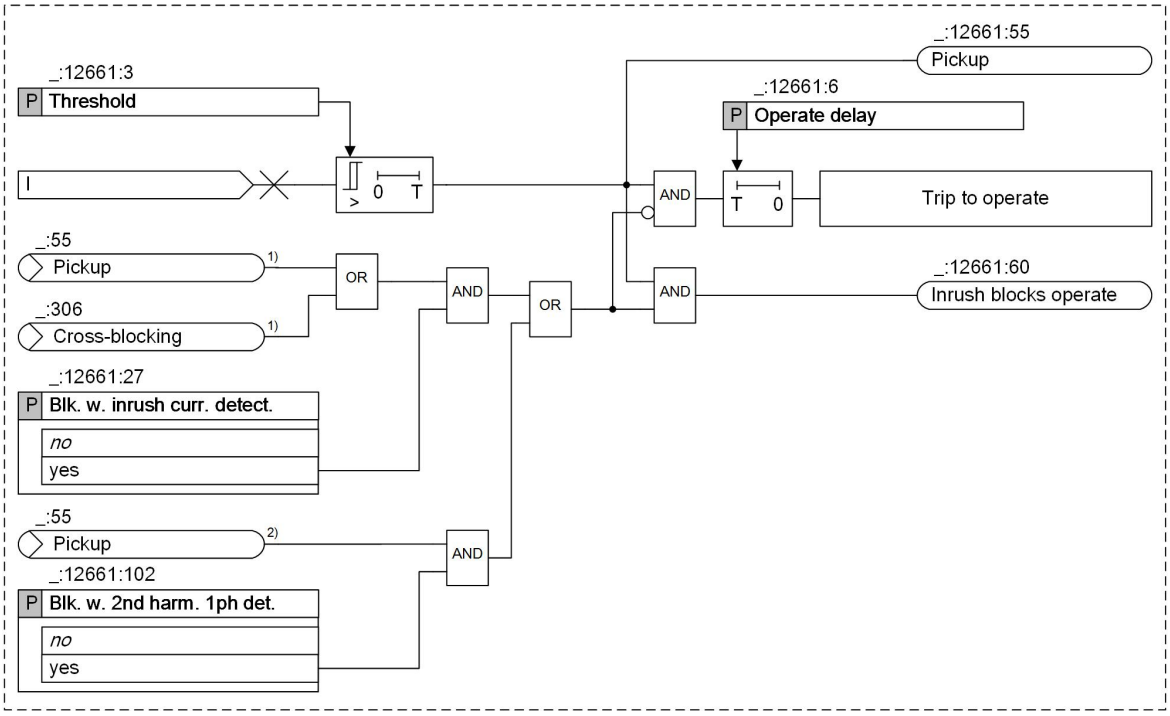
6.25.8 Blocking of the Tripping by Device-Internal Inrush-Current Detection



6.25.8.1 Description

The **`Blk. w. inrush curr. detect.`** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

The **`Blk. w. 2nd harm. 1ph det.`** parameter allows you to define whether the operate indication of the stage should be blocked when the detected 2nd harmonic component of the 1-phase current exceeds a threshold value. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time

delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

The following figure only shows the part of the stage (exemplified by definite-time overcurrent protection stage 1) that illustrates the influence of the inrush-current detection. Only if the central function **Inrush-current detection** (see section *12.62 Inrush-Current Detection*) is in effect can the blocking be set.

[lo_blk_by_inrush_ocp_1phase, 1, en_US]

(1) From FB **Inrush-current detection**

(2) From FB **2nd harmonic detection 1-phase**

6.25.8.2 Application and Setting Notes

Parameter: **`Blk. w. inrush curr. detect.`**

- Default setting **`(_:12661:27) Blk. w. inrush curr. detect.`** = ***`no`***

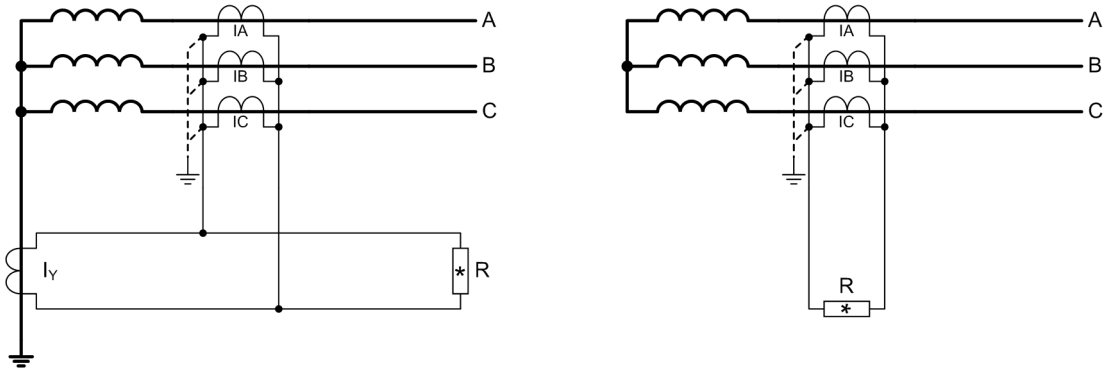
Parameter Value	Description
no	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This, for example, applies to the high-current stage that is set such according to the short-circuit voltage V_{sc} of the transformer that it only picks up on faults from the high-voltage side. The transformer inrush current cannot become larger than the maximum transmittable short-circuit current.
yes	When the transformer inrush-current detection detects an inrush current that would lead to a tripping of the stage, the start of the time delay and tripping of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

Parameter: **`Blk. w. 2nd harm. 1ph det.`**

- Default setting **`(_:12661:102) Blk. w. 2nd harm. 1ph det.`** = ***no***

Parameter Value	Description
no	If no 1-phase current flow due to CT saturation with a level above the pickup threshold is expected, select this setting.
yes	If 1-phase current flow due to CT saturation with a level above the pickup threshold is expected, the blocking must be activated. This provides stability for the following conditions: • CT saturation without inrush current since a saturated signal also contains 2nd-harmonic content • Phase inrush current that leads to CT saturation and therefore causes 2nd-harmonic inrush current being present also in the parasitic 1-phase current

6.25.9 Application Example: High-Impedance Restricted Ground-Fault Protection



6.25.9.1 Description

With the high-impedance method, all current transformers operate in parallel at the limits of the protection range on a common, relatively high-impedance resistor R, the voltage of which is measured.

The current transformers must be of the same type of construction and have at least one core of their own for the High-impedance restricted ground-fault protection. Furthermore, they must have the same transfer ratio and approximately the same knee-point voltage.

The high-impedance principle is especially suited for ground-fault detection in grounded networks at transformers, generators, motors, and shunt reactors.

The left part of *Figure 6-460* shows an application example for a grounded transformer winding or a grounded motor/generator. The example at the right shows an ungrounded transformer winding or an ungrounded motor/generator. In this example, it is assumed that the network is grounded at a different point.

[dw_himpef, 2, en_US]

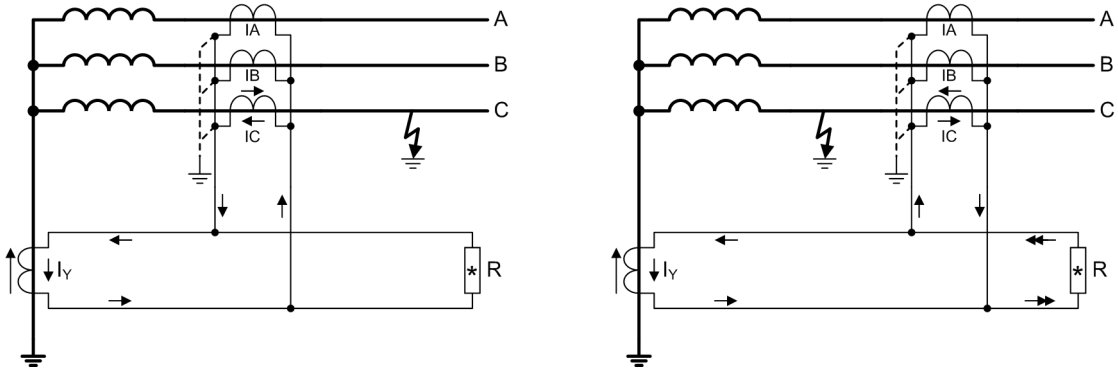


Figure 6-460 Restricted Ground-Fault Protection According to the High-Impedance Principle

Function of the High-Impedance Principle

The high-impedance principle is explained using the example of a grounded transformer winding.

In normal state, no residual currents flow, that is, in the transformer neutral point $I_Y = 0$ and in the phases $3I_0 = I_A + I_B + I_C = 0$.

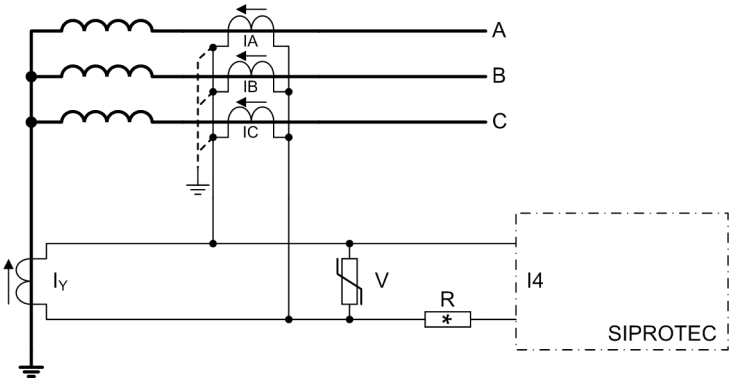
With an external ground fault (on the left in *Figure 6-461*), the short-circuit current of which is fed via a grounded neutral point, the same current flows in the transformer neutral point and in the phases. The respective secondary currents (with the same transfer ratio of all current transformers) draw each other off. They are connected in series. At the resistor R, only a little voltage arises, which results from the internal resistances of the transformers and those of the transformer connection lines. Even if a current transformer is briefly saturated, it becomes a low-impedance during the time of the saturation and forms a low-impedance shunt to the high-impedance resistor R. The high resistance of the resistor thus has a stabilizing effect (so-called resistor stabilization).

[dw_prhimp, 2, en_US]

Figure 6-461 Principle of the Restricted Ground-Fault Protection According to the High-Impedance Principle

With a ground-fault in the protection range (on the right in *Figure 6-461*), a neutral-point current I_Y flows in any case. The magnitude of the residual current in the phase currents depends on the grounding conditions in the rest of the network. A secondary current corresponding to the entire short-circuit current attempts to flow via the resistor R. But since this resistor is high-impedance, a high voltage arises there which causes the saturation of the current transformers. The effective voltage at the resistor therefore corresponds approximately to the knee-point voltage of the current transformers.

The resistor R is thus dimensioned in such a way that even the smallest ground-fault current to be detected leads to a secondary voltage that corresponds to half of the knee-point voltage of the current transformers (see chapter 2.5.4).



Further information can be found at *Sensitivity view for high-impedance ground-fault differential protection* in chapter *6.25.9.2 Application and Setting Notes* .

High-Impedance Restricted Ground-Fault Protection with a SIPROTEC 5 Device

Use the I4 measuring input of the SIPROTEC 5 device for the high-impedance restricted ground-fault protection. This input for this application is to be executed as a sensitive measuring input. Since this is a current input, the current is detected by this resistor instead of the voltage at the resistor R.

Figure 6-462 shows the connection diagram. The protection device is connected in series with the resistor R and thus measures its current.

The varistor V limits the voltage in case of an internal fault. The varistor cuts the high instantaneous voltage peaks in the case of transformer saturation. Simultaneously, a smoothing of the voltage arises without any relevant reduction of the average value.

[dw_anedif, 2, en_US]

Figure 6-462 Connection Diagram of the Restricted Ground-Fault Protection According to the High-Impedance Principle

As a protection against overvoltages, it is important that you connect the device directly at the grounded side of the current transformer. The high voltage at the resistor is thus kept away from the device.

In a similar manner, the high-impedance restricted ground-fault protection for generators, motors, and shunt reactors is used. With auto transformers, you must connect the upper-voltage side and low-voltage side current transformers and neutral-point transformer in parallel.

The method can be realized for each protected object. As busbar protection, the device, for example, is connected via the resistor to the parallel connection of the transformers of all feeders.

6.25.9.2 Application and Setting Notes

A prerequisite for the application of the high-impedance restricted ground-fault protection is that neutral-point current detection is possible on the station side (see example in (*Figure 6-462*). Furthermore, a sensitive input transformer must be available at device input I4. Set the pickup value for current at input I4 with the function **Overcurrent protection, 1-phase**.

Observe the interaction between current-transformer characteristic curve, external resistor R, and the voltage at R for the overall function of the high-impedance restricted ground-fault protection. Notes on this follow.

Current Transformer Data for High-Impedance Restricted Ground-Fault Protection

All affected current transformers must have the same ratio and approximately the same knee-point voltage. This is normally the case when the current transformers are of the same type and have the same rated data. You can calculate the knee-point voltage from the rated data as follows:

$$V_{KP} = \left(R_i + \frac{P_{rated}}{I_{rated}^2} \right) \cdot n \cdot I_{rated}$$

[fo_ukniep, 1, en_US]

V_{KP}	Knee-point voltage
Ri	Internal resistance of the current transformer
P_{rated}	Rated power of the current transformer

I_{rated}	Secondary rated current of the current transformer
n	Rated overcurrent factor

Rated current, rated power, and overcurrent factor are found on the name plate of the transformer.

EXAMPLE

Current transformer with the following data on the name plate: 800/5; 5P10; 30 VA
You can read the following transformer data with this data:

I_{rated}	= 5 A (out of 800/**5**)
n	= 10 (out of 5P**10**)
P_{rated}	= **30** VA

The internal resistance is frequently to be found in the test report of the transformer. If it is not known, it can be approximately determined by a direct current measurement at the secondary winding.

EXAMPLE

Calculation of the knee-point voltage
Current transformer 800/5; 5P10; 30 VA with $R_i = 0.3\ \Omega$

$$V_{KP} = \left(R_i + \frac{P_{rated}}{I_{rated}^2} \right) \cdot n \cdot I_{rated} = \left(0.3\ \Omega + \frac{30\ \text{VA}}{(5\ \text{A})^2} \right) \cdot 10 \cdot 5\ \text{A} = 75\ \text{V}$$

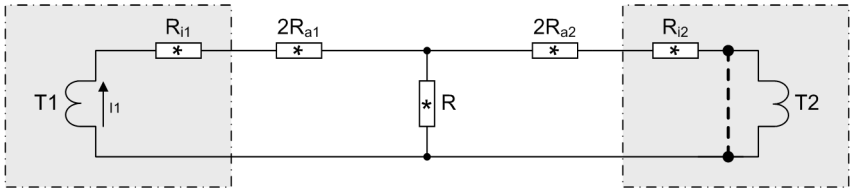
[fo_ukp5aw, 1, en_US]

Current transformer 800/1; 5P10; 30 VA with $R_i = 5\ \Omega$

$$V_{KP} = \left(R_i + \frac{P_{rated}}{I_{rated}^2} \right) \cdot n \cdot I_{rated} = \left(5\ \Omega + \frac{30\ \text{VA}}{(1\ \text{A})^2} \right) \cdot 10 \cdot 1\ \text{A} = 350\ \text{V}$$

[fo_ukp1aw, 1, en_US]

Besides the current-transformer data, the resistance of the longest connection line between transformer and device must be known.



Stability Consideration for High-Impedance Restricted Ground-Fault Protection

The stability condition is based on the simplified assumption that one current transformer is completely saturated and the others transfer their partial currents proportionately in the case of an external fault. This is theoretically the worst case. A safety margin is automatically provided, since, in practice, even the saturated transformer still delivers some current.

Figure 6-463 shows an equivalent circuit of this simplification. CT1 and CT2 are assumed to be ideal transformers with their internal resistances R_{i1} and R_{i2}. R_a are the core resistances of the connection lines between transformer and resistance R; they are used doubled (forward line and return line). R_{a2} is the resistance of the longest connection line.

CT1 transmits the current I1. CT2 is assumed to be saturated. This is indicated by the dotted short-circuit line. The transformer thus represents a low-impedance shunt by its saturation.

A further prerequisite is $R >> (2R_{a2} + R_{i2})$.

[dw_vebhdi, 2, en_US]

Figure 6-463 Simplified Connection Diagram of a Layout for High-Impedance Restricted Ground-Fault Protection

The voltage at R is, then,

$V_R = I_1 \cdot (2R_{a2} + R_{i2})$

A further assumption is that the pickup value of the SIPROTEC 5 device corresponds to half of the knee-point voltage of the current transformers. In the edge case,

$V_R = V_{KP}/2$

The stability limit I_{SL} results, which means the through fault current up to which the arrangement remains stable:

$$I_{SL} = \frac{V_{KP}/2}{2 \cdot R_{a2} + R_{i2}}$$

[fo_istabl, 1, en_US]

EXAMPLE

For the 5 A transformer as above with V_{KP} = 75 V and R_i = 0.3 Ω

Longest connection line = 22 m with 4 mm² cross-section; that corresponds to R_a = 0.1 Ω

$$I_{SL} = \frac{V_{KP}/2}{2 \cdot R_{a2} + R_{i2}} = \frac{37.5\ V}{2 \cdot 0.1\,\Omega + 0.3\,\Omega} = 75\ A$$

[fo_isl5aw, 1, en_US]

In the example, the stability limit is 15 × rated current or 12 kA primary.

For the 1 A transformer as above with V_{KP} = 350 V and R_i = 5 Ω

Longest connection line = 107 m with 2.5 mm² cross-section; that corresponds to R_a = 0.75 Ω

$$I_{SL} = \frac{V_{KP}/2}{2 \cdot R_{a2} + R_{i2}} = \frac{175\ V}{2 \cdot 0.75\,\Omega + 5\,\Omega} = 27\ A$$

[fo_isl1aw, 1, en_US]

In the example, the stability limit is 27 × rated current or 21.6 kA primary.

Sensitivity Consideration for High-Impedance Restricted Ground-Fault Protection

The voltage present at the set of current transformers is supplied to the protection device via a series resistor R as proportional current for evaluation. For dimensioning of the resistor, the following must be taken into account:

The high-impedance restricted ground-fault protection should pick up at approximately half of the knee-point voltage of the current transformers. From this, you can calculate the resistor R.

Since the device measures the current through the resistor, the resistor and measuring input of the device must be connected in series. Since the resistor still should be high-impedance (aforementioned condition R >> $2R_{a2} + R_{i2}$), the inherent resistance of the measuring input can be neglected. The resistance results thus from the pickup current I_{pick} and half of the knee-point voltage:

$$R = \frac{V_{KP} / 2}{I_{pick.}}$$

[fo_berecr, 1, en_US]

EXAMPLE

For the 5 A transformer as above
Desired pickup value I_{pick} = 0.1 A (corresponds to 16 A primary)

$$R = \frac{V_{KP} / 2}{I_{pick.}} = \frac{75\ V / 2}{0.1\ A} = 375\ \Omega$$

[fo_ber5aw, 1, en_US]

For the 1 A transformer as above
Desired pickup value I_{pick} = 0.05 A (corresponds to 40 A primary)

$$R = \frac{V_{KP} / 2}{I_{pick.}} = \frac{350\ V / 2}{0.05\ A} = 3500\ \Omega$$

[fo_ber1aw, 1, en_US]

The series resistor R must be designed for a minimum continuous load $P_{continuous}$.

$$P_{continuous} \geq \frac{(V_{KP} / 2)^2}{R} = \frac{37.5^2}{375} = 3.75\ W \qquad \text{at the 5-A-transformer}$$

[fo_pdau5a, 1, en_US]

$$P_{continuous} \geq \frac{(V_{KP} / 2)^2}{R} = \frac{175^2}{3500} = 8.75\ W \qquad \text{at the 1-A-transformer}$$

[fo_pdau1a, 1, en_US]

Further, the series resistor R must be designed for a fault current lasting approximately 0.5 s. This time is usually sufficient for fault clearing through backup protection.
The thermal stress of the series resistor depends on the voltage $V_{RMS,stab}$ that is present during an internal fault.
It is calculated according to the following equations:

$$V_{RMS,rest} = 1.3 \cdot \sqrt[4]{V_{KP}^3 \cdot R \cdot I_{K,max,int}} = 1.3 \cdot \sqrt[4]{75^3 \cdot 375 \cdot 250} = 579.7\ V \qquad \text{at the 5-A-transformer}$$

[fo_usta5a, 1, en_US]

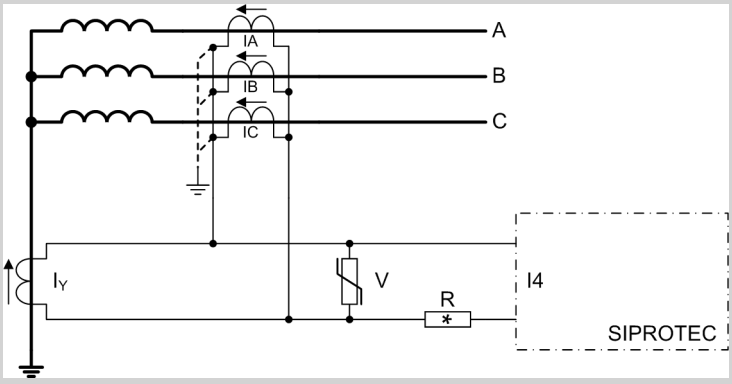
$$V_{RMS,rest} = 1.3 \cdot \sqrt[4]{V_{KP}^3 \cdot R \cdot I_{K,max,int}} = 1.3 \cdot \sqrt[4]{350^3 \cdot 3500 \cdot 50} = 2151.6\ V \qquad \text{at the 1-A-transformer}$$

[fo_usta1a, 1, en_US]

$I_{K,max,int}$ corresponds to the maximum fault current here in the case of an internal fault.
5-A current transformer 800/5 with 40 kA primary corresponds to $I_{K,max,int}$ = 250 A secondary.
1-A current transformer 800/1 with 40 kA primary corresponds to $I_{K,max,int}$ = 50 A secondary.
This results in a temporary load for the series resistor over 0.5 s of:

$$P_{0.5\,s} = \frac{V_{RMS,rest}^2}{R} = \frac{579.7^2}{375} = 896\ W \qquad \text{at the 5-A-transformer}$$

[fo_p05s5a, 1, en_US]



$$P_{0.5\,s} = \frac{V_{RMS,rest}^2}{R} = \frac{2151.6^2}{3500} = 1322.7\ W \qquad \text{at the 1-A-transformer}$$

[fo_p05s1a, 1, en_US]

Observe that with the selection of a higher pickup value I_{pick}, the resistor value must be lowered and therefore the dissipation rises sharply.

The varistor (see following figure) must be sized such that it remains high impedance up to the knee-point voltage, for example:

- Approx. 100 V with 5 A transformer
- Approx. 500 V with 1 A transformer

[dw_anedif, 2, en_US]

Figure 6-464 Connection Diagram of the Restricted Ground-Fault Protection According to the High-Impedance Principle

Even with unfavorable wiring, the maximum occurring voltage peaks do not exceed 2 kV for safety reasons.

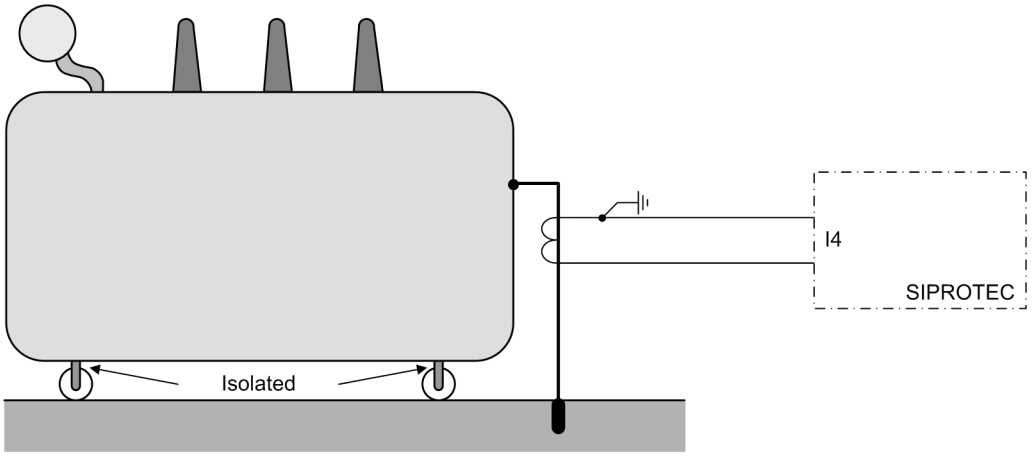
When for performance reasons, several varistors must be connected in parallel, give preference to types with flat characteristic curves, in order to avoid an unbalanced load. Siemens therefore recommends the following types by METROSIL:

600A/S1/S256 (k = 450, β = 0.25)

600A/S1/S1088 (k = 900, β = 0.25)

In the example, set the pickup value of the first Definite-time overcurrent protection stage (setting **Threshold**) to 0.1 A for 5-A transformers or 0.05 A for 1-A transformers. No further protection stages are needed. Delete these or switch them off. Set the **Operate delay** setting to 0 s.

If several current transformers are connected in series, for example, with use as busbar protection with several feeders, the magnetization currents of the transformers switched in parallel can no longer be neglected. In this case, add up the magnetization currents at half of the knee-point voltage (corresponds to the set **Threshold**). These magnetization currents reduce the current through the resistor R. Thus, the actual pickup value is correspondingly higher.



6.25.10 Application Example: Tank Leakage Protection

6.25.10.1 Description

Tank leakage protection records short-circuits to ground – including high-impedance ones – between a phase and the tank of a transformer. The tank is thus insulated, or at least grounded with high impedance. The tank must be connected with a line to ground. The current that flows through this line is fed to the protection device. If a short-circuit to ground occurs in a tank, a fault current (tank current) flows to substation ground via the ground connection.

The function **Overcurrent protection, 1-phase** detects the tank current. If the tank current exceeds the set **Threshold**, the function **Overcurrent protection, 1-phase** generates an operate indication. Depending on the set **Operate delay**, the transformer is tripped immediately or time-delayed on all sides.

For tank protection, a sensitive, 1-phase current measuring input is used.

[dw_prkess, 2, en_US]

Figure 6-465 Tank-Control Principle

6.25.10.2 Application and Setting Notes

A prerequisite for the application of tank protection is the availability of a sensitive input transformer at device input I4.

If you connect **Measuring point I 1-ph** with the function group **Voltage-current 1-phase**, the function **Overcurrent protection, 1-phase** works with the 1-phase current connected to input I4.

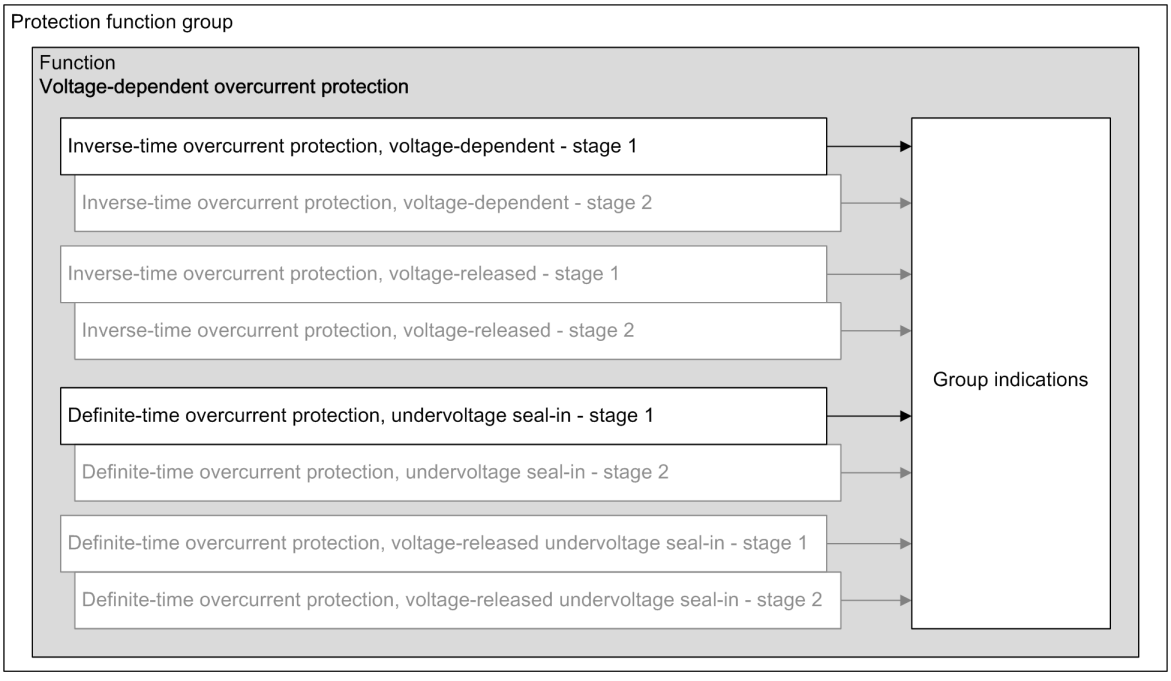
Use only the first definite-time overcurrent protection stage of function **Overcurrent protection, 1-phase**. The **`Threshold`** setting is used to set the pickup value. No further protection stages are needed. Delete these or switch them off. Set the **`Operate delay`** setting to 0 s.

6.26 Voltage-Dependent Overcurrent Protection, Phases

6.26.1 Overview of Functions

The **Voltage-dependent overcurrent protection** (ANSI 51V) function:

- Detects short circuits affecting electric equipment
- Can be used for special network conditions where the overcurrent pickup level should be decreased depending on the fault voltage
- Can be used for generators where the excitation voltage is derived from the machine terminals and the overcurrent pickup should be kept depending on the fault voltages



6.26.2 Structure of the Function

The **Voltage-dependent overcurrent protection** function is used in protection function groups with 3-phase current and voltage measurement.
The function **Voltage-dependent overcurrent protection** comes with the following factory-set stages:

- Inverse-time overcurrent protection, voltage-dependent stage
- Definite-time overcurrent protection, undervoltage seal-in stage

In this function, the following stages can operate simultaneously:

- A maximum of 2 inverse-time overcurrent protection, voltage-dependent stages
- A maximum of 2 inverse-time overcurrent protection, voltage-released stages
- A maximum of 2 definite-time overcurrent protection, undervoltage seal-in stages
- A maximum of 2 definite-time overcurrent protection, voltage-released undervoltage seal-in stages

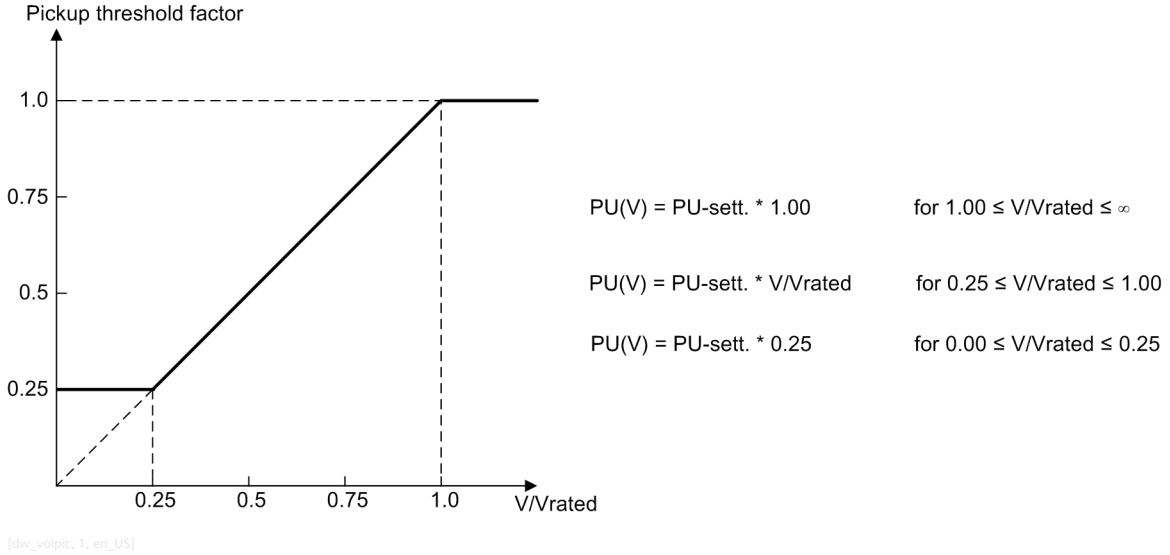
6.26.3 Stage with Inverse-Time Overcurrent Protection, Voltage-Dependent

6.26.3.1 Description

Logic of the Stage

[lo_ocp_volt-dependent, 3, en_US]

Figure 6-467 Logic Diagram of the Inverse-Time Overcurrent Protection, Voltage-Dependent



Method of Measurement

You use the **`Method of measurement`** parameter to define whether the stage uses the *`fundamental comp.`* (standard method) or the calculated *`RMS value`*.

- Measurement of the fundamental comp.:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Voltage-Dependent Pickup Threshold

The pickup threshold of the overcurrent stage depends on the voltage magnitude. A lower voltage decreases the current pickup value (see *Figure 6-468*). In the range between V/V_{rated} = 1.00 to 0.25 a linear, directly proportional dependence is realized.

[dw_volpic, 1, en_US]

Figure 6-468 Voltage Influence of the Pickup Threshold

With:

V	=	Measured phase-to-phase voltage
V_{rated}	=	Rated voltage (parameter Rated voltage in the function block General of the protection function group)
PU sett.	=	Pickup threshold setting (parameter address: _11491:3)
PU(V)	=	Applied pickup threshold according to the voltage influence

The minimum current pickup threshold value is 0.03 * Irated. This value cannot be decreased any further even not by voltage-dependent pickup threshold factor.

Decreasing the pickup threshold is carried out phase-selectively. The following table shows the assignment of voltages to current-carrying phases.

Table 6-11 Controlling Voltages in Relation to the Fault Current

Current	Controlling Voltage
I_A	V_{AB}
I_B	V_{BC}
I_C	V_{CA}

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI

When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results

from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Influence On the Operate Curve

The current pickup threshold is decreased proportional to the voltage decrease. Consequently, for a constant current I the I/Threshold-value ratio is increased and the operate time is reduced. Compared with the standard curves represented in the **Technical Data**, the operate curve shifts to the left side as the voltage decreases.

Measuring-Voltage Failure Detection

In case of a measuring-voltage failure detection the input voltage value is automatically set to V_{rated}, so that the pickup threshold factor will be 1.

Blocking of the Time Delay

You can use the binary input signal *>Block delay & op.* to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.23.7.1 Description* .

6.26.3.2 Application and Setting Notes

Parameter: **Blk. w. inrush curr. detect.**

- Default setting **(_:11491:27) Blk. w. inrush curr. detect.** = ***no***

Parameter Value	Description
no	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This applies, for example, to the high-current stage that is set according to the short-circuit voltage u_k of the transformer in such a way that the stage only picks up on faults from the high-voltage side. The transformer-inrush current cannot become larger than the maximum transmittable short-circuit current.
yes	When the transformer inrush-current detection detects an inrush current that would lead to a tripping of the stage, the start of the time delay and tripping of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

Parameter: Method of measurement

- Recommended setting value **(_:11491:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Threshold

- Default setting **(_:11491:3) Threshold** = ***1.500 A***

The recommended setting value of 1.500 A is suitable for most applications.

Set the **Threshold** and **Type of character. curve** parameters for the specific application.

The setting depends on the maximum occurring operating current. Pickup by overload must be excluded since overcurrent protection operates with short tripping times as short-circuit protection and not as overload protection.

Set the **Threshold** parameter for lines to approx.10 %, for transformers and motors to approx. 20 % above the maximum expected load.

Note that a safety margin is set between pickup value and threshold value. The stage only picks up at approx. 10 % above the **Threshold**.

Parameter Type of character. curve

- Default setting **(_:11491:101) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application.

Parameter: Reset

- Default setting **(_:11491:102) Reset** = ***disk emulation***

The **Reset** parameter allows you to define whether the stage decreases according to the dropout characteristic curve (behavior of a disk emulation = rotor disc) or instantaneously.

Parameter Value	Description
disk emulation	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Select this setting if the dropout does not have to be performed after a disk emulation and an instantaneous dropout is desired instead.

Parameter: Time dial

- Default setting **(_:11491:103) Time dial** = ***1***

You can use the **Time dial** parameter to displace the characteristic curve in the time direction.

The setting value for the **Time dial** parameter is derived from the time-grading chart that has been prepared for the electrical power system.
Where no time grading and therefore no displacement of the characteristic curve is required, leave the parameter **Time dial** at 1 (default setting).

6.26.4 Stage with Inverse-Time Overcurrent Protection, Voltage-Released

6.26.4.1 Description

Logic of the Stage

[lo_ocp_volt-release, 3, en_US]

Figure 6-469 Logic Diagram of the Inverse-Time Overcurrent Protection, Voltage-Released

This stage is structured in the same way as the Inverse-time overcurrent, voltage-dependent stage (see *6.26.3.1 Description*). The only differences are the conditions for the pickup and the influence on the operate curve.

Measuring-Element Release

When the controlling voltage drops below the setting **Undervoltage threshold**, the respective measuring element is released.

The release of the measuring elements is carried out phase-selectively. The assignment of voltages to current-carrying phases is shown in *Figure 6-468*.

Blocking of the Stage with Measuring-Voltage Failure

The stage can be blocked if a measuring-voltage failure occurs. In case of a blocking, the picked up stage is reset. The following blocking options are available for the stage:

- From an internal source upon pickup of the **Measuring-voltage failure detection** function
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker

The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

6.26.4.2 Application and Setting Notes

This stage is structured in the same way as the **Inverse-time overcurrent, voltage-dependent** stage. The only differences are the conditions for the pickup and the influence on the operate curve. This chapter only provides the application and setting notes for the setting **Blk. by meas.-volt. failure** and **Undervoltage threshold**. For guidance on the other parameters of this stage, refer to *6.26.3.2 Application and Setting Notes*.

Parameter: Blk. by meas.-volt. failure

- Recommended setting value **(_:10) Blk. by meas.-volt. failure** = ***yes***

You can use the **Blk. by meas.-volt. failure** parameter to control the response of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal **Measuring-voltage failure detection** function is configured and switched on.
- The binary input signal *>Open* of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker.

Parameter Value	Description
no	The overcurrent-protection stage is not blocked when a measuring-voltage failure is detected.
yes	The overcurrent-protection stage is blocked when a measuring-voltage failure is detected. Siemens recommends using the default setting, as correct operation of the stage cannot be guaranteed if a measuring-voltage failure occurs.

Parameter: Undervoltage threshold

- Default setting **(_:104) Undervoltage threshold** = ***75.0 V***

When the controlling voltage is below the set value, the **Inverse-time overcurrent protection** stage is released.

The parameter is set to a value just below the lowest phase-to-phase voltage admissible during operation, for example, from 75 % to 80 % of V_{rated}.

6.26.5 Stage with Definite-Time Overcurrent Protection, Undervoltage Seal-In

6.26.5.1 Description

Logic of the Stage

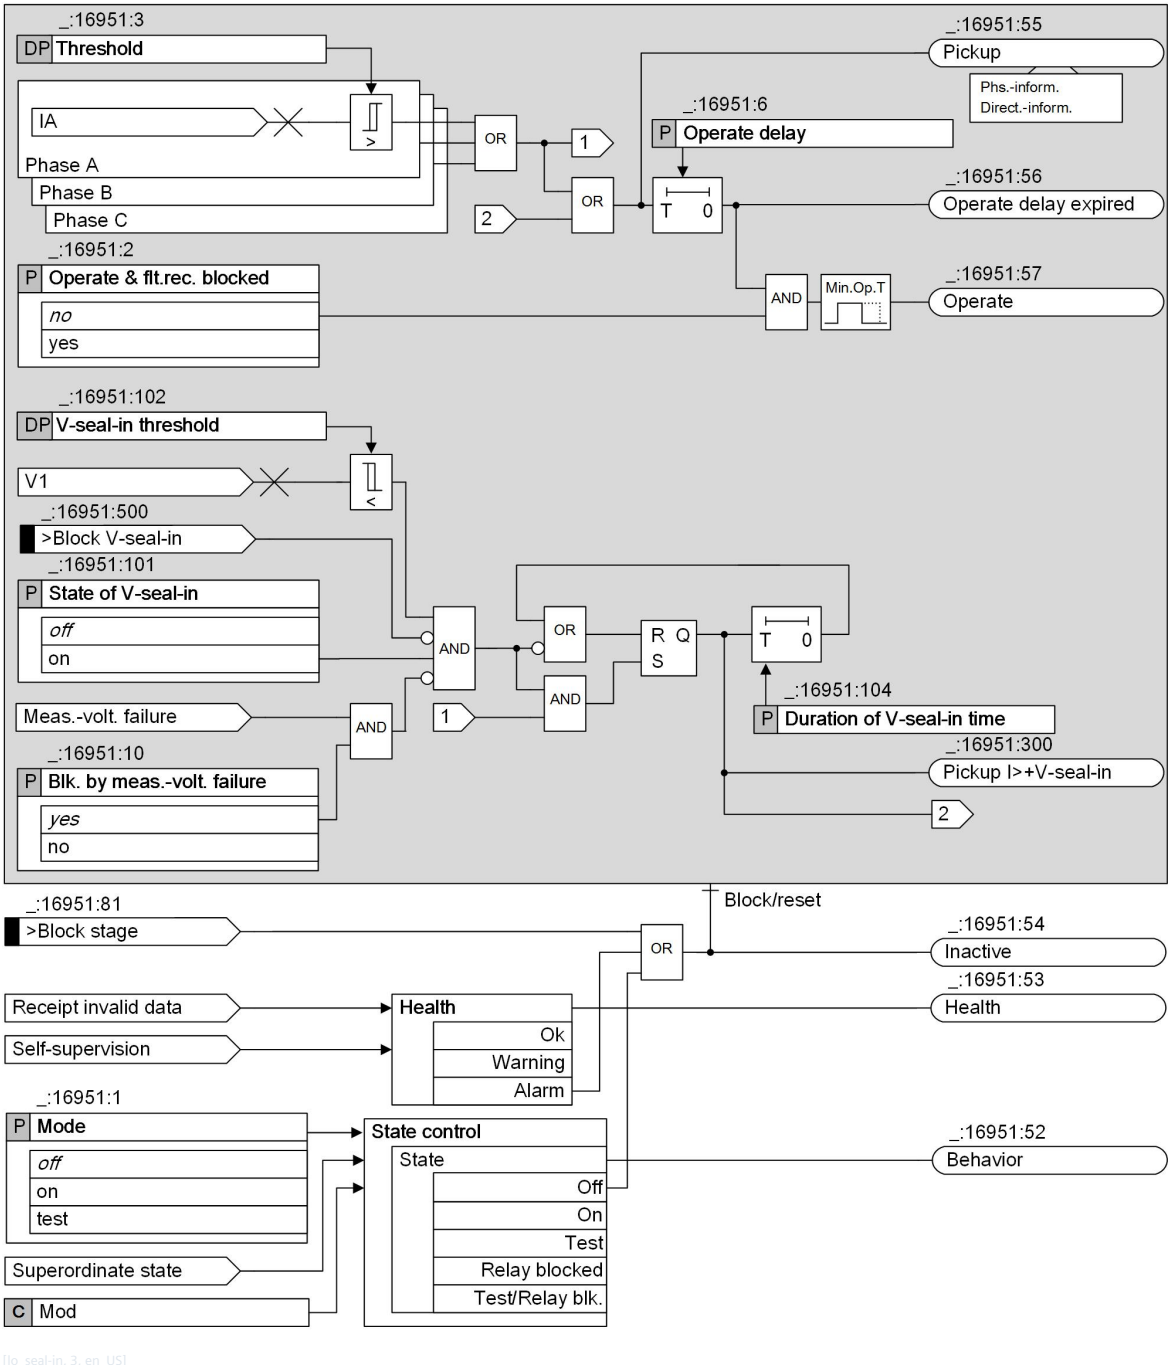

Figure 6-470 Logic Diagram of the Definite-Time Overcurrent Protection, Undervoltage Seal-in

Undervoltage Seal-In

In generators where the excitation voltage is derived from the machine terminals, the short-circuit current decreases quickly in the event of close-in faults (for example, in a generator or a generator-transformer range). The current decreases to a value below the current threshold within a few seconds because of the

absence of the excitation voltage. To avoid a dropout of the relay, the positive-sequence voltages are used as an additional criterion for detecting a short circuit.

The pickup signal is maintained for a settable seal-in time **Duration of V-seal-in time**, if the positive-sequence voltage falls below a settable threshold **V-seal-in threshold** after an overcurrent pickup, even if the current falls below the threshold again. If the voltage recovers before the seal-in time has elapsed, or if the undervoltage seal-in is blocked via a binary input *>Block V-seal-in*, the signal *Pickup I>+V-seal-in* drops out immediately.

You can switch off the undervoltage seal-in via the parameter **State of V-seal-in**.

Blocking of the Undervoltage Seal-in with Measuring-Voltage Failure

The **Undervoltage seal-in** can be blocked if a measuring-voltage failure occurs. In case of a blocking, the pickup signal *Pickup I>+V-seal-in* drops out immediately. The following blocking options are available for the **Undervoltage seal-in**:

- From an internal source upon pickup of the **Measuring-voltage failure detection** function.
- From an external source via the binary input signal *>Open* of the function block **VT miniature CB**, which links in the tripping of the voltage-transformer circuit breaker.

The parameter **Blk. by meas.-volt. failure** can be used to control the measuring-voltage failure detection. The **Undervoltage seal-in** remains unaffected if the parameter **Blk. by meas.-volt. failure** is switched off.

6.26.5.2 Application and Setting Notes

Parameter: Operate & flt.rec. blocked

- Default setting **(_:16951:2) Operate & flt.rec. blocked** = ***no***

With the parameter **Operate & flt.rec. blocked**, you can block the operate indication, the fault recording, and the fault log.

Parameter: Threshold

- Default setting **(_:16951:3) Threshold** = ***1.350 A***

The setting is mainly determined by the maximum operating current.

Pickup by overload must be excluded since the protection may trip if a short operate delay time is set. Set the **Threshold** parameter for generators to a value between 20 % and 30 %, for transformers and motors approx. 40 % above the expected peak load.

Parameter: Operate delay

- Default setting **(_:16951:6) Operate delay** = ***3.00 s***

The parameter **Operate delay** must be coordinated with the time grading of the network protection to guarantee the selectivity. Practical time delays are between 1 s to 2 s.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:16951:10) Blk. by meas.-volt. failure** = ***yes***

With the parameter **Blk. by meas.-volt. failure**, you can activate (***yes***) or deactivate (***no***) the blocking by the **Measuring voltage failure detection** function. The recommended setting is the default setting.

Parameter: State of V-seal-in

- Default setting **(_:16951:101) State of V-seal-in** = ***off***

With the parameter **State of V-seal-in**, the seal-in functionality can be activated (switched ***on***). Siemens recommends this setting if the excitation transformer is connected to the main lead of the generator.

Parameter: `V-seal-in threshold`

- Default setting **`(_:16951:102) V-seal-in threshold`** = ***`46.2 V`***

The **`V-seal-in threshold`** (positive-sequence voltage) is set to a value below the lowest phase-to-phase voltage admissible during an operation, for example 80 % of the rated voltage of a generator. The positive-sequence voltage is evaluated. The practicable value for a voltage transformer with a rated secondary voltage of 100 V is 46.2 V.

The following table shows an example of a specification:

Threshold	1.4 * $I_{rated, Gen}$		
Operate delay	3.00 s		
Undervoltage seal-in	0.8 * $V_{rated, Gen}$		
Duration of V-seal-in time	4.00 s		
Dropout ratio	0.95		
Rated current $I_{rated, Gen}$	483 A	Rated voltage $V_{rated, Gen}$	6.3 kV
Rated current $I_{rated, VT, prim}$	500 A	Rated voltage $V_{rated, VT, prim}$	6.3 kV
Rated current $I_{rated, VT, sec}$	1 A	Rated voltage $V_{rated, VT, sec}$	100 V

The following secondary setting values result from this specification:

$$\text{Threshold} = \frac{1.4 \times I_{rated,Gen}}{I_{rated,CT,prim}} \times I_{rated,VT,sec} = \frac{1.4 \times 483\ A}{500\ A} \times 1\ A = 1.35\ A$$

[fo_ocp_uvsi_threshold, 1, en_US]

$$\text{Undervoltage seal} - \text{in} = \frac{0.8 \times V_{rated,Gen}}{V_{rated,VT,prim}} \times \frac{V_{reated,VT,sec}}{\sqrt{3}} = \frac{0.8 \times 6.3\ kV}{6.3\ kV} \times \frac{100\ V}{\sqrt{3}} = 46.200\ V$$

[fo_ocp_uvsi_seal-in, 1, en_US]

Parameter: `Duration of V-seal-in time`

- Default setting **`(_:16951:104) Duration of V-seal-in time`** = ***`4.00 s`***

The parameter **`Duration of V-seal-in time`** limits the pickup seal-in induced by an overcurrent or undervoltage. The value must be set higher than the value of the parameter **`Operate delay`**. The difference shall be greater than 0.5 s. In the default setting, a difference of 1 s is used.

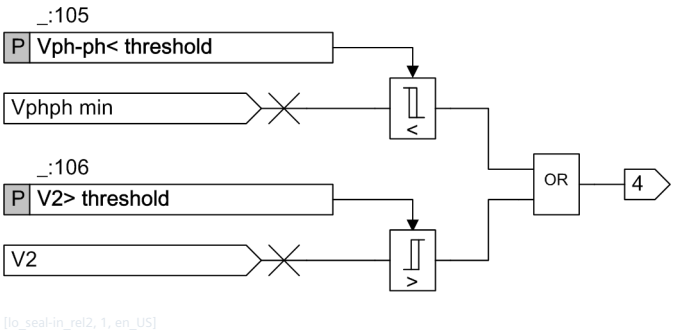
6.26.6 Stage with Definite-Time Overcurrent Protection, Voltage-Released Undervoltage Seal-In

6.26.6.1 Description



Logic of the Stage

[lo_seal-in_rel, 3, en_US]

Figure 6-471 Logic Diagram of the Definite-Time Overcurrent Protection, Voltage-Released Undervoltage Seal-in, Part 1

Signal 4 in the following figure refers to *Figure 6-471*.

[lo_seal-in_rel2, 1, en_US]

Figure 6-472 Logic Diagram of the Definite-Time Overcurrent Protection, Voltage-Released Undervoltage Seal-in, Part 2

Voltage Release

In addition to the current criterion with undervoltage seal-in, a voltage-released logic must be present to issue the indication *Pickup*. The voltage-released logic monitors the negative-sequence voltage and phase-to-phase voltages respectively for detecting unsymmetrical faults and symmetrical faults. With the voltage-released logic, the setting value of the parameter **Threshold** can be reduced in a certain range and the reliability and sensibility of this function can be improved correspondingly.

Undervoltage Seal-In

In generators where the excitation voltage is derived from the machine terminals, the short-circuit current decreases quickly in the event of close-in faults (for example, in a generator or a generator-transformer range). The current decreases to a value below the current threshold within a few seconds because of the absence of the excitation voltage. To avoid a dropout of the relay, the positive-sequence voltages are used as an additional criterion for detecting a short circuit.

The pickup signal is maintained for a settable seal-in time **Duration of V-seal-in time**, if the positive-sequence voltage falls below a settable threshold **V-seal-in threshold** after an overcurrent pickup, even if the current falls below the threshold again. If the voltage recovers before the seal-in time has elapsed, or if the undervoltage seal-in is blocked via a binary input *>Block V-seal-in*, the signal *Pickup I>+V-seal-in* drops out immediately.

You can switch off the undervoltage seal-in via the parameter **State of V-seal-in**.

Blocking of the Undervoltage Seal-in with Measuring-Voltage Failure

The **Undervoltage seal-in** can be blocked if a measuring-voltage failure occurs. In case of a blocking, the pickup signal *Pickup I>+V-seal-in* drops out immediately. The following blocking options are available for the **Undervoltage seal-in**:

- From an internal source upon pickup of the **Measuring-voltage failure detection** function.
- From an external source via the binary input signal *>Open* of the function block **VT miniature CB**, which links in the tripping of the voltage-transformer circuit breaker.

The parameter **Blk. by meas.-volt. failure** can be used to control the measuring-voltage failure detection. The **Undervoltage seal-in** remains unaffected if the parameter **Blk. by meas.-volt. failure** is switched off.

6.26.6.2 Application and Setting Notes

Parameter: Operate & flt.rec. blocked

- Default setting **(_:2) Operate & flt.rec. blocked** = *no*

With the parameter **Operate & flt.rec. blocked**, you can block the operate indication, the fault recording, and the fault log.

Parameter: `Threshold`

- Default setting **`(_:3) Threshold`** = ***`1.350 A`***

The setting is mainly determined by the maximum operating current.

Pickup by overload must be excluded since the protection may trip if a short operate delay time is set. Set the **`Threshold`** parameter for generators to a value between 20 % and 30 %, for transformers and motors approx. 40 % above the expected peak load.

Parameter: `Operate delay`

- Default setting **`(_:6) Operate delay`** = ***`3.00 s`***

The parameter **`Operate delay`** must be coordinated with the time grading of the network protection to guarantee the selectivity. Practical time delays are between 1 s to 2 s.

Parameter: `Blk. by meas.-volt. failure`

- Default setting **`(_:10) Blk. by meas.-volt. failure`** = ***`yes`***

With the parameter **`Blk. by meas.-volt. failure`**, you can activate (***`yes`***) or deactivate (***`no`***) the blocking by the **Measuring voltage failure detection** function. The recommended setting is the default setting.

Parameter: `State of V-seal-in`

- Default setting **`(_:101) State of V-seal-in`** = ***`off`***

With the parameter **`State of V-seal-in`**, the seal-in functionality can be activated (switched ***`on`***). Siemens recommends this setting if the excitation transformer is connected to the main lead of the generator.

Parameter: `V-seal-in threshold`

- Default setting **`(_:102) V-seal-in threshold`** = ***`46.2 V`***

The **`V-seal-in threshold`** (positive-sequence voltage) is set to a value below the lowest phase-to-phase voltage admissible during an operation, for example 80 % of the rated voltage of a generator. The positive-sequence voltage is evaluated. The practicable value for a voltage transformer with a rated secondary voltage of 100 V is 46.2 V.

The following table shows an example of a specification:

Threshold	1.4 * $I_{rated, Gen}$		
Operate delay	3.00 s		
Undervoltage seal-in	0.8 * $V_{rated, Gen}$		
Duration of V-seal-in time	4.00 s		
Dropout ratio	0.95		
Rated current $I_{rated, Gen}$	483 A	Rated voltage $V_{rated, Gen}$	6.3 kV
Rated current $I_{rated, VT, prim}$	500 A	Rated voltage $V_{rated, VT, prim}$	6.3 kV
Rated current $I_{rated, VT, sec}$	1 A	Rated voltage $V_{rated, VT, sec}$	100 V

The following secondary setting values result from this specification:

$$\text{Threshold} = \frac{1.4 \times I_{rated,Gen}}{I_{rated,CT,prim}} \times I_{rated,VT,sec} = \frac{1.4 \times 483\ A}{500\ A} \times 1\ A = 1.35\ A$$

[fo_ocp_uvsi_threshold, 1, en_US]

$$\text{Undervoltage seal} - \text{in} = \frac{0.8 \times V_{rated,Gen}}{V_{rated,VT,prim}} \times \frac{V_{reated,VT,sec}}{\sqrt{3}} = \frac{0.8 \times 6.3\ kV}{6.3\ kV} \times \frac{100\ V}{\sqrt{3}} = 46.200\ V$$

[fo_ocp_uvsi_seal-in, 1, en_US]

Parameter: `Duration of V-seal-in time`

- Default setting **`(_:104) Duration of V-seal-in time`** = ***`4.00 s`***

The parameter **`Duration of V-seal-in time`** limits the pickup seal-in induced by an overcurrent or undervoltage. The value must be set higher than the value of the parameter **`Operate delay`**. The difference shall be greater than 0.5 s. In the default setting, a difference of 1 s is used.

Parameter: `Vph-ph< threshold`

- Default setting **`(_:105) Vph-ph< threshold`** = ***`60.000 V`***

With the parameter **`Vph-ph< threshold`**, you can set the threshold at which the output signal *Voltage release* is activated when the minimum phase-to-phase voltage falls below this threshold.

Parameter: `V2> threshold`

- Default setting **`(_:106) V2> threshold`** = ***`4.600 V`***

With the parameter **`V2> threshold`**, you can set the threshold at which the output signal *Voltage release* is issued when V2 exceeds the threshold.

6.27 Directional Overcurrent Protection, Phases

6.27.1 Overview of Functions

The **Directional overcurrent protection, phases** function (ANSI 67):

- Detects short circuits at electrical equipment
- Can be used as backup overcurrent protection in addition to the main protection
- Ensures selective fault detection for parallel lines or transformers with infeed at one end
- Ensures selective fault detection in cable runs with infeed at both ends or in lines connected to form ring topologies

6.27.2 Structure of the Function

The **Directional overcurrent protection, phases** function is used in protection function groups. 2 function types are offered:

- **Directional overcurrent protection, phases – advanced** (67 Dir.OC-3ph-A)
- **Directional overcurrent protection, phases – basic** (67 Dir.OC-3ph-B)

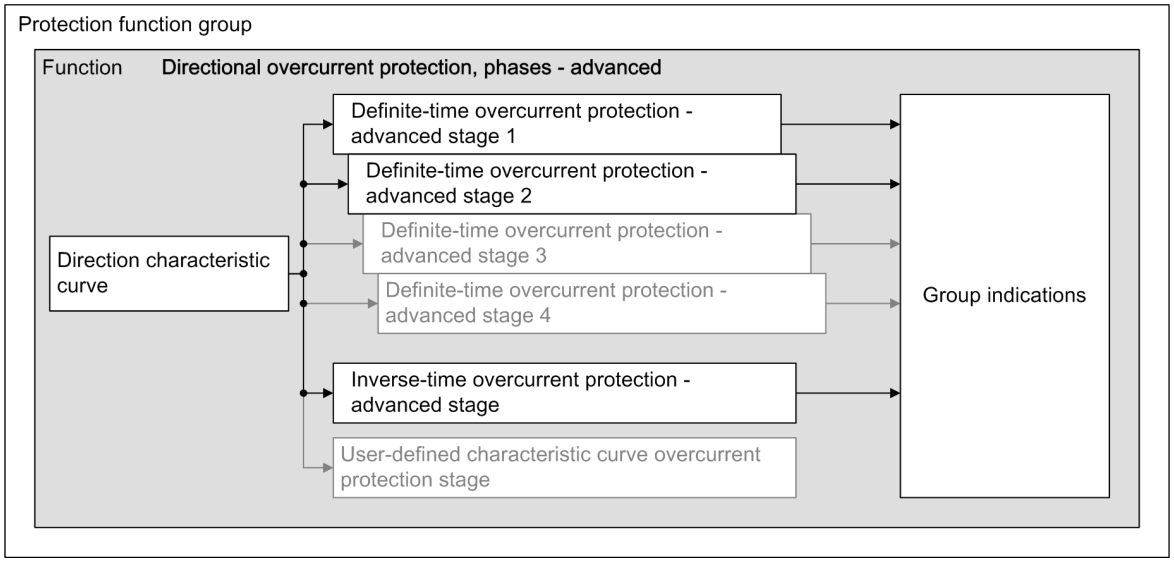
The Basic function type is provided for standard applications. The function type Advanced offers advanced functionality and is provided for more complex applications.

Both function types are preconfigured by the manufacturer with 2 **Directional, definite-time overcurrent protection** stages and with 1 **Directional inverse-time overcurrent protection** stage.

In the Advanced function type **Directional overcurrent protection, phases – advanced**, the following stages can be operated simultaneously:

- Maximum of 4 stages **Definite-time overcurrent protection – advanced**
- 1 stage **Inverse-time overcurrent protection – advanced**
- 1 stage **User-defined overcurrent protection characteristic curve**

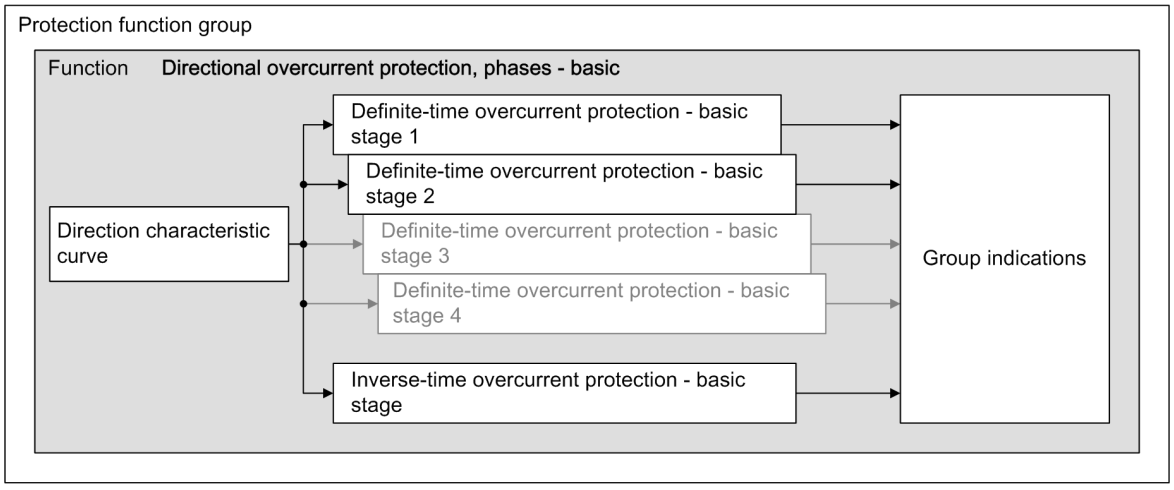
In the Basic function type **Directional overcurrent protection, phases – basic** the following stages can be operated simultaneously:



- Maximum of 4 stages **Definite-time overcurrent protection – basic**
- 1 stage **Inverse-time overcurrent protection – basic**

Stages that are not preconfigured are shown in gray in the following figures. Apart from the tripping delay characteristic, the stages are identical in structure.

The direction determination occurs on a functional level and has the same effects in all stages (see *Figure 6-473* and *6.27.7.1 Description*). In this way, it is ensured that all stages of a function receive the same direction result. Every stage can be set to the forward or reverse direction.



The group-indication output logic generates the following group indications of the protection function by the logical OR of the stage-selective indications:

- **`Pickup`**
- **`Operate`**

[dw_diocan, 4, en_US]

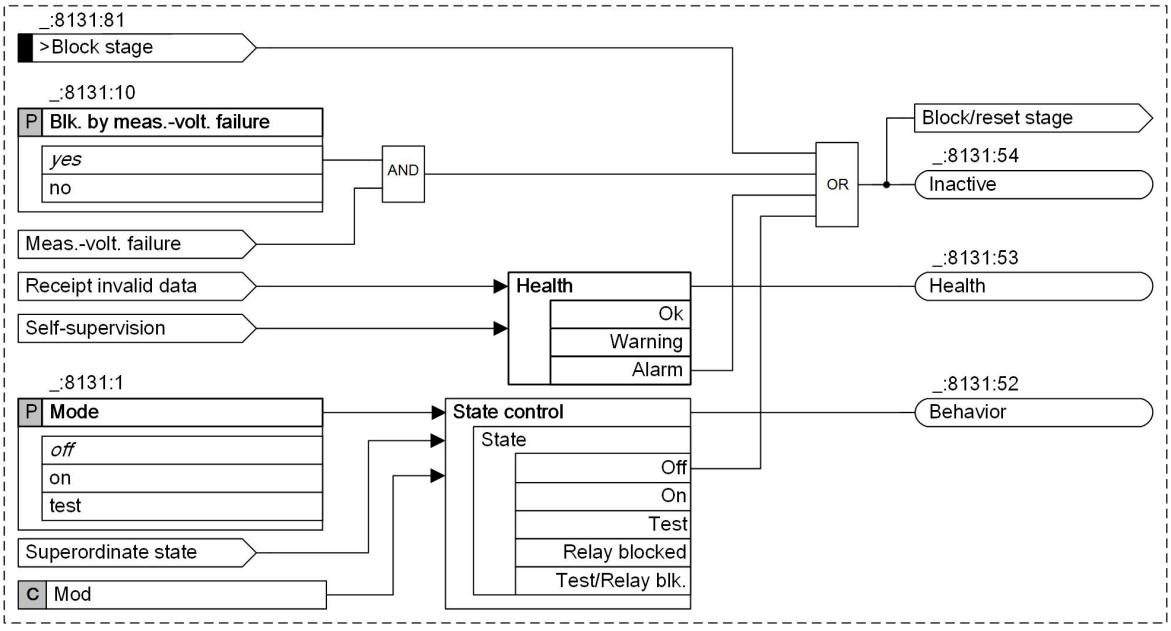
Figure 6-473 Structure/Embedding the Function Directional Overcurrent Protection, Phases – Advanced

[dw_diocba, 5, en_US]

Figure 6-474 Structure/Embedding the Function Directional Overcurrent Protection, Phases – Basic

If the device-internal functions listed in the following are present in the device, these functions can influence the pickup values and tripping delays of the stages or block the stages. The stage can also be affected by an external source via a binary input signal.

- Automatic reclosing (AREC)
- Cold-load pickup detection
- Binary input signal



If the device is equipped with the **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer-inrush currents.

6.27.3 Stage Control

6.27.3.1 Description

Logic

The following figure represents the stage control. It applies to all types of stages.

[lo_docp_n2, 2, en_US]

Figure 6-475 Stage-Control Logic Diagram

Blocking of the Stage with Measuring-Voltage Failure (Basic and Advanced Stage)

The stage can be blocked if a measuring-voltage failure occurs. In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- From inside on pickup of the **Measuring-voltage failure detection** function (see chapter *8.3.2.1 Overview of Functions*)
- From an external source via the binary input signal **>Open** of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker

The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

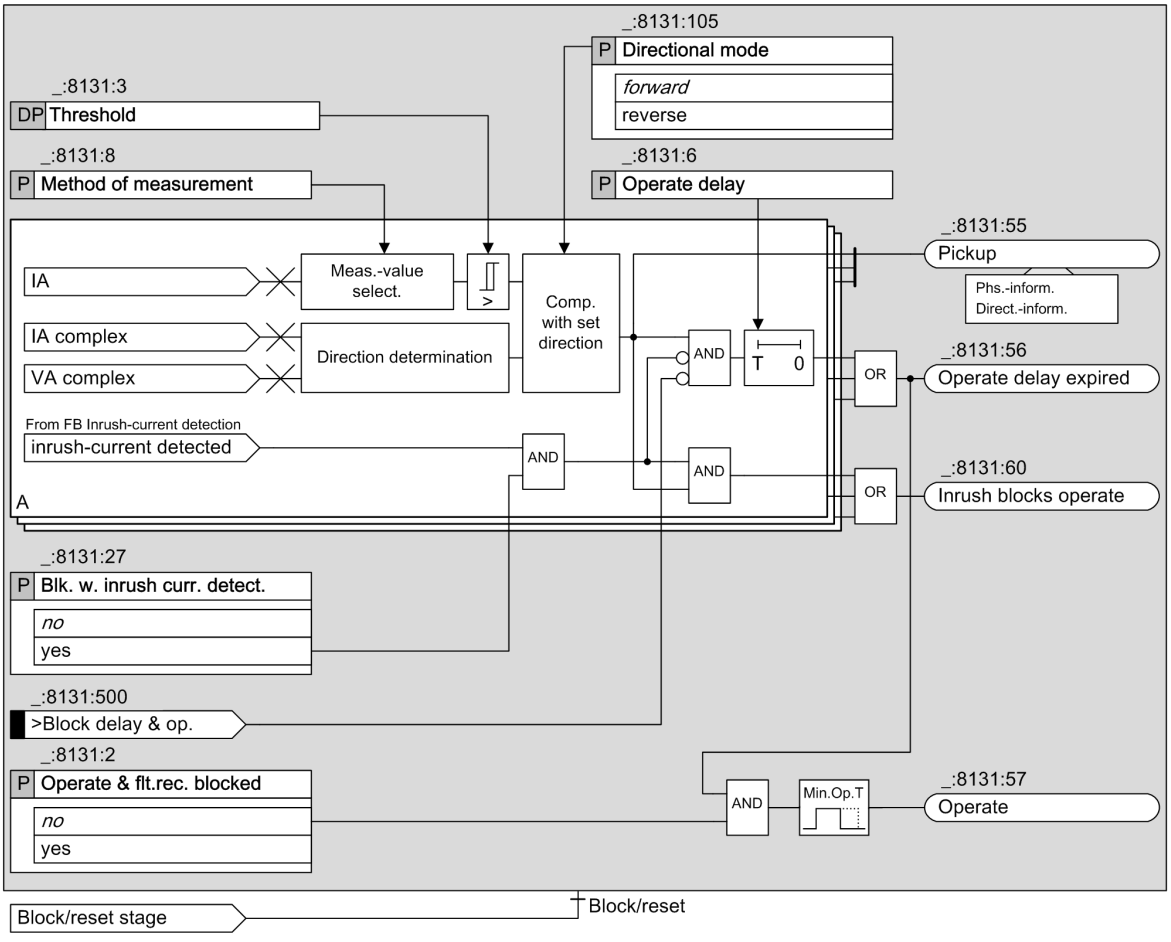
6.27.3.2 Application and Setting Notes

Parameter: Blk. by meas.-volt. failure

- Recommended setting value **(_:8131:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following two conditions is met:

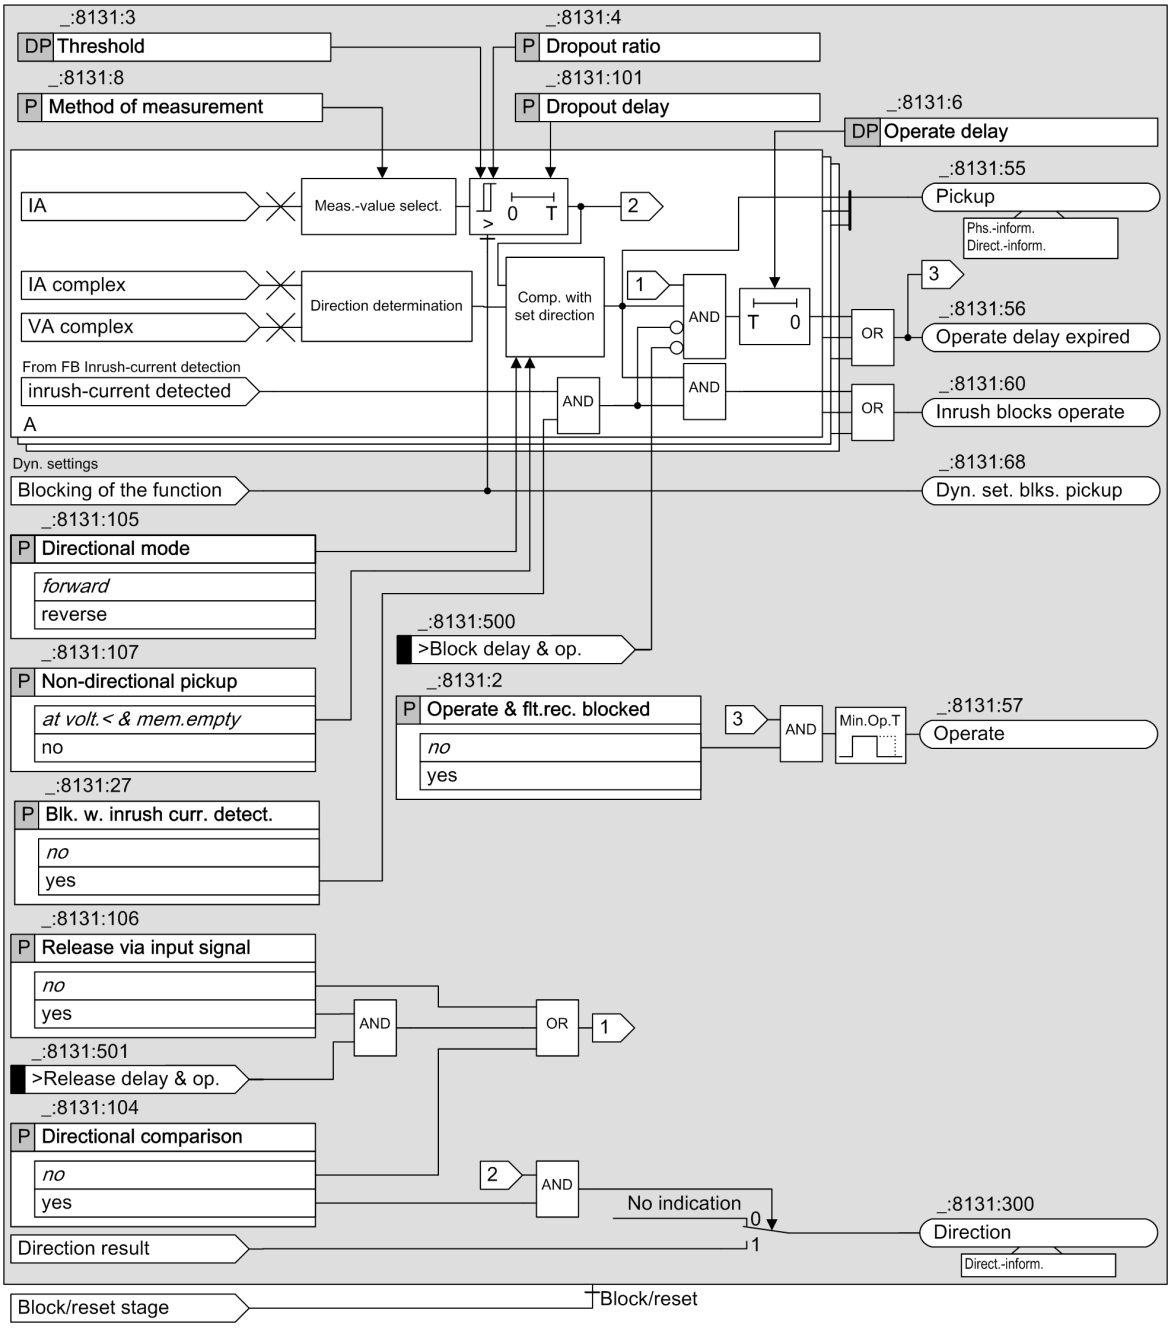


- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see chapter *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The directional overcurrent-protection stage is blocked. Siemens recommends that you retain the default setting, as correct direction determination cannot be guaranteed if a measuring-voltage failure occurs.
no	The directional overcurrent-protection stage is not blocked.

6.27.4 Stage with Definite-Time Characteristic Curve

6.27.4.1 Description



Logic of the Basic Stage

[lo_docg6b_2_en_US]

Figure 6-476 Logic Diagram of the Directional, Definite-Time Overcurrent Protection, Phases - Basic

Logic of the Advanced Stage

[lo_docp_31, 1, en_US]

Figure 6-477 Logic Diagram of the Directional, Definite-Time Overcurrent Protection, Phases - Advanced

Directional Mode (Basic and Advanced Stage)

You use the **`Directional mode`** parameter to define whether the stage works in a forward or reverse direction.

Direction determination itself works across stages (see section *6.27.7.1 Description*).

Non-Directional Pickup, Voltage Memory (Basic and Advanced Stage)

If a 3-phase close-up fault occurs, all 3 phase-to-ground voltages drop to almost 0. If this happens, direction determination can fall back on a voltage memory (see chapter *6.27.7.1 Description*). If no voltage

measurements which can be used to determine the direction are available in the voltage memory, the basic stage generally picks up without direction determination, that is non-directionally. For the advanced stage, the response can be defined via the **Non-directional pickup** parameter. With the ***at volt.< & mem.empty*** setting, the function picks up in such a situation without direction determination. With the ***no*** setting, the function does not pick up.

Directional Comparison Protection (Advanced Stage)

The stage can be used for directional comparison protection. This is set using the **Directional comparison** parameter. With the ***yes*** setting, the function uses the threshold-value violation to determine the direction (forward or reverse) and reports the indication **Direction**. The direction indicated is independent of the directional mode set for the stage.

The **Release via input signal** setting and the **>Release delay & op.** input signal are available with directional comparison protection. If the **Release via input signal** parameter is set to ***yes***, the start of the time delay, and therefore the tripping of the stage, are only enabled if the **>Release delay & op.** input signal is active.

Method of Measurement (Basic and Advanced Stage)

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically.
- Measurement of the RMS value:
  This method of measurement determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Dropout Delay (Advanced Stage)

If the value falls below the dropout threshold, the dropout can be delayed. The pickup is maintained for the specified time. The tripping delay continues to run. If the time delay expires while the pickup is still maintained, the stage operates.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Externally or internally via the binary input signal **>Block stage** (see chapter *6.27.3.1 Description*)
- Measuring-voltage failure (see chapter *6.27.3.1 Description*)
- Via the dynamic settings function (only provided in the Advanced function type, see chapter **Influence of other functions via dynamic settings** and chapter *6.23.8.1 Description*)

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and the fault logging and recording takes place.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.23.7.1 Description* .

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in chapter *6.23.8.1 Description* .

6.27.4.2 Application and Setting Notes

Parameter: `Directional mode`

- Default setting **`(_:8131:105) Directional mode`** = ***`forward`***

You use the **`Directional mode`** parameter to define the directional mode of the stage.

Parameter Value	Description
`forward`	Select this setting if the stage is to work in a forward direction (in the direction of the line).
`reverse`	Select this setting if the stage is to work in a reverse direction (in the direction of the busbar).

Parameter: `Method of measurement`

- Recommended setting value **`(_:8131:8) Method of measurement`** = ***`fundamental comp.`***

With the **`Method of measurement`** parameter, you define whether the stage uses the ***`fundamental comp.`*** (standard method) or the calculated ***`RMS value`***.

Parameter Value	Description
`fundamental comp.`	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
`RMS value`	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **`threshold value`** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: `Directional comparison`, `Release via input signal`

- Default setting **`(_:8131:104) Directional comparison`** = ***`no`***
- Default setting **`(_:8131:106) Release via input signal`** = ***`no`***

These 2 parameters are not visible in the basic stage.

You use these parameters to define whether the stage is to be used for directional comparison protection. Directional comparison protection is performed via the **`Direction`** and **`>Release delay & op.`** signals.

Parameter Value	Description
no	The stage is not used for directional comparison protection.
yes	If the **Directional comparison** parameter is set to ***yes***, the **Release via input signal** parameter, the **Direction** output signal, and the **>Release delay & op.** input signal become available. If the **Release via input signal** parameter is set to ***yes***, the start of the time delay, and therefore also the operate signal of the stage, are only enabled if the **>Release delay & op.** input signal is active. The **>Release delay & op.** input signal must be connected to the release information from the opposite end (forward information from the **Direction** output signal); see also the application example in *6.27.10 Application Notes for Directional Comparison Protection* .

Parameter: **Non-directional pickup**

- Recommended setting value **(_:8131:107) Non-directional pickup** = ***at volt.< & mem.empty***

This parameter is not visible in the basic stage.

Parameter Value	Description
at volt.< & mem.empty	Select this setting if the stage is to pick up in a non-directional manner if the voltage memory is empty and determining of direction has to be performed at low voltages (3-phase close-up fault). An empty voltage memory may exist, for example, if there is a voltage transformer at the line end and the circuit breaker (CB) trips. Siemens recommends using the default setting.
no	Select this setting if determining of direction is required under all circumstances, that is, even in the event of pickup on a 3-phase close-up fault.

Parameter: **Threshold**

- Default setting **(_:8131:3) Threshold** = ***1.50 A*** (for the first stage)

The same considerations apply to setting the threshold value as for non-directional overcurrent protection. For further information, refer to section *6.23.4.2 Application and Setting Notes*.

Parameter: **Operate delay**

- Default setting **(_:8131:6) Operate delay** = ***0.300 s*** (for the 1st stage)

The Operate delay to be set is derived from the time-grading schedule that has been prepared for the system. Where overcurrent protection is used in emergency mode, shorter time delays might be reasonable (one grading time above fast tripping), since the emergency mode only operates if the main protection function fails.

Typical examples of grading times are provided in *6.27.9 Application Notes for Parallel Lines* and *6.27.10 Application Notes for Directional Comparison Protection* .

Parameter: **Dropout ratio**

- Recommended setting value **(_:8131:4) Dropout ratio** = ***0.95***

This parameter is not visible in the basic stage.

The recommended set value of 0.95 is appropriate for most applications.

For high-precision measurements, the setting value of the **Dropout ratio** parameter can be reduced, for example to 0.98. If you expect heavily fluctuating measurands at the response threshold, you can increase the setting value of the **Dropout ratio** parameter. This avoids chattering of the tripping stage.

Parameter: `Dropout delay`

- Recommended setting value **`(_:8131:101) Dropout delay`** = ***`0 s`***

This parameter is not visible in the basic stage.

Siemens recommends using this setting value, since the dropout of a protection stage must be performed as fast as possible.

You can use the **`Dropout delay`** parameter ≠ ***`0 s`*** to obtain a uniform dropout behavior if you use it together with an electromechanical relay. This is required for time grading. The dropout time of the electromechanical relay must be known for this purpose. Subtract the dropout time of your own device (see Technical Data) and set the result.

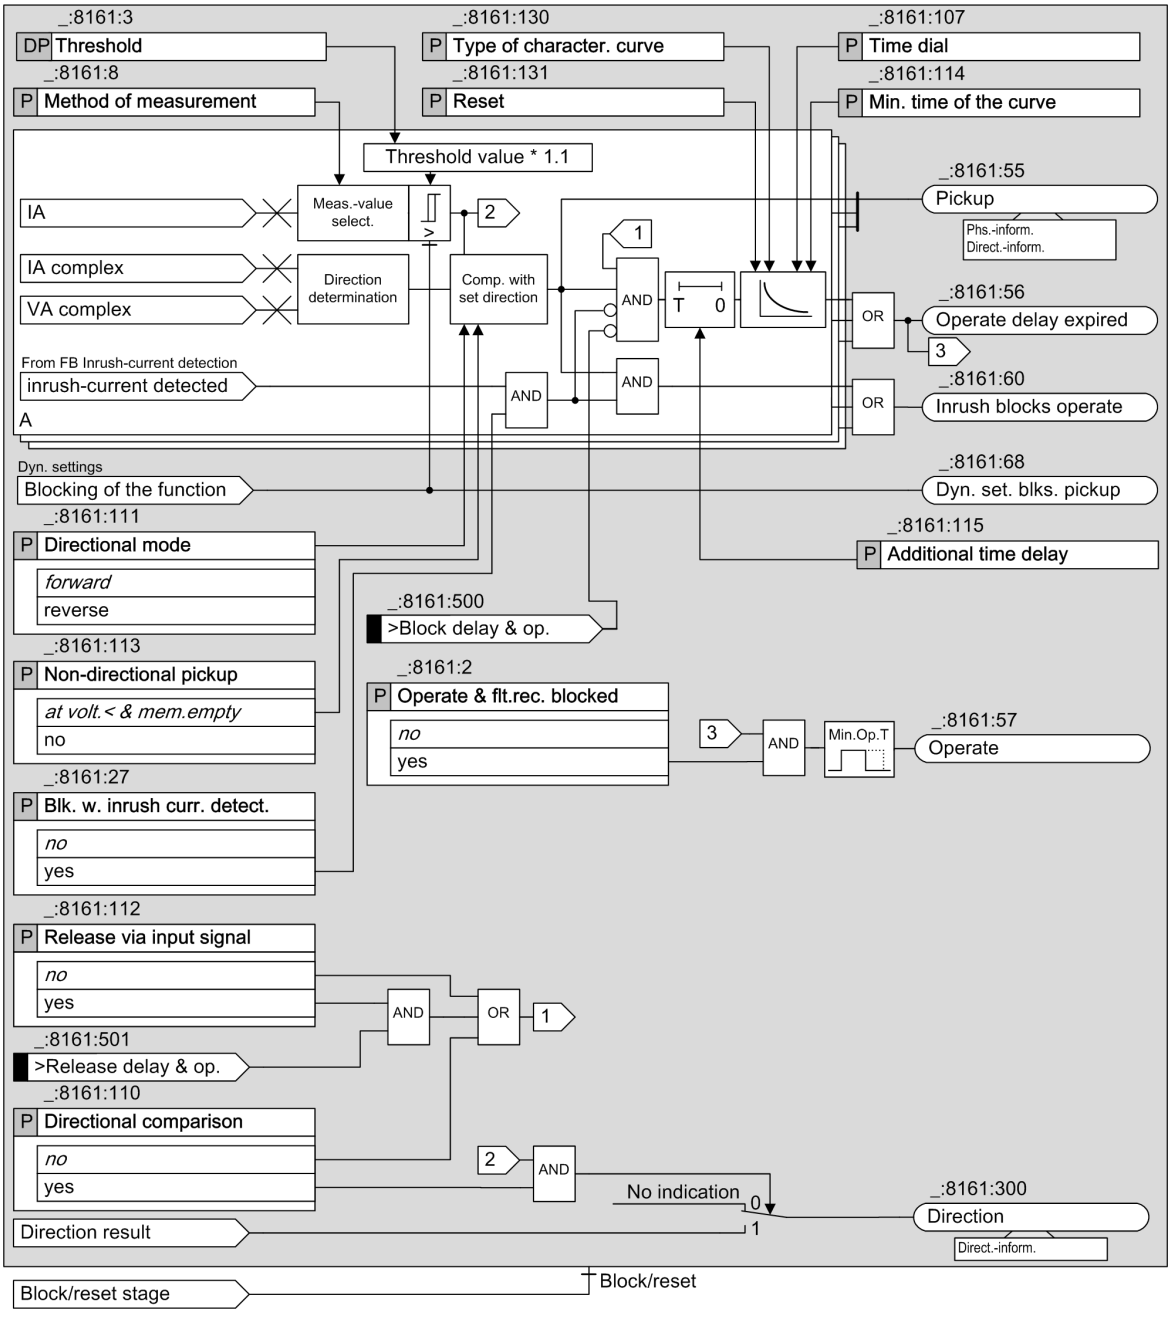
6.27.5 Stage with Inverse-Time Characteristic Curve

6.27.5.1 Description



Logic of the Basic Stage

[lo_doci6b, 2, en_US]

Figure 6-478 Logic Diagram of the Directional, Inverse-Time Overcurrent Protection, Phases - Basic

Logic of the Advanced Stage

[lo_docp_33, 2, en_US]

Figure 6-479 Logic Diagram of the Directional, Inverse-Time Overcurrent Protection, Phases - Advanced

Directional Mode (Basic and Advanced Stage)

You use the **`Directional mode`** parameter to define whether the stage works in a forward or reverse direction.

The direction determination works across stages (see chapter *6.27.7.1 Description*).

Non-Directional Pickup, Voltage Memory (Basic and Advanced Stage)

If a 3-phase close-up fault occurs, all 3 phase-to-ground voltages drop to almost 0. If this happens, direction determination can fall back on a voltage memory (see chapter *6.27.7.1 Description*). If no voltage measurements which can be used to determine the direction are available in the voltage memory, the basic

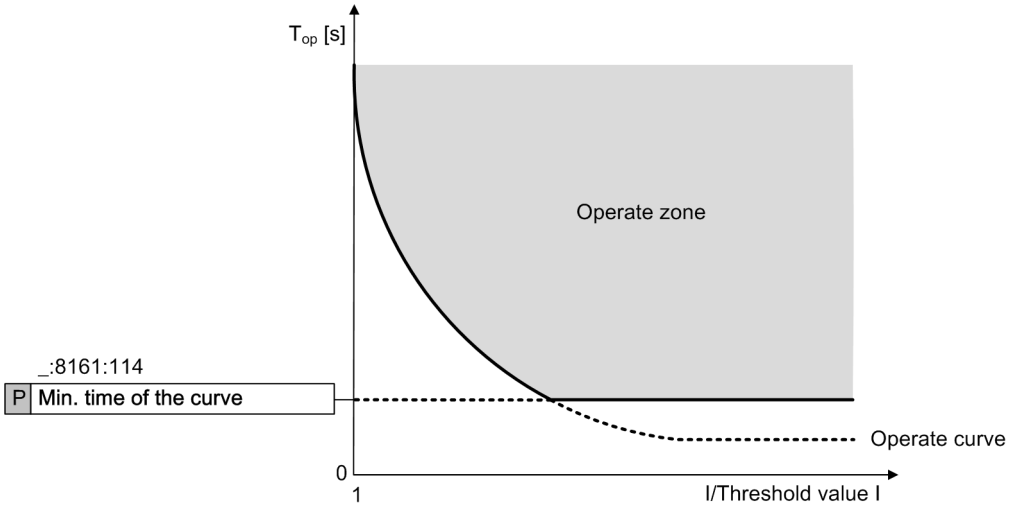
stage generally picks up without direction determination, that is non-directionally. For the advanced stage, the response can be defined via the **Non-directional pickup** parameter. With the ***at volt.< & mem.empty*** setting, the function picks up in such a situation without direction determination. With the ***no*** setting, the function does not pick up.

Directional Comparison Protection (Advanced Stage)

The stage can be used for directional comparison protection. This is set using the **Directional comparison** parameter. With the ***yes*** setting, the function uses the threshold-value violation to determine the direction (forward or reverse) and reports the indication **Direction**. The direction indicated is independent of the directional mode set for the stage.

The **Release via input signal** setting and the **>Release delay & op.** input signal are available with directional comparison protection. If the **Release via input signal** parameter is set to ***yes***, the start of the time delay, and therefore the tripping of the stage, are only enabled if the **>Release delay & op.** input signal is active.

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI (Basic and Advanced Stage)



When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Minimum Time of the Curve (Advanced Stage)

With the parameter **Min. time of the curve**, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time.

[dw_docp_01, 1, en_US]

Figure 6-480 Minimum Operating Time of the Curve

Additional Time Delay (Advanced Stage)

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay. With this setting, the whole curve is shifted on the time axis by this additional definite time.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Externally or internally via the binary input signal **>Block stage** (see chapter *6.27.3.1 Description*)
- Measuring-voltage failure (see chapter *6.27.3.1 Description*)
- Via the functionality of the **dynamic settings** (only in the advanced function type, see subtitle **Influence of other functions via dynamic settings** and chapter *6.23.8.1 Description*).

Blocking of the Time Delay (Basic and Advanced Stage)

You can use the binary input signal **>Block delay & op.** to prevent the start of the time delay and thus also the operate signal. A running time delay is reset. The pickup is indicated and a fault record is opened.

Blocking of the Operate Delay and the Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.23.7.1 Description* .

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can influence the overcurrent-protection stages:

- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in chapter *6.23.8.1 Description* .

6.27.5.2 Application and Setting Notes

Parameter: Directional mode

- Default setting **(_:8161:111) Directional mode** = ***forward***

You use the **Directional mode** parameter to define the directional mode of the stage.

Parameter Value	Description
forward	Select this setting if the stage is to work in a forward direction (in the direction of the line).
reverse	Select this setting if the stage is to work in a reverse direction (in the direction of the busbar).

Parameter: Method of measurement

- Recommended setting value **(_:8161:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Directional comparison, Release via input signal

- Default setting **(_:8161:110) Directional comparison** = ***no***
- Default setting **(_:8161:112) Release via input signal** = ***no***

These 2 parameters are not visible in the basic stage.

You use these parameters to define whether the stage is to be used for directional comparison protection. Directional comparison protection is performed via the **Direction** and **>Release delay & op.** signals.

Parameter Value	Description
no	The stage is not used for directional comparison protection.
yes	If the **Directional comparison** parameter is set to ***yes***, the **Release via input signal** parameter, the **Direction** output signal, and the **>Release delay & op.** input signal become available. If the **Release via input signal** parameter is set to ***yes***, the start of the time delay, and therefore also the operate signal of the stage, are only enabled if the **>Release delay & op.** input signal is active. The **>Release delay & op.** input signal must be connected to the release information from the opposite end (forward information from the **Direction** output signal); see also the application example in *6.27.10 Application Notes for Directional Comparison Protection* .

Parameter: Non-directional pickup

- Recommended setting value **(_:8161:113) Non-directional pickup** = ***at volt.< & mem.empty***

This parameter is not visible in the basic stage.

Parameter Value	Description
at volt.< & mem.empty	Select this setting if the stage is to pick up in a non-directional manner if the voltage memory is empty and determining of direction has to be performed at low voltages (3-phase close-up fault). An empty voltage memory may exist, for example, if there is a voltage transformer at the line end and the CB trips. Siemens recommends using the default setting.
no	Select this setting if determining of direction is required under all circumstances, that is, even in the event of pickup on a 3-phase close-up fault.

Parameter: Type of character. curve

- Default setting **(_:8161:130) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application.

Parameter: Min. time of the curve

- Default setting **(_:8161:114) Min. time of the curve** = ***0.00 s***

This parameter is only available in the advanced stage.

With the parameter **Min. time of the curve**, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time. If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

NOTE

If the set value is smaller than the smallest possible time delay of the inverse-time characteristic curve, the parameter has no influence on the delay time.

Parameter: Additional time delay

- Default setting **(_:8161:115) Additional time delay** = ***0.00 s***

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay.

If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

Parameter: Threshold

- Default setting **(_:8161:3) Threshold** = ***1.50 A***

The same considerations apply to setting the threshold value as for non-directional overcurrent protection. Therefore, refer to *6.23.5.2 Application and Setting Notes* for further information.

Parameter: Time dial

- Default setting **(_:8161:101) Time dial** = ***1***

Use the **Time dial** parameter to displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading chart that has been prepared for the electrical power system. Where overcurrent protection is used in emergency mode, shorter time delays might be reasonable (one grading time above fast tripping), since the emergency mode only operates if the main protection function fails.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the **Time dial** parameter at ***1*** (default setting).

Parameter: Reset

- Default setting **(_:8161:131) Reset** = ***disk emulation***

You use the **Reset** parameter to define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
disk emulation	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Use this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

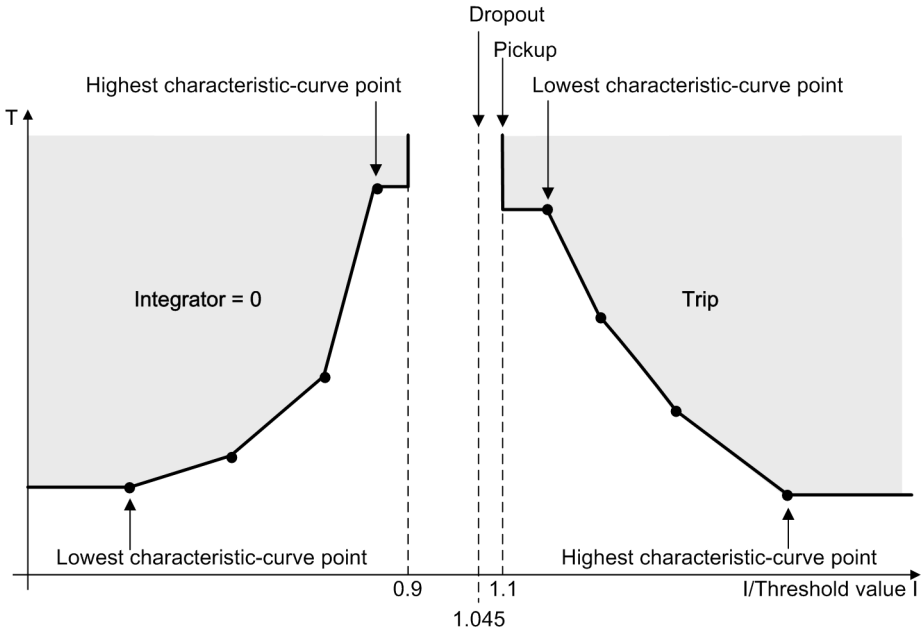
6.27.6 Stage with User-Defined Characteristic Curve

6.27.6.1 Description

The structure of this stage is identical to that of the advanced stage with directional inverse-time characteristic curve (*6.27.4.1 Description*). The only difference is that you can define the characteristic curve as desired.

User-Defined Characteristic Curve



With the directional, user-defined characteristic curve, you can define the operate curve point by point using up to 30 value pairs of current and time. The device uses linear interpolation to calculate the characteristic curve from these values. You can also define a dropout characteristic curve if you wish.

Pickup and Dropout Behaviors with User-Defined Characteristic Curve

When the input variable exceeds the threshold value by 1.1 times, the characteristic curve is processed.

An integrating method of measurement totalizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls short of the pickup value by a factor of 1.045 (0.95 x 1.1 x threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

[dw_ocp_ken_02, 2, en_US]

Figure 6-481 Pickup and Dropout Behaviors when Using a Directional User-Defined Characteristic Curve

NOTE

Note that the currents that are lower than the current value of the smallest characteristic-curve point do not extend the operate time. The pickup characteristic runs in parallel to the current axis up to the smallest characteristic-curve point. Currents that are larger than the current value of the largest characteristic-curve point do not reduce the operate time. The pickup characteristic runs in parallel to the current axis from the largest characteristic-curve point.

6.27.6.2 Application and Setting Notes

This stage is structured in the same way as the stage with a directional inverse-time characteristic curve. The only difference is that you can define the characteristic curve as desired. This chapter only provides application and setting notes for setting characteristic curves.

Parameter: `Current/time value pairs` (from the operate curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **`Threshold`** parameter to ***`1.00`*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to displace the characteristic curve.

Set the time value in seconds. The characteristic curve is displaced using the **`Time dial`** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: `Time dial`

- Default setting **`(_:101) Time dial`** = ***`1`***

Use the **`Time dial`** parameter to displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading chart that has been prepared for the electrical power system. Where no time grading and therefore no displacement of the characteristic curve is required, leave the **Time dial** parameter set to ***1***.

Parameter: Reset

- Default setting **(_:115) Reset** = ***disk emulation***

You use the **Reset** parameter to define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
disk emulation	In the case of this setting, a dropout characteristic curve has to be set in addition to the operate curve. Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Use this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

Parameter: Current/time value pairs (of the dropout characteristic curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **Threshold** parameter to ***1.00*** in order to obtain a simple relation. You can change the threshold value setting afterwards if you want to displace the characteristic curve.

Set the time value in seconds. The characteristic curve is displaced using the **Time dial** parameter.

NOTE

The value pairs must be entered in continuous order.

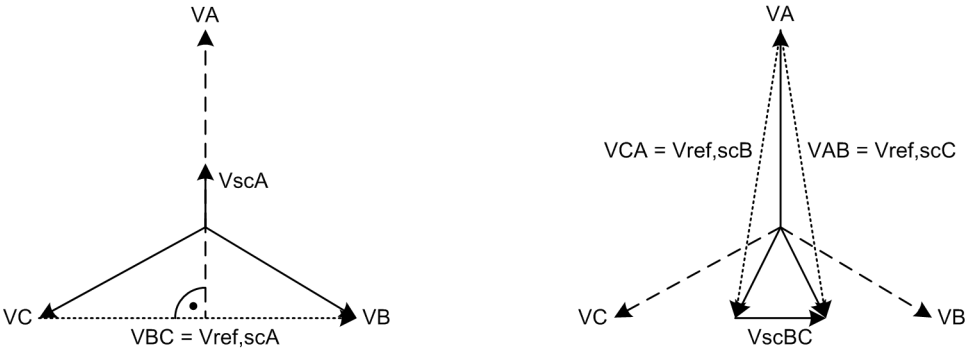
6.27.7 Direction Determination

6.27.7.1 Description

General

Every phase has a separate direction-measuring element. If the threshold value in a phase is exceeded, the direction determination is started for this phase. If there are multiphase short circuits, all measuring elements involved perform direction determination independently. If one of the determined directions matches the set direction, the stage picks up (see descriptions of the stage logic).



The direction is determined by calculating the phase angle between the short-circuit current and a reference voltage.

Measurands for Direction Determining

The directional measuring element uses the short-circuit current of the phase concerned and the cross-polarized phase-to-phase voltage (as the reference voltage) to determine the direction. This means that the direction can still be determined unambiguously and correctly, even if the short-circuit voltages collapse completely when a 1-phase or 2-phase fault occurs (close-up fault).

The phase-to-phase voltages are calculated when phase-to-ground voltages are connected.

The cross-polarized voltage (reference voltage) is vertical in relation to the short-circuit voltages for 1-phase-to-ground faults (*Figure 6-482*, left). For 2-phase short circuits, the position of the reference voltages changes up to 30°, depending on the extent to which the short-circuit voltages collapse (*Figure 6-482*, right).

[dw_docp_02, 1, en_US]

Figure 6-482 Cross-Polarized Voltages for Direction Determination

The following table shows how measurands are assigned for direction-determination purposes in the event of different types of fault.

Table 6-12 Measurands for Direction Determining

Threshold-Value Exceeding	Measuring Element							
	A		B		C		Ground	
	Current	Voltage	Current	Voltage	Current	Voltage	Current	Voltage

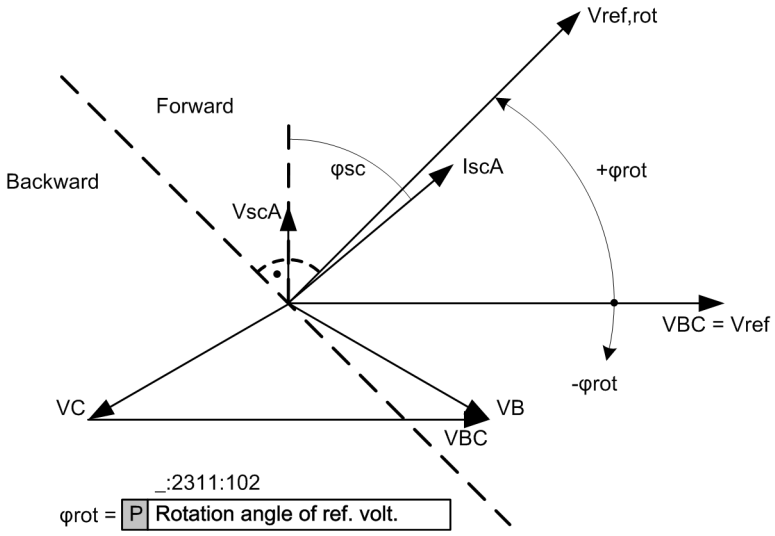
A, B, C	I_A	V_{BC}	I_B	V_{CA}	I_C	V_{AB}	–	–
A, B, C, Gnd	I_A	V_{BC}	I_B	V_{CA}	I_C	V_{AB}	I_r	V_0

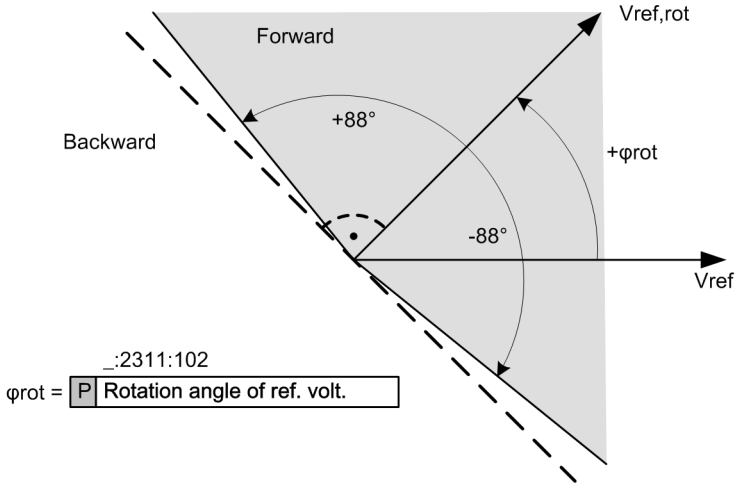


Voltage Memory

Saved voltages are used if, when a 3-pole close-up fault occurs, the measuring voltages are not sufficient for reliable direction determination. Insofar as and as long as no sufficient measuring voltage is available after the storage time (2 s) has elapsed, the detected direction is retained. If the memory does not contain any voltages (when closing onto a short circuit, for example), the behavior of the stage is defined using the **`Non-directional pickup`** parameter.

Direction Determination

As mentioned in the **General** section, the direction is determined by calculating the phase angle between short-circuit current and reference voltage. To take different system conditions and applications into account, the reference voltage can be rotated through an adjustable angle (**`Rotation angle of ref. volt.`** parameter). This moves the vector of the rotated reference voltage close to the vector of the short-circuit



current. Consequently, the result of direction determination is as reliable as possible. *Figure 6-483* illustrates the relationship based on a 1-phase ground fault in phase A. The short-circuit current I_{scA} lags the short-circuit voltage by the short-circuit angle φ_{sc}. The reference voltage, in this case V_{BC} for measuring element A, is rotated positively (counterclockwise) by the setting value of the **`Rotation angle of ref. volt.`** parameter. In the scenario illustrated here, the rotation is +45°.

[dw_docp_33, 2, en_US]

Figure 6-483 Rotation of the Reference Voltage, Phase-Measuring Element

The rotated reference voltage defines the forward and reverse range, as shown in *Figure 6-484*. The forward range is calculated as ±88° around the rotated reference voltage $V_{ref,rot}$. If the short-circuit current vector is located in this range, the device decides on the forward direction. In the mirrored range, the device decides on the backward direction. In the intermediate range, the direction is undetermined.

[dw_docp_34, 2, en_US]

Figure 6-484 Forward Characteristic of the Directional Function, Phase-Measuring Element

Direction Determination for Test Purposes

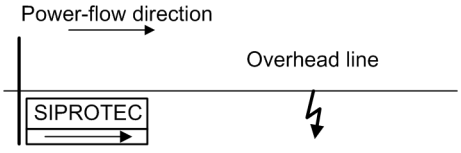
If you activate the binary input signal **`>Test of direction`**, the direction is determined and indicated even without the current threshold being exceeded in one of the stages. The direction can be determined as soon as current and voltage are greater than approx. 7 % of their secondary rated values.

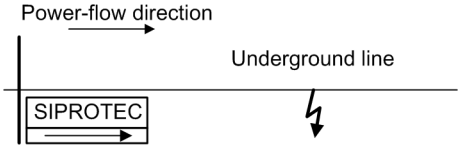
6.27.7.2 Application and Setting Notes

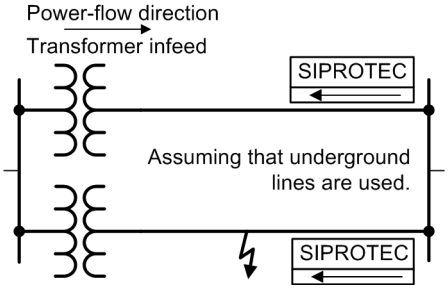
Parameter: `Rotation angle of ref. volt.`

- Default setting **`(_:2311:102) Rotation angle of ref. volt.`** = ***45°***

The directional characteristic, that is, the position of the **forward** and **reverse** ranges, is set with the **`Rotation angle of ref. volt.`** parameter. The short-circuit angle is typically to be found in a range from 30° to 60° inductive. Therefore, in most cases, the default setting of +45° can be retained to position the reference voltage, as it ensures a reliable directional result.







Some example settings for special applications appear in the following (*Table 6-13*). Please note that for phase-to-ground faults (PG faults), the reference voltage (fault-free voltage) is vertical in relation to the short-circuit voltage. This results in the following setting for the rotation angle:

`Rotation angle of ref. volt.` = 90 - φsh phase-measuring elements (PG faults)

Please also note that for phase-to-phase faults, the reference voltage is rotated between 0° (distant fault) and 30° (close-up fault) dependent upon the collapse of the faulted voltage (see *Figure 6-483*). You can take this into account with an average value of 15°.

`Rotation angle of ref. volt.` = 90 - φsh - 15° phase-measuring elements (PP faults)

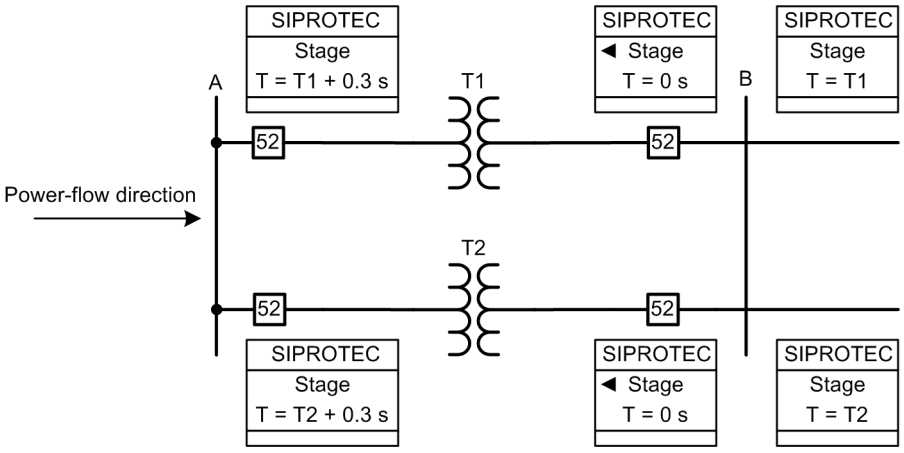
Table 6-13 Example settings

Application	φsh typical	Setting `Rotation angle of ref. volt.`
	60°	Range 30° to 0° for PP faults Selected: 15°
	30°	Range 60° to 30° for PP faults Selected: 45°
	30°	Range 60° to 30° for PP faults Selected: 45°

Input signal: `>Test of direction`

If you activate the binary input signal **`>Test of direction`**, the direction is determined and indicated even without the current threshold being exceeded in one of the stages. This provides an easy means of checking the direction during commissioning, without changing the threshold values of the stages.

6.27.8 Influence of Other Functions via Dynamic Settings



The influence of these functions via dynamic settings is described in chapter *6.23.8.1 Description* and chapter *6.23.8.2 Application and Setting Notes (Advanced Stage)* .

6.27.9 Application Notes for Parallel Lines

Parallel Lines or Transformers

In parallel lines or transformers with infeed at one end (see *Figure 6-485*), if there is no directional measuring element, a fault on feeder T1 will also trip the other feeder T2. In contrast, a directional measuring element in the devices on busbar B prevents the tripping of the circuit breaker in the parallel feeder. Therefore, in *Figure 6-485*, directional overcurrent protection is used in the places marked with direction arrows. Please note that the forward direction of the protection device represents the direction towards the object to be protected. This does not have to be the same as the power direction of normal power flow.

Set time grading in opposition to the power flow with increasing time. As load can only flow in one direction, you can set the directional devices without time delay.

[dw_docp_05, 1, en_US]

Figure 6-485 Parallel Line with Transformers

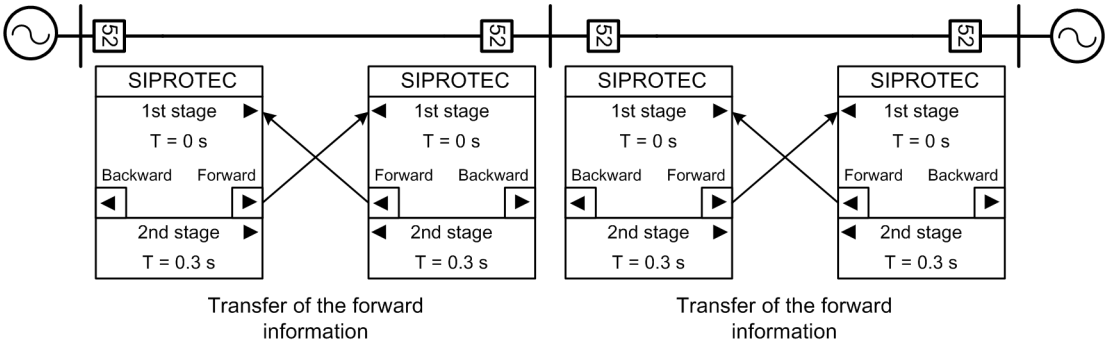
Legend for *Figure 6-485*

Stage ►:	Directional stage, **forward** direction set
Stage:	Non-directional stage
T:	Grading time

6.27.10 Application Notes for Directional Comparison Protection

The direction determination of directional overcurrent protection can be used to implement directional comparison protection for cable runs with infeed at both ends. Directional comparison protection is used for the selective isolation of a faulted line section (for example, subsections of closed rings). Sections are isolated in fast time, that is, they do not suffer the disadvantage of long grading times.

This technique requires that directional information can be exchanged between the individual protection stations. You can implement this information exchange using a communication channel (protection interface or IEC 61850 GOOSE) or with pilot wires for signal transmission via an auxiliary voltage loop.



Protection Principle

The protection principle is shown in *Figure 6-486*. 2 devices (one at the start of the line and the other at the end of the line) work together in each line section. The information **fault in forward direction** is transferred between them. A directional definite-time overcurrent protection level is in operation in both devices in the forward direction (1st level). However, this level is not enabled in the idle state. The level is only released when the information **fault in forward direction** is received from the opposite end. If the enabled level also defines the fault in the forward direction, the fault must be on this line section and the level trips immediately. As this protection principle works with an enable procedure (and not with a blocking procedure), there is no need to delay the level.

A second directional definite-time overcurrent protection stage with standard time grading works in parallel with the first stage as a selective backup stage. This ensures full selectivity of protection in the following situations:

- Infeed at one end or weak infeed at one end: In this case, no release signal is generated.
- Failure of the communication route: In this case, the release signal is not transmitted.

To provide selective protection in fast time for busbars between the line sections also, you can combine this protection principle with the principle of reverse interlocking. This principle is not discussed in further detail in this document.

[dw_docp_07, 2, en_US]

Figure 6-486 Selectivity through Directional Comparison Protection

Legend for *Figure 6-486*

Stage ►:	Stage is set in the **forward** direction; stage 1 is instantaneous, stage 2 is graded
►, ◄:	If a threshold value is exceeded, the stage indicates the direction (forward or reverse)

If you are using a communication channel, the protocol-transmission methods detect if the channel is interrupted. If you are using pilot wires, Siemens recommends an operation based on a closed-circuit connection. The device uses a CFC chart to check and indicate if the binary input is dead for an unexpectedly long period. In contrast with the blocking procedure, overfunction is not possible if communication is lost. Therefore, a loss of communication is not critical where this procedure is concerned, although it must be detected and indicated.

Directional comparison protection can also be implemented as a blocking procedure. This procedure works under all system switching states, i.e. also with infeed at one end (or weak infeed). However, to use it you must delay the stage (typically by 100 ms) so that the blocking signal is received in time under all circumstances. It is also essential that you monitor the communication channel to avoid overfunction in the event of failure followed by a system incident.

Configuration of the Stage, CFC Chart

To configure the stage, proceed as follows:

- The **Directional mode** parameter of both stages must be set to ***forward***
- The **Directional comparison** and **Release via input signal** parameters of the first stage must be set to ***yes***. This is so that the first stage is only released if the **>Release delay & op.** input signal is active. Furthermore, the direction is indicated if a threshold value is exceeded.
- The first stage can be set without a time delay. The second stage has to be graded
- The information ***forward*** from the **Direction** signal in the first stage must be transmitted to the opposite end. The routing is determined by the type of transmission
- A CFC chart has to be implemented at the receive end to link the received (***forward*** information) and release signals, dependent upon the type of transmission.

6.28 Directional Overcurrent Protection, Ground

6.28.1 Overview of Functions

The **Directional overcurrent protection, ground** function (ANSI 67N):

- Detects short circuits to ground affecting electric equipment
- Ensures selective ground-fault detection for parallel lines or transformers with infeed at one end
- Ensures selective ground-fault detection in cable runs with infeed at both ends or in lines connected to form ring topologies

6.28.2 Structure of the Function

The **Directional overcurrent protection, ground** function can be used in protection function groups which provide zero-sequence current and zero-sequence voltage measurements. 2 function types are offered:

- **Directional overcurrent protection, ground – advanced** (67N Dir.OC-gnd-A)
- **Directional overcurrent protection, ground – basic** (67N Dir.OC-gnd-B)

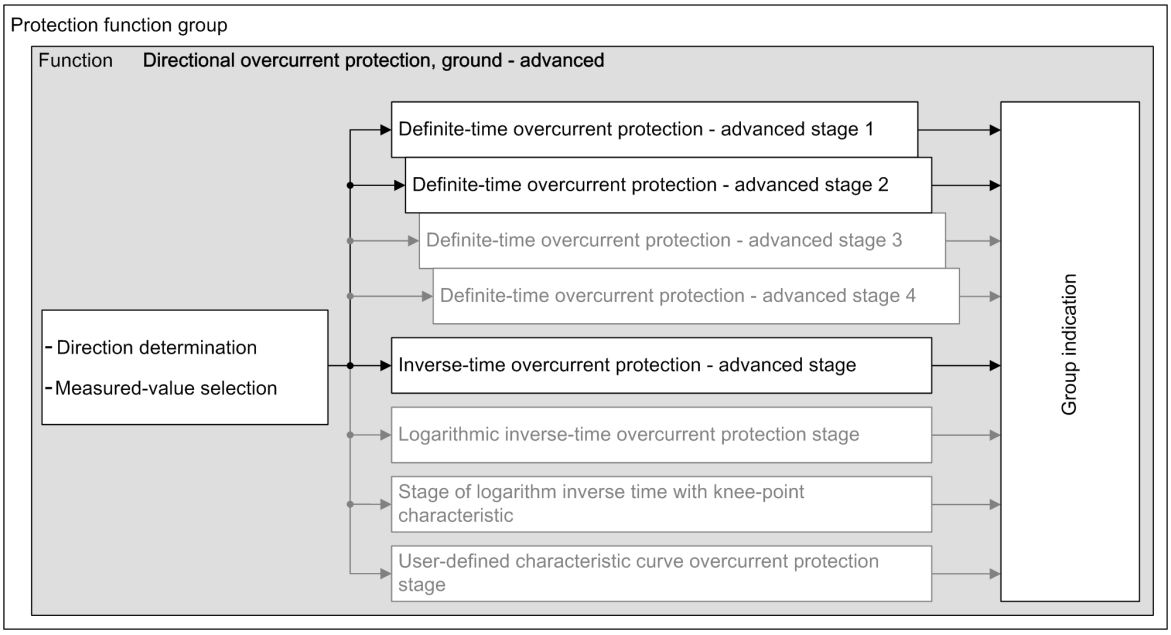
The basic function type shall be used for standard applications. The advanced function type provides more functionalities and is intended for more sophisticated applications.

Both function types are preconfigured by the manufacturer with 2 **Definite-time overcurrent protection** stages and 1 **Inverse-time overcurrent protection** stage.

In the advanced function type **Directional overcurrent protection, ground – advanced**, the following stages can operate simultaneously:

- A maximum of 4 **Definite-time overcurrent protection – advanced** stages
- 1 **Inverse-time overcurrent protection – advanced** stage
- 1 **Logarithmic inverse-time overcurrent protection** stage
- 1 **Logarithmic inverse time with knee-point overcurrent protection** stage
- 1 **User-defined characteristic curve overcurrent protection** stage

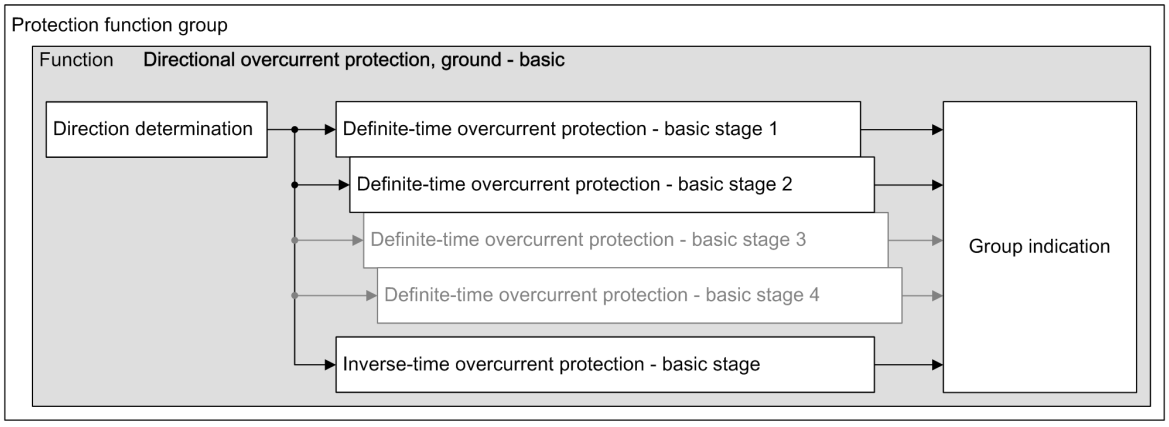
In the basic function type **Directional overcurrent protection, ground – basic**, the following stages can operate simultaneously:



- A maximum of 4 **Definite-time overcurrent protection – basic** stages
- 1 **Inverse-time overcurrent protection – basic** stage

Referring to *Figure 6-487* and *Figure 6-488*, the stages not preconfigured are shown in gray. Apart from the operate-delay characteristic curve, the stages are similar in structure.

The general functionality includes the direction determination and the measured-value selection (only advanced function). They take place on the functional level and have a uniform effect on the stages (see *Figure 6-487* and chapter *6.13.3 General Functionality*). This ensures that all stages of the function receive the same measured current value and the same direction result. Each stage can be set to work in forward or reverse direction.



The group indication output logic generates the following group indications for the protection function by the logic OR from the stage-selective indications:

- Pickup
- Operate

[dw_rdirad, 3, en_US]

Figure 6-487 Structure/Embedding of the Function Directional Overcurrent Protection, Ground – Advanced

[dw_rdirba, 2, en_US]

Figure 6-488 Structure/Embedding of the Function Directional Overcurrent Protection, Ground – Basic

If the following listed device-internal functions are present in the device, these functions can influence the pickup values and operate delays of the stages or block the stages. The stage can also be affected by an external source via a binary input signal.

- Automatic reclosing (AREC)
- Cold-load pickup detection
- Binary input signal

If the device is equipped with the **Inrush-current detection** function, the stages can be stabilized against operate due to transformer-inrush currents.

6.28.3 General Functionality

6.28.3.1 Measured-Value Selection

Logic

The function provides the option to select between the values ***IN measured*** or ***3I0 calculated***.

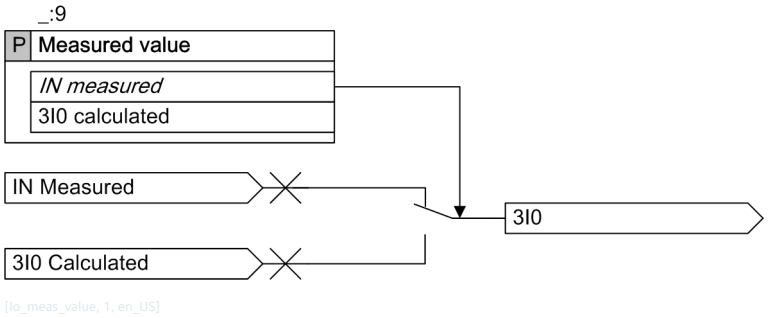


Figure 6-489 Logic Diagram of Measured-Value Selection

Both options are only available for the current-transformer connection types ***3-phase + IN*** and ***3-phase + IN-separate***. For other connection types respectively, only one option is possible. If you select an option that is not allowed, an inconsistency message is given.

Depending on the CT secondary rated current, the CT connection type, and the selected setting, the secondary threshold setting range varies according to the following table.

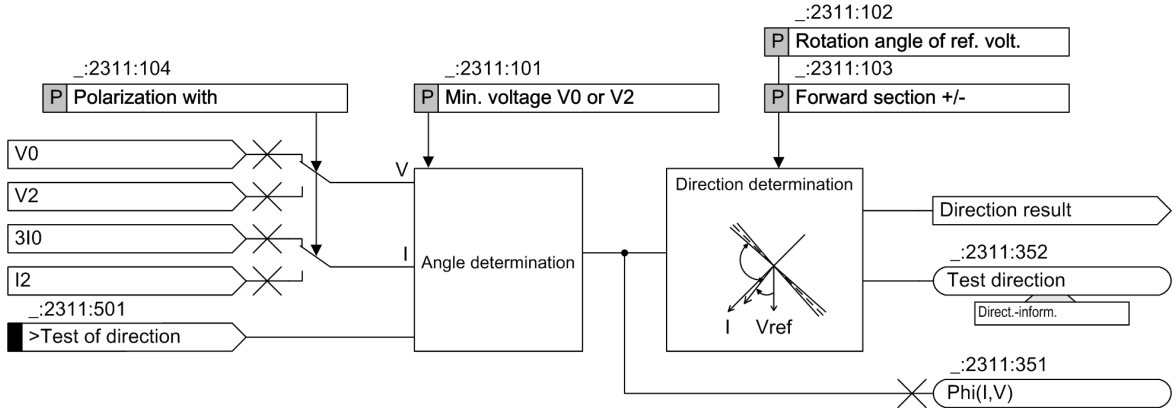

Table 6-14 Threshold Setting Range

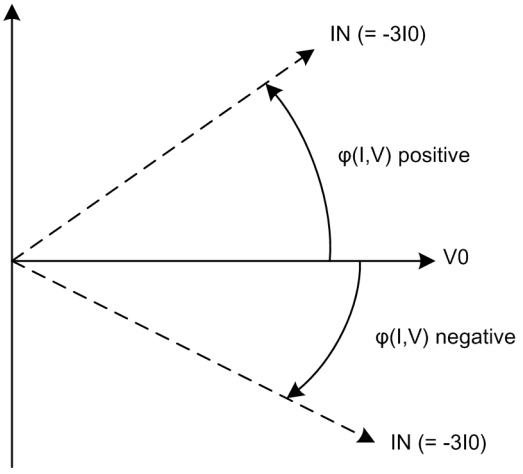
Connection Type	Measured Value	CT Terminal Type	Threshold Setting Range (rated I-sec.: ph = 1 A, IN = 1 A)	Threshold Setting Range (rated I-sec.: ph = 1 A, IN = 5 A)	Threshold Setting Range (rated I-sec.: ph = 5 A, IN = 1 A)	Threshold Setting Range (rated I-sec.: ph = 5 A, IN = 5 A)
3ph + IN	3I0 calculated	4 * Protection	0.030 A to 40.000 A	N/A	N/A	0.15 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	N/A	N/A	0.005 A to 8.000 A
	IN measured	4 * Protection	0.030 A to 40.000 A	N/A	N/A	0.15 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	N/A	N/A	0.005 A to 8.000 A
3ph + IN-separate	3I0 calculated	4 * Protection	0.030 A to 40.000 A	0.030 A to 40.000 A	0.15 A to 200.00 A	0.15 A to 200.00 A
		3 * Protection, 1 * sen.	0.030 A to 40.000 A	0.030 A to 40.000 A	0.15 A to 200.00 A	0.15 A to 200.00 A
		4 * Measurement	0.001 A to 1.600 A	0.001 A to 1.600 A	0.005 A to 8.000 A	0.005 A to 8.000 A
	IN measured	4 * Protection	0.030 A to 40.000 A	0.15 A to 200.00 A	0.030 A to 40.000 A	0.15 A to 200.00 A
		3 * Protection, 1 * sen.	0.001 A to 1.600 A	0.005 A to 8.000 A	0.001 A to 1.600 A	0.005 A to 8.000 A
		4 * Measurement	0.001 A to 1.600 A	0.005 A to 8.000 A	0.001 A to 1.600 A	0.005 A to 8.000 A

6.28.3.2 Direction Determination

Logic of Direction Determination

The following figure represents the logic of the direction determination. It applies to all types of stages.



[lo_dirdet, 1, en_US]

Figure 6-490 Logic Diagram of Direction Determination

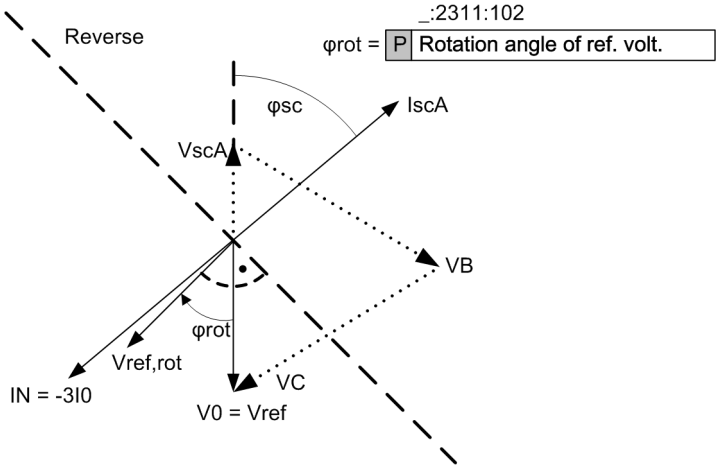
Measurand for the Direction Determination

With the parameter **`Direct. determination with`** you define whether the direction determination is calculated with the zero-sequence components 3I0 and V0 or with the negative-sequence components I2 and V2, which are present during faults in the network.

The angle between IN (=-3I0) and V0 (respectively -I2 and V2) in case of using the negative-sequence components is available as a functional measured value. This value is only present during faults in the network.

[dw_UI_kenn, 1, en_US]

Figure 6-491 Measured-Value Definition

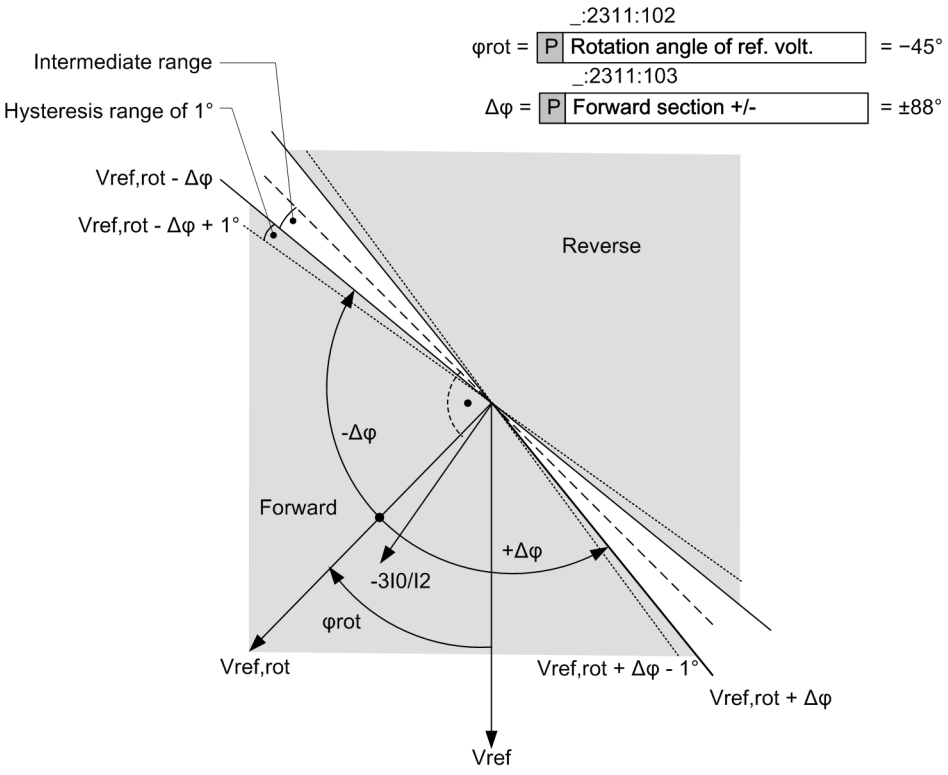


Start of the Direction Determination

If the zero-sequence current 3I0 exceeds the pickup threshold of a stage and the selected voltage (V0 or V2) exceeds the parameter **`Min. voltage V0 or V2`** as well, the direction determination is started.

Direction Determination with Zero-Sequence Values

The direction is determined by calculating the phase angle between the short-circuit current -3I0 and the rotated reference voltage $V_{ref, rot}$. Contrary to the **Directional overcurrent protection, phase** function, which works with the healthy voltage as reference voltage, the fault voltage V0 itself is the reference voltage for the **Directional overcurrent protection, ground** function. To take different system conditions and applications



into account, the reference voltage V0 can be rotated through an adjustable angle (parameter **`Rotation angle of ref. volt.`**). This moves the vector of the rotated reference voltage close to the vector of the short-circuit current -3I0. Consequently, the result of direction determination is as reliable as possible. *Figure 6-492* illustrates the relationship based on a 1-phase-to-ground fault in phase A. The fault current has a phase displacement of 180° to the fault current IscA and lags the fault voltage by the fault angle φsc. The reference voltage V0 is rotated by φrot which is -45°.

[dw_roreze, 2, en_US]

Figure 6-492 Rotation of the Reference Voltage, Directional Overcurrent Protection, Ground Function with Zero-Sequence Values

The rotated reference voltage $V_{ref, rot}$ and the parameter **`Forward section +/-`** define the forward and reverse ranges, see *Figure 6-493*. The forward range is calculated as ± Δφ° around the rotated reference voltage $V_{ref, rot}$. Δφ is set with the parameter **`Forward section +/-`** . If the short-circuit current vector -3I0 is located in this range, the device decides on the forward direction. In the mirrored range, the device decides on the reverse direction. In the intermediate range, the direction is undetermined.

[dw_forrev, 2, en_US]

Figure 6-493 Forward/Reverse Characteristic of the Directional Overcurrent Protection, Ground Function

Direction Determination with Negative-Sequence Values

The method works in the same way as for zero-sequence values. Instead of 3I0 and V0, the negative-sequence values I2 and V2 are used for determining the direction.

Direction Determination for Test Purposes

If you activate the binary input signal *>Test of direction* , the direction is determined and indicated even without the current threshold being exceeded in one of the stages. The direction can be determined as soon as the zero-sequence current 3I0 and the zero-sequence voltage V0 exceeds approx. 7 % of the secondary rated values of phase current and voltage.

6.28.3.3 Application and Setting Notes

Parameter: `Measured value`

- Recommended setting value **`(_:9) Measured value`** = ***`IN Measured`***

This parameter is not available in the basic function.

Parameter Value	Description
`IN Measured`	The function operates with the measured ground current IN. This is the recommended setting unless there is a specific reason to use the calculated zero-sequence current 3I0.
`3I0 Calculated`	The function operates with the calculated zero-sequence current 3I0. This setting option can be used when applying a redundant 50N/51N function for safety reasons.

Parameter: `Min. voltage V0 or V2`

- Recommended setting value **`(_:2311:101) Min. voltage V0 or V2`** = ***`2 V`***

This parameter is not available in the basic function. The basic function uses a fixed value of 2 V.

You use the **Min. voltage V0 or V2** parameter to define the minimum zero-sequence voltage or negative-sequence voltage for the direction determination. The minimum voltage must be set greater than the maximum operational unbalance plus the voltage-transformer measuring errors.

As the measuring error of the individual voltage transformer is not added up, the critical measuring-error influence is the unbalance of the primary system.

Siemens recommends observing the operational zero-sequence voltage V0 of the protected object (for example, the line) via the operational measured values of the device and providing the maximum value with a certainty of 50 %.

EXAMPLE

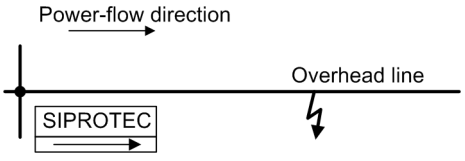
Maximum operational measured value of zero-sequence voltage V0 = 0.5 Vsec

Min. voltage V0 or V2 = 1.5 · 0.5 V = 0.75 Vsec

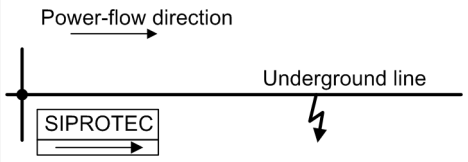
If you have no information about maximum operational unbalance, Siemens recommends using the default setting.

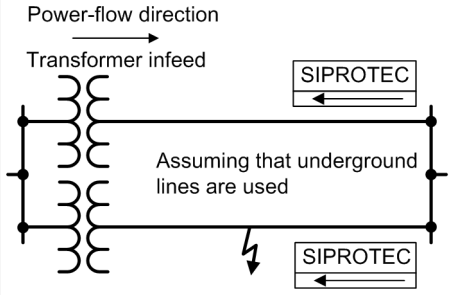
Parameter: Rotation angle of ref. volt. / Forward section +/-

- Recommended setting value **(_:2311:102) Rotation angle of ref. volt.** = ***-45°***
- Recommended setting value **(_:2311:103) Forward section +/-** = ***88°***



The parameter **Forward section +/-** is not available in the basic function. The basic function uses a fixed value of 88°.





The direction characteristic, that is, the area of the forward and reverse ranges, is set with the **Rotation angle of ref. volt.** and the **Forward section +/-** parameters. The short-circuit angle is typically to be found in a range from -30° to -60° inductively. Therefore, in most cases, the default setting of -45° can be retained to position the reference voltage, as it ensures a reliable directional result.

Some example settings for special applications appear below *Table 6-15*. Note that for 1-phase-to-ground faults (PG faults), the reference voltage is the zero-sequence voltage V0. This results in the following setting for the rotation angle:

Rotation angle of ref. volt. = -φk ground-measuring elements (PG faults)

Table 6-15 Example Settings

Application	φk Typical	Setting **Rotation angle of ref. volt.**
	60°	-60°

	30°	-30°
	30°	-30°

Parameter: **`Direct. determination with`**

- Recommended setting value **`(_:2311:104) Direct. determination with`** = ***`zero sequence`***

This parameter is not available in the basic function. The basic function uses always zero-sequence components for the direction determination.

You use the parameter **`Direct. determination with`** to select the values for the direction determination.

Parameter Value	Description
`zero sequence`	Select ***`zero sequence`*** to determine the direction via the zero-sequence components V0 and 3I0. Siemens recommends using the zero-sequence components for the direction determination.
`negative sequence`	Select ***`negative sequence`*** to determine the direction via the negative-sequence components V2 and I2. The negative-sequence system can be used in case of danger that the zero-sequence voltage is too small due to unfavorable zero-sequence impedance conditions or that a parallel line influences the zero-sequence system.

Input Signal: ***`>Test of direction`***

If you activate the binary input signal ***`>Test of direction`***, the direction is determined and indicated even without the current threshold being exceeded in one of the stages. This provides an easy means of checking the direction during commissioning, without changing the threshold values of the stages.

6.28.3.4 Settings

Addr.	Parameter	C	Setting Options	Default Setting
`General`				
_:2311:9	General:Measured value		• 3I0 calculated • IN measured	IN measured

6.28.4 Stage Control

6.28.4.1 Description

Logic

The following figure represents the stage control. It applies to all types of stages.

[lo_sta_con, 2, en_US]

Figure 6-494 Logic Diagram of the Stage Control

Blocking of Stage in Case of Measuring-Voltage Failure

The stages can be blocked if a measuring-voltage failure occurs. In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- From an internal source on the pickup of the **Measuring-voltage failure detection** function
- From an external source via the binary input signal *>Open* of the function block **Voltage-transformer circuit breaker**, which links to the trip of the voltage-transformer circuit breaker

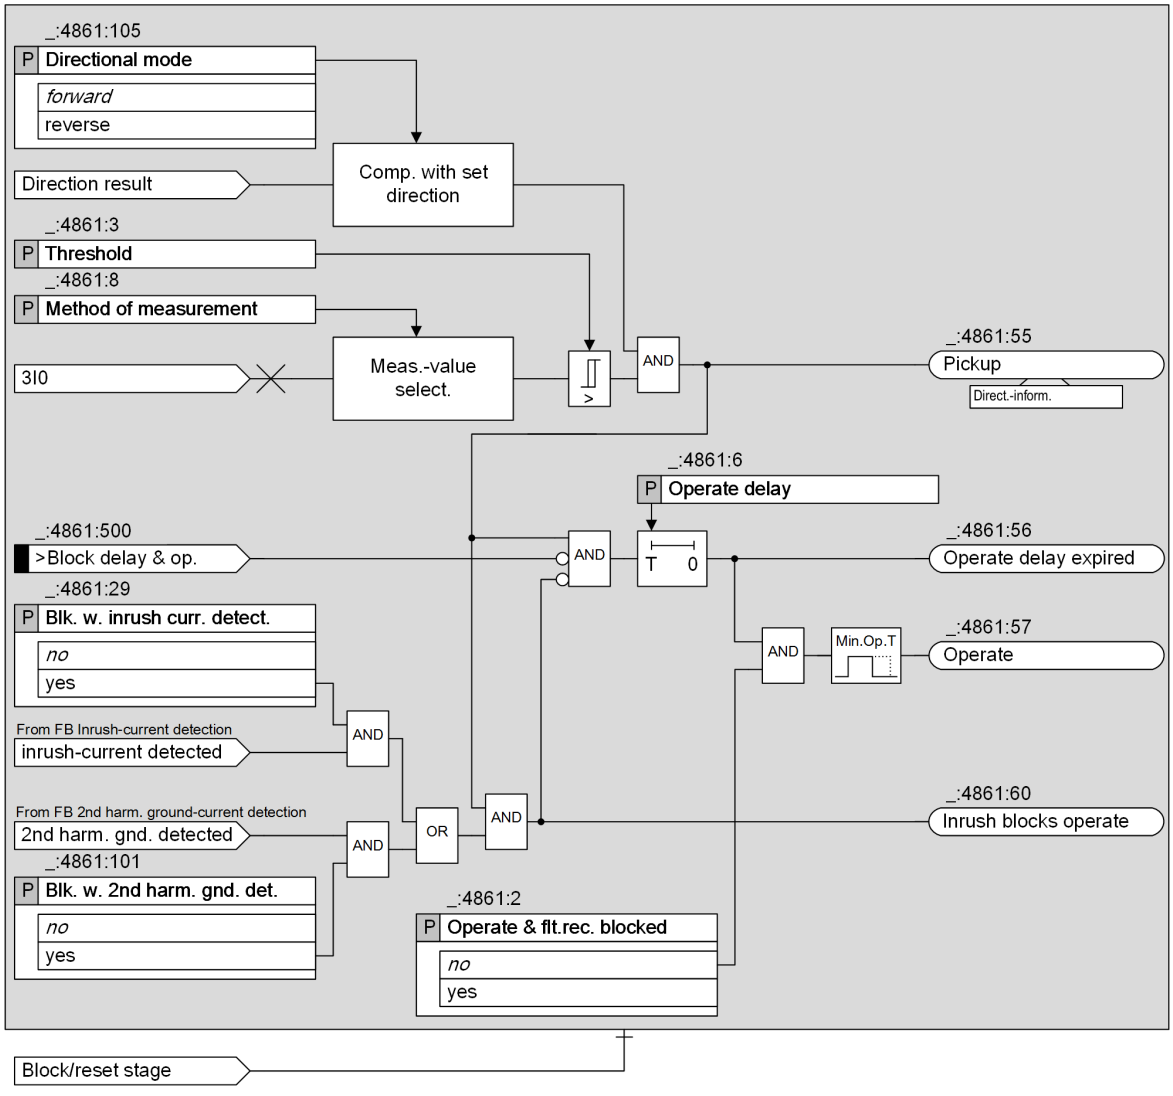
The **Blk. by meas.-volt. failure** parameter can be set to either block or not block the stage when the **Measuring-voltage failure detection** function picks up.

6.28.4.2 Application and Setting Notes

Parameter: **Blk. by meas.-volt. failure**

- Recommended setting value **(_:4861:10) Blk. by meas.-volt. failure** = ***yes***

You can use the **Blk. by meas.-volt. failure** parameter to control the response of the stage when a measuring-voltage failure is detected.
A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

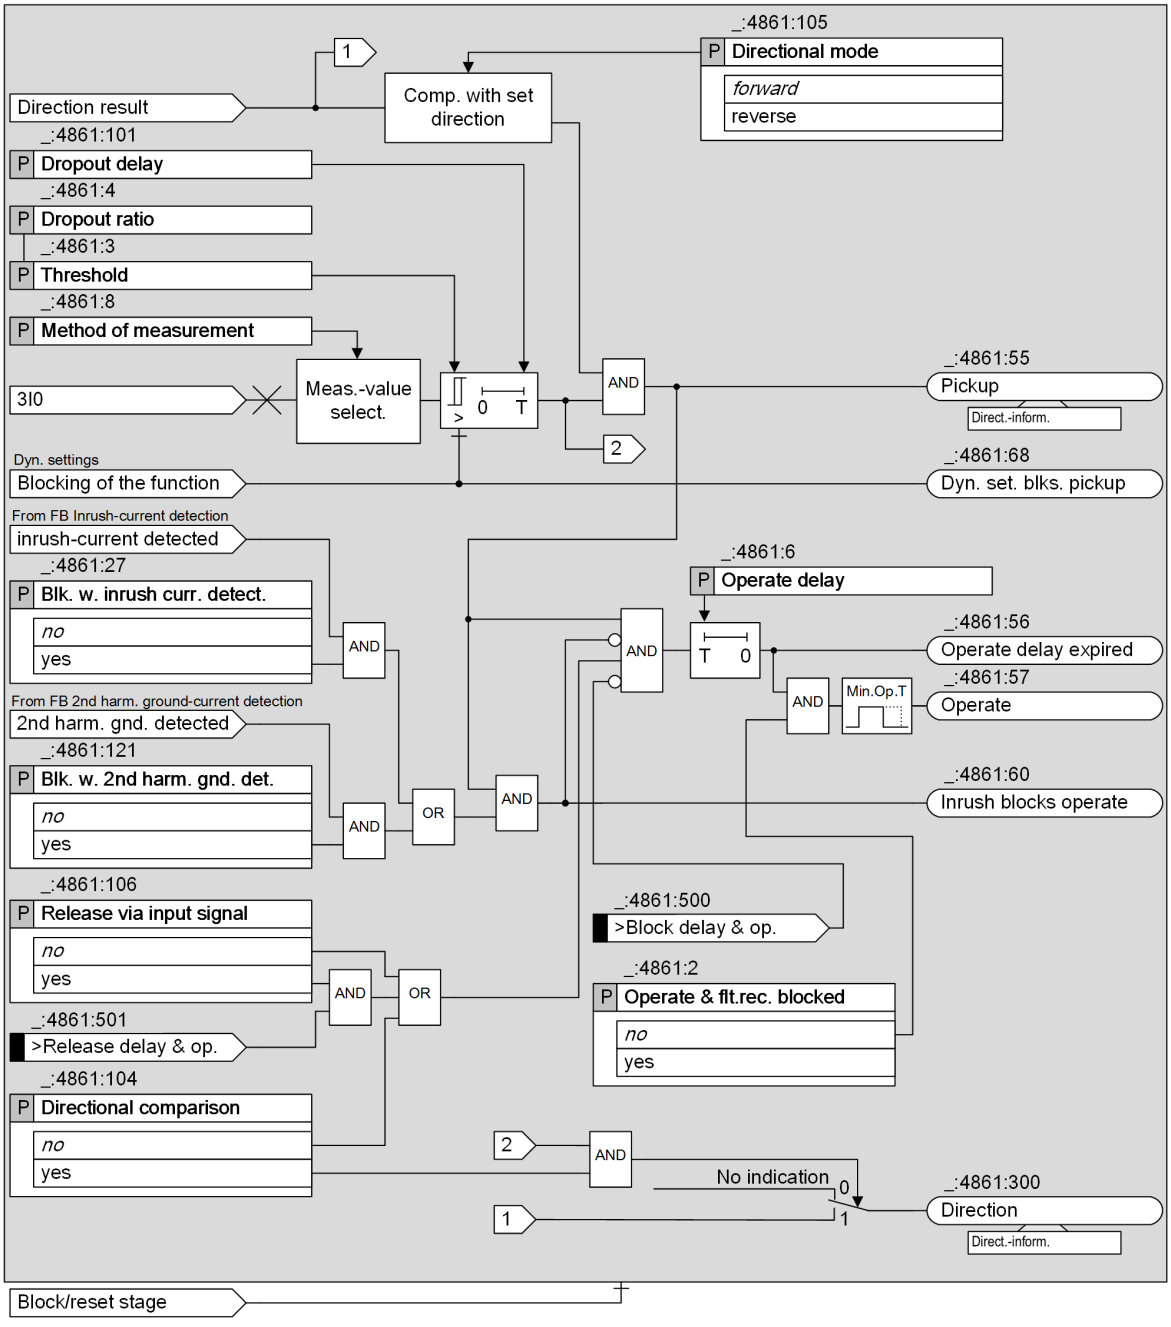


- The device-internal **Measuring-voltage failure detection** function is configured and switched on.
- The binary input signal *>Open* of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker.

Parameter Value	Description
yes	The directional overcurrent-protection stage is blocked when a measuring-voltage failure is detected. Siemens recommends using the default setting, as correct direction determination cannot be guaranteed if a measuring-voltage failure occurs.
no	The directional overcurrent-protection stage is not blocked when a measuring-voltage failure is detected.

6.28.5 Stage with Definite-Time Characteristic Curve

6.28.5.1 Description



Logic of the Basic Stage

[lo_dirovb, 2, en_US]

Figure 6-495 Logic Diagram of the Directional Definite-Time Overcurrent Protection, Ground – Basic

Logic of the Advanced Stage

[lo_dirova, 1, en_US]

Figure 6-496 Logic Diagram of the Directional Definite-Time Overcurrent Protection, Ground – Advanced

Measurand (Basic and Advanced Stage)

The function uses the zero-sequence current (3I0) as a criterion for the ground fault.

Depending on the parameter setting connection type of the **Measuring point I-3ph**, the zero-sequence current is measured or calculated. Depending on the applied CT terminal type, the 3I0 **`Threshold`** range varies according to the following table.

Table 6-16 Threshold Setting Range

Connection Type of the Measuring Point I-3ph	Ground Current	CT Terminal Type	Threshold Setting Range (Secondary)
3-phase	Calculated	4 * Protection	0.030 A to 40.000 A
		3 * Protection, 1* sensitive	0.030 A to 40.000 A
		4 * Measurement	0.001 A to 1.600 A
x + IN x + IN-separate	Measured	4 * Protection	0.030 A to 40.000 A
		3 * Protection, 1* sensitive	0.001 A to 1.600 A
		4 * Measurement	0.001 A to 1.600 A

Method of Measurement (Basic and Advanced Stage)

You use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

- Measurement of the fundamental component:
  This measuring procedure processes the sampled current values and filters out the fundamental components numerically.
- Measurement of the RMS value:
  This measuring procedure determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Directional Mode (Basic and Advanced Stage)

You can use the **Directional mode** parameter to define whether the stage works in a forward or reverse direction.

The direction determination works across all stages (see chapter *6.28.3.2 Direction Determination*).

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Externally or internally via the binary input signal *>Block stage* (see chapter *6.28.4.1 Description*)
- Measuring-voltage failure (see chapter *6.28.4.1 Description*)
- Via the dynamic settings functionality (only available in the advanced function type, see **Influence of Other Functions via Dynamic Settings** and chapter *6.28.10 Influence of Other Functions via Dynamic Settings*)

Blocking of the Operate Delay (Basic and Advanced Stage)

You can use the binary input signal *>Block delay & op.* to prevent the start of the operate delay and thus also the generation of the operate signal. A running operate delay is reset. The pickup is indicated. Fault logging and fault recording take place.

Blocking of the Operate Delay and Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in chapter *6.24.7.1 Description*

Dropout Delay (Advanced Stage)

In case of undershooting of the dropout threshold, the dropout can be delayed. The pickup is maintained for the specified time. The operate delay continues to run. If the operate delay expires while the pickup is still maintained, the stage operates.

Directional Comparison Protection (Advanced Stage)

The stage can be used for directional comparison protection. This is set using the **Directional comparison** parameter. With the ***yes*** setting, the direction indication *Direction* is released and the direction (forward or reverse) is determined, if the current exceeds the threshold of the stage. The direction indicated is independent of the directional mode set for the stage.

The **Release via input signal** parameter and the *>Release delay & op.* input signal are available with directional comparison protection. If the **Release via input signal** parameter is set to ***yes***, the start of the operate delay, and therefore the operate signal of the stage, are only enabled when the *>Release delay & op.* input signal is active.

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can exert an influence on the overcurrent-protection stage:

- Automatic reclosing
- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in chapter *6.28.10 Influence of Other Functions via Dynamic Settings*.

6.28.5.2 Application and Setting Notes

Parameter: Directional mode

- Default setting **(_:4861:105) Directional mode** = ***forward***

You can use the **Directional mode** parameter to define the directional mode of the stage.

Parameter Value	Description
forward	Select this setting if the stage is to work in forward direction (in the direction of the line).
reverse	Select this setting if the stage is to work in reverse direction (in the direction of the busbar).

Parameter: Method of measurement

- Recommended setting value **(_:4861:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: **Directional comparison**, **Release via input signal**

- Default setting **(_:4861:104) Directional comparison** = ***no***
- Default setting **(_:4861:106) Release via input signal** = ***no***

The parameters **Directional comparison** and **Release via input signal** are not visible for the basic stage.

You can use these settings to define whether the stage is to be used for directional comparison protection. Directional comparison protection is performed via the *Direction* and *>Release delay & op.* signals.

Parameter Value	Description
no	The stage is not used for directional comparison protection.
yes	If the **Directional comparison** parameter is set to ***yes***, the **Release via input signal** parameter, the *Direction* output signal, and the *>Release delay & op.* input signal become available. If the **Release via input signal** parameter is set to ***yes***, the starts of the operate delay and operate signal are only enabled when the *>Release delay & op.* input signal is active. The *>Release delay & op.* input signal must be connected to the enable information from the opposite end (forward information from the *Direction* output signal). See also the application example in *6.27.10 Application Notes for Directional Comparison Protection*

Parameter: **Dynamic settings**

- Default setting **(_:4861:26) Dynamic settings** = ***no***

This parameter is not visible for the basic stage.

Parameter Value	Description
no	The influence on the overcurrent-protection stage by device-internal or external functions is not necessary.
yes	If a device-internal function (**Automatic reclosing** or **Cold-load pickup detection**) or an external function should affect the overcurrent-protection stage (such as change the setting of the threshold value or operate delay, blocking of the stage), the setting must be changed to ***yes***. This makes the configuration parameters affected by **Auto reclosing**/**Cold-load PU**/**Binary input** as well as the dynamic settings **Threshold**, **Operate delay**, and **Stage blocked** of the stage visible and enables the settings to be set for the specific influence.

For further setting notes, refer to *6.24.8.2 Application and Setting Notes (Advanced Stage)* of the function **Overcurrent Protection, Ground**.

Parameter: **Blk. w. inrush curr. detect.**

- Default setting **(_:4861:27) Blk. w. inrush curr. detect.** = ***no***

Parameter Value	Description
no	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This applies, for example, to the high-current stage that is set according to the short-circuit voltage Vsc of the transformer in such a way that the stage only picks up on faults from the high-voltage side. The transformer inrush current cannot become larger than the maximum transmittable short-circuit current.
yes	When the transformer inrush-current detection detects an inrush current that would lead to an operate of the stage, the start of the operate delay and operate of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

Parameter: `Threshold`

- Default setting **`(_:4861:3) Threshold`** = ***`1.20 A`***

For setting the threshold value, the same considerations apply as for the non-directional overcurrent protection function.

For further information, refer to *6.24.4.2 Application and Setting Notes* .

Parameter: `Dropout ratio`

- Recommended setting value **`(_:4861:4) Dropout ratio`** = ***`0.95`***

This parameter is not visible for the basic stage.

The recommended setting value of ***`0.95`*** is appropriate for most applications.

For high-precision measurements, the setting value of the **`Dropout ratio`** parameter can be reduced, for example to 0.98. If you expect highly fluctuating measurands at the pickup threshold, you can increase the setting value of the **`Dropout ratio`** parameter. This avoids chattering of the stage.

Parameter: Dropout delay

- Recommended setting value **`(_:4861:101) Dropout delay`** = ***`0 s`***

This parameter is not visible for the basic stage.

Siemens recommends using the dropout delay of 0 s, since the dropout of a protection stage must be performed as fast as possible.

You can use the **`Dropout delay`** parameter ≠ ***`0 s`*** to obtain a uniform dropout behavior if you use it together with an electromechanical relay. This is required for time grading. The dropout time of the electromechanical relay must be known for this purpose. Subtract the dropout time of your own device (see Technical data) and set the result.

Parameter: `Operate delay`

- Default setting **`(_:4861:6) Operate delay`** = ***`0.300 s`*** (for the 1st stage)

The **`Operate delay`** to be set is derived from the time-grading chart that has been prepared for the system.

Typical examples of grading times are provided in sections *6.27.9 Application Notes for Parallel Lines* and *6.27.10 Application Notes for Directional Comparison Protection* .

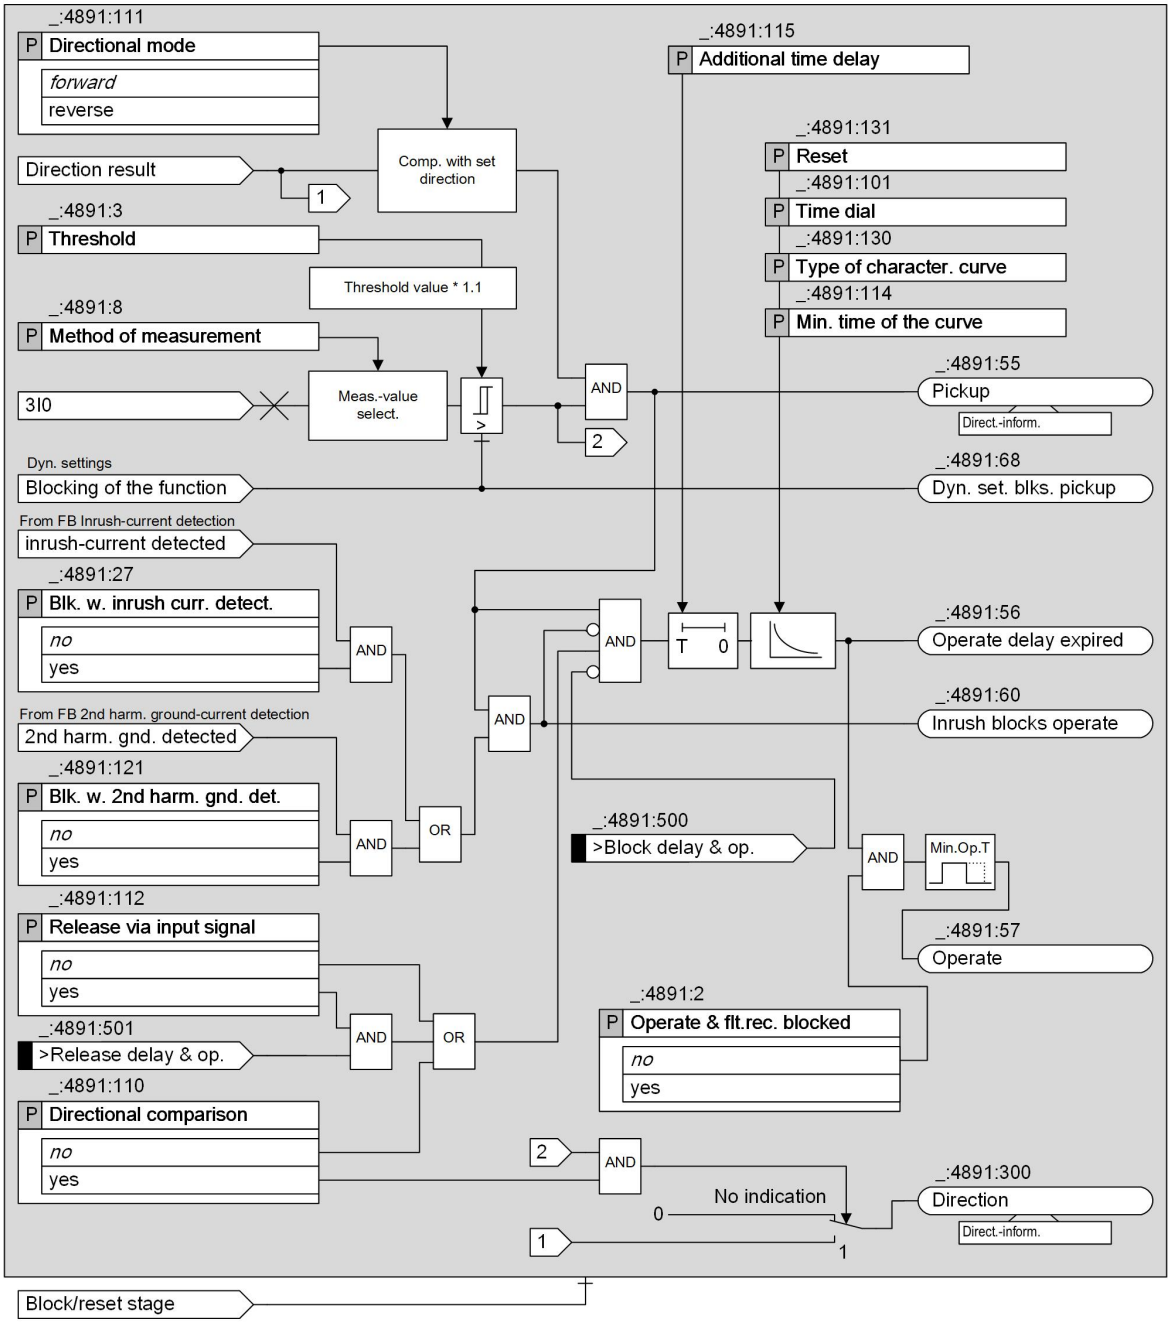
6.28.6 Stage with Inverse-Time Characteristic Curve

6.28.6.1 Description



Logic of the Basic Stage

{Io_diinvb, 3, en_US}

Figure 6-497 Logic Diagram of the Directional Inverse-Time Overcurrent Protection, Ground – Basic

Logic of the Advanced Stage

[lo_diinva, 3, en_US]

Figure 6-498 Logic Diagram of the Directional Inverse-Time Overcurrent Protection, Ground – Advanced

Measurand (Basic and Advanced Stage)

The function uses the zero-sequence current (3I0) as a criterion for the ground fault.

Depending on the parameter setting connection type of the **Measuring point I-3ph**, the zero-sequence current is measured or calculated. Depending on the applied CT terminal type, the 3I0 **Threshold** range varies according to the following table.

Table 6-17 Threshold Setting Range

Connection Type of the Measuring Point I-3ph	Ground Current	CT Terminal Type	Threshold Setting Range (Secondary)
3-phase	Calculated	4 * Protection	0.030 A to 40.000 A
		3 * Protection, 1* sensitive	0.030 A to 40.000 A
		4 * Measurement	0.001 A to 1.600 A
x + IN x + IN-separate	Measured	4 * Protection	0.030 A to 40.000 A
		3 * Protection, 1* sensitive	0.001 A to 1.600 A
		4 * Measurement	0.001 A to 1.600 A

Method of Measurement (Basic and Advanced Stage)

You use the **Method of measurement** parameter to define whether the stage uses the standard method (***fundamental comp.***) or the calculated ***RMS value***.

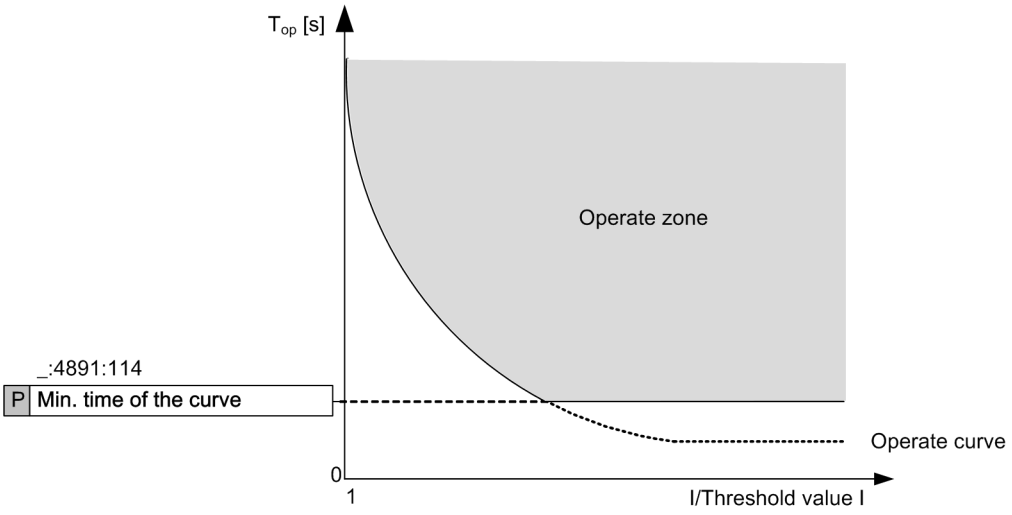
- Measurement of the fundamental component:
  This measuring procedure processes the sampled current values and filters out the fundamental components numerically.
- Measurement of the RMS value:
  This measuring procedure determines the current amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Directional Mode (Basic and Advanced Stage)

You can use the **Directional mode** parameter to define whether the stage works in a forward or reverse direction.

The direction determination works across all stages (see *6.28.3.2 Direction Determination*).

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI (Basic and Advanced Stage)



When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Minimum Time of the Curve (Advanced Stage)

With the parameter **Min. time of the curve**, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time.

[dw_min_time, 1, en_US]

Figure 6-499 Minimum Operating Time of the Curve

Additional Time Delay (Advanced Stage)

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay. With this setting, the whole curve is shifted on the time axis by this additional definite time.

Blocking of the Stage (Basic and Advanced Stage)

The following blockings reset the picked up stage completely:

- Externally or internally via the binary input signal *>Block stage* (see *6.28.4.1 Description*)
- Measuring-voltage failure (see *6.28.4.1 Description*)
- Via the dynamic settings functionality (only available in the advanced function type, see **Influence of Other Functions via Dynamic Settings** and *6.28.10 Influence of Other Functions via Dynamic Settings*)

Blocking of the Operate Delay (Basic and Advanced Stage)

You can use the binary input signal *>Block delay & op.* to prevent the start of the operate delay and thus also the generation of the operate signal. A running operate delay is reset. The pickup is indicated. Fault logging and fault recording take place.

Blocking of the Operate Delay and Operate Signal via the Device-Internal Inrush-Current Detection Function (Basic and Advanced Stage)

Blocking of the operate delay and the operate signal via the device-internal **Inrush-current detection** function is described in Blocking of the Tripping by Device-Internal Inrush-Current Detection

For more information, refer to *6.24.7.1 Description*.

Directional Comparison Protection (Advanced Stage)

The stage can be used for directional comparison protection. This is set using the **Directional comparison** parameter. With the ***yes*** setting, the direction indication *Direction* is released and the direction (forward or reverse) is determined, if the current exceeds the threshold of the stage. The direction indicated is independent of the directional mode set for the stage.

The **Release via input signal** parameter and the *>Release delay & op.* input signal are available with directional comparison protection. If the **Release via input signal** parameter is set to ***yes***, the start of the operate delay, and therefore the operate signal of the stage, are only enabled when the *>Release delay & op.* input signal is active.

Influence of Other Functions via Dynamic Settings (Advanced Stage)

If available in the device, the following functions can exert an influence on the overcurrent-protection stage:

- Automatic reclosing
- Cold-load pickup detection
- Binary input signal

The influence of these functions via dynamic settings is described in *6.28.10 Influence of Other Functions via Dynamic Settings*.

6.28.6.2 Application and Setting Notes

Parameter: Directional mode

- Default setting **(_:4891:111) Directional mode** = ***forward***

You can use the **Directional mode** parameter to define the directional mode of the stage.

Parameter Value	Description
forward	Select this setting if the stage is to work in forward direction (in the direction of the line).
reverse	Select this setting if the stage is to work in reverse direction (in the direction of the busbar).

Parameter: Method of measurement

- Recommended setting value **(_:4891:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: Directional comparison, Release via input signal

- Default setting **(_:4891:110) Directional comparison** = ***no***
- Default setting **(_:4891:112) Release via input signal** = ***no***

The parameters **Directional comparison** and **Release via input signal** are not visible for the basic stage.

You can use these settings to define whether the stage is to be used for directional comparison protection. Directional comparison protection is performed via the *Direction* and *>Release delay & op.* signals.

Parameter Value	Description
no	The stage is not used for directional comparison protection.
yes	If the **Directional comparison** parameter is set to ***yes***, the **Release via input signal** parameter, the *Direction* output signal, and the *>Release delay & op.* input signal become available. If the **Release via input signal** parameter is set to ***yes***, the starts of the operate delay and operate signal are only enabled when the *>Release delay & op.* input signal is active. The *>Release delay & op.* input signal must be connected to the release information from the opposite end (forward information from the *Direction* output signal). See also the application example in chapter *6.27.10 Application Notes for Directional Comparison Protection* .

Parameter: **Dynamic settings**

- Default setting **(_:4891:26) Dynamic settings** = ***no***

This parameter is not visible for the basic stage.

Parameter Value	Description
no	The influence on the overcurrent-protection stage by device-internal or external functions is not necessary.
yes	If a device-internal function (**Automatic reclosing** or **Cold-load pickup detection**) or an external function should affect the overcurrent-protection stage (such as change the setting of the threshold value or operate delay, blocking of the stage), the setting must be changed to ***yes***. This makes the configuration parameters affected by **Auto reclosing**/**Cold-load PU**/**Binary input** as well as the dynamic settings **Threshold**, **Time dial**, and **Stage blocked** of the stage visible and enables the settings to be set for the specific influence.

For further setting notes, refer to chapter *6.24.8.2 Application and Setting Notes (Advanced Stage)* of the function **Overcurrent Protection, Ground**.

Parameter: **Blk. w. inrush curr. detect.**

- Default setting **(_:4891:27) Blk. w. inrush curr. detect.** = ***no***

Parameter Value	Description
no	The transformer inrush-current detection does not affect the stage. Select this setting in the following cases: • In cases where the device is not used on transformers. • In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer. This applies, for example, to the high-current stage that is set according to the short-circuit voltage V_{sc} of the transformer in such a way that the stage only picks up on faults from the high-voltage side. The transformer inrush current cannot become larger than the maximum transmittable shortcircuit current.
yes	When the transformer inrush-current detection detects an inrush current that would lead to an operate of the stage, the start of the operate delay and operate of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer. This applies to the overcurrent-protection stage, which is used as a backup stage with grading time for faults on the undervoltage side of the transformer.

Parameter: **Min. time of the curve**

- Default setting **(_:4891:114) Min. time of the curve** = ***0.00 s***

This parameter is only available in the advanced stage.

With the parameter **Min. time of the curve**, you define a minimum operate delay time. The operate delay time of inverse-time characteristic curve never falls below the minimum operate delay time. If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommends keeping the default setting of 0 s.

NOTE

If the set value is smaller than the smallest possible time delay of the inverse-time characteristic curve, the parameter has no influence on the delay time.

Parameter: **Additional time delay**

- Default setting **(_:4891:115) Additional time delay** = ***0.00 s***

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay.

If the setting is left on its default value of 0 s, this parameter has no effect on the inverse-time characteristic curve.

This parameter is only required for time coordination in recloser schemes. For all other applications, Siemens recommend keeping the default setting of 0 s.

Parameter: **Threshold**

- Default setting **(_:4891:3) Threshold** = ***1.20 A***

The setting depends on the minimal occurring ground-fault current. This must be detected.

Consider that a safety margin is set between pickup value and threshold value. The stage only picks up at approx. 10 % above the **Threshold**.

Parameter: `Type of character. curve`

- Default setting **`(_:4891:130) Type of character. curve`** = ***`IEC normal inverse`***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **`Type of character. curve`** required for your specific application.

Parameter: `Time dial`

- Default setting **`(_:4891:101) Time dial`** = ***`1`***

You can use the **`Time dial`** parameter to displace the characteristic curve in the time direction.
The setting value for the **`Time dial`** parameter is derived from the time-grading chart that has been prepared for the electrical power system.
Where no time grading and therefore no displacement of the characteristic curve is required, leave the **`Time dial`** parameter at ***`1`*** (default setting).

Parameter: `Reset`

- Default setting **`(_:4891:131) Reset`** = ***`disk emulation`***

You can use the **`Reset`** parameter setting to define whether the stage decreases according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Select this setting if the dropout does not have to be performed after a disk emulation and an instantaneous dropout is desired instead.

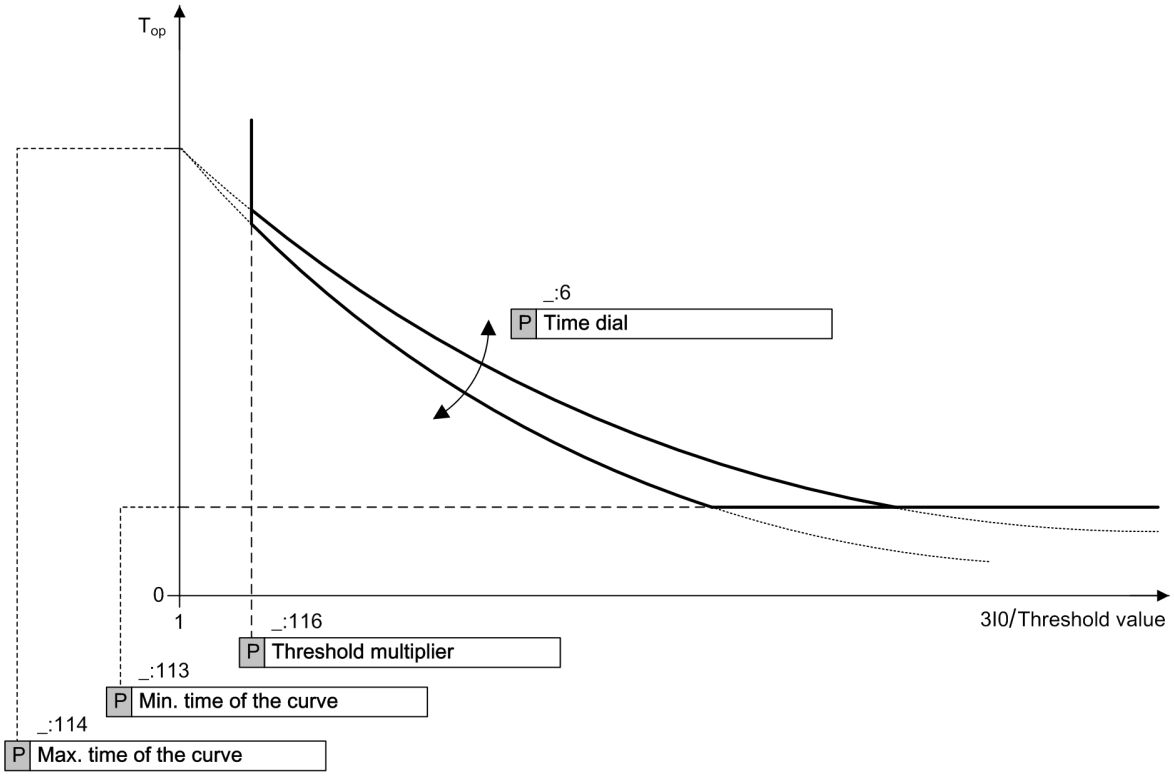
6.28.7 Stage with Inverse-Time Overcurrent Protection with Logarithmic-Inverse Characteristic Curve

6.28.7.1 Description

Logic of the Stage

[lo_diloin, 4, en_US]

Figure 6-500 Logic Diagram of the Directional Logarithmic Inverse-Time Overcurrent Protection, Ground



Apart from the operate curve, this type of stage is identical to the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.28.6.1 Description*).

This section will only discuss the nature of the operate curve. For further functionality, refer to chapter *6.28.6.1 Description*.

Operate Curve

If the function picks up, the logarithmic inverse-time characteristic curve is processed. A time value T_{op} is calculated for every input value exceeding 95 % of the pickup value. An integrator accumulates the value $1/T_{op}$. If the accumulated integral reaches the fixed value 1, the stage operates.

The curve used to calculate the time value T_{op} is shown in the following figure. The **Threshold multiplier** parameter defines the beginning of the characteristic curve. The **Max. time of the curve** determines the initial value of the characteristic curve. The **Time dial** parameter changes the slope of the characteristic curve. At high currents, the **Min. time of the curve** parameter indicates the lower time limit.

[dw_loginv, 3, en_US]

Figure 6-501 Operate Curve of Logarithmic Inverse-Time Characteristic

The time to operate is calculated with the following formula:

$$T_{op} = T_{max} - T_d \ln\left(\frac{3I0}{I_{thresh} \times I_{mul}}\right)$$

[fo_mula_01, 1, en_US]

Where

T_{max}	Maximum time of the curve (parameter **Max. time of the curve**)
T_d	Time dial (parameter **Time dial**)
T_{op}	Operate time
3I0	Measured zero-sequence current

I_{thresh} Threshold value (parameter **Threshold**)

I_{mul} Threshold multiplier (parameter **Threshold multiplier**)

If the calculated time is less than T_{min} (parameter **Min. time of the curve**), T_{min} is used.

6.28.7.2 Application and Setting Notes

Apart from the operate curve, this type of stage is identical to the ground-fault protection type with inverse-time delay according to IEC and ANSI (advanced function type) (see *6.28.6.1 Description*).

This section only discusses the nature of the operate curve. For further functionality, refer to chapter *6.28.6.2 Application and Setting Notes*.

Stage Type Selection

If the operate delay is to be dependent on the current level according to a logarithmic characteristic curve, select this stage type.

Dynamic Settings: Threshold

- Default setting **(_:3) Threshold** = ***1.20 A***

Define the pickup value corresponding to the application. In doing so, for time-graded stages, the settings of the superordinate and of the subordinate stages in the time-grading chart must be taken into consideration.

Parameter: Threshold multiplier

- Default setting **(_:116) Threshold multiplier** = ***1.1***

You can use the **Threshold multiplier** parameter to define the beginning of the characteristic curve on the current axis (in relation to the threshold value).

General information cannot be provided. Define the value corresponding to the application.

EXAMPLE

Threshold (Secondary current)	I_{thresh} = 1.2 A
Threshold multiplier	I_{mul} = 1.1
Pickup value (Secondary current)	I_{PU} = 1.2 A ×1.1 = 1.32 A

Dynamic Settings: Time dial

- Default setting **(_:6) Time dial** = ***1.250 s***

You can use the **Time dial** parameter to change the slope of the characteristic curve.

General information cannot be provided. Define the value corresponding to the application.

Parameter: Max. time of the curve

- Default setting **(_:114) Max. time of the curve** = ***5.800 s***

The parameter **Max. time of the curve** determines the initial value of the characteristic curve (for 3I0 = **Threshold**).

General information cannot be provided. Define the value corresponding to the application.

Parameter: Min. time of the curve

- Default setting **(_:113) Min. time of the curve** = ***1.200 s***

The parameter **Min. time of the curve** determines the lower time limit (at high currents).

General information cannot be provided. Define the value corresponding to the application.

Parameter: `Additional time delay`

- Recommended setting value **`(_:115) Additional time delay`** = ***`0 s`***

You can set an additional current-independent time delay. This additional delay is intended for special applications.

Siemens recommends setting this time to ***`0 s`*** so that it has no effect.

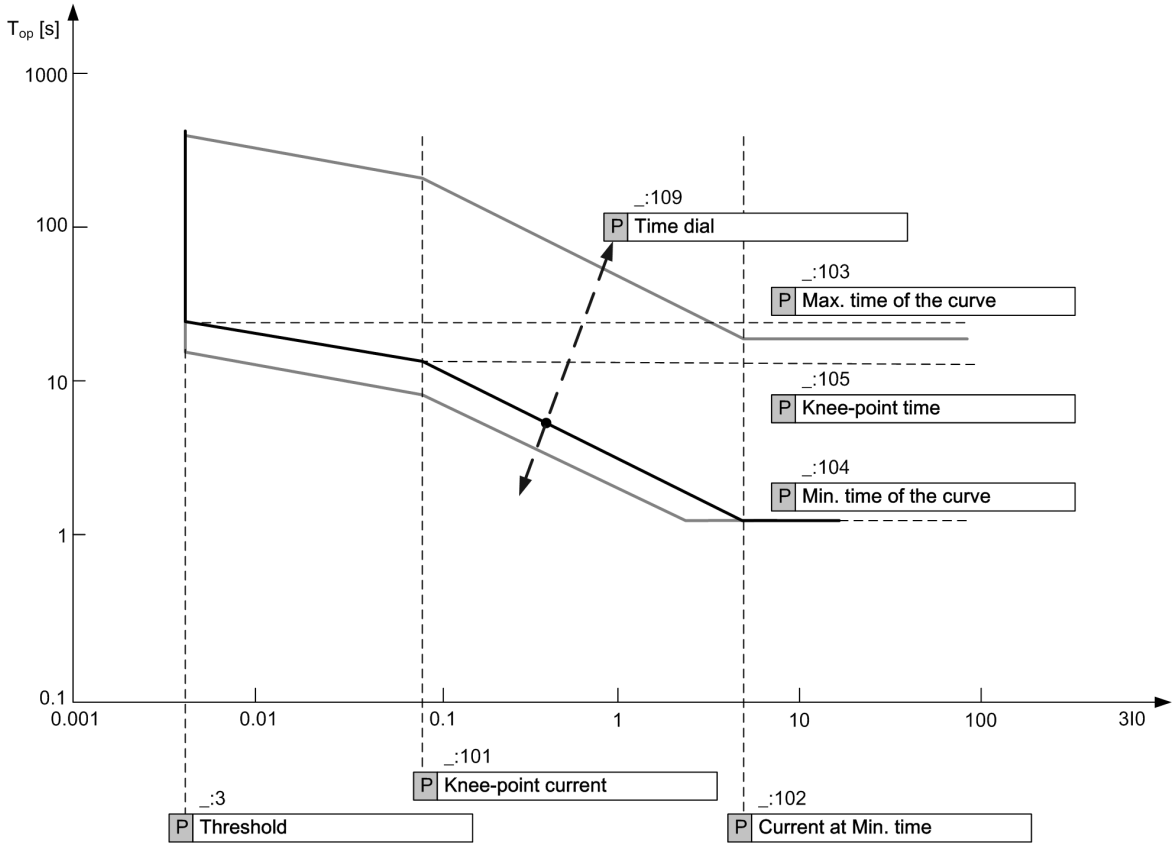
6.28.8 Stage with Knee-Point Characteristic Curve

6.28.8.1 Description

Logic of the Stage

[lo_dilokn, 4, en_US]

Figure 6-502 Logic Diagram of the Directional Logarithmic Inverse Time with Knee-Point Overcurrent Protection, Ground



Apart from the operate curve, this type of stage is almost identical to the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.28.6.1 Description*). The only difference is that the dynamic settings change functionality is not available.

This section only discusses the nature of the operate curve. For further functionality, refer to chapter *6.28.6.1 Description*.

Operate Curve

If the function picks up, the logarithmic inverse-time characteristic curve is processed. A time value T_{op} is calculated for every input value exceeding 95 % of the threshold value. An integrator accumulates the value $1/T_{op}$. If the accumulated integral reaches the fixed value 1, the stage operates.

The curve used to calculate the time value T_{op} is shown in the following graphic. The curve is composed of 2 sections with different slops. 7 parameters are used to define the logarithmic inverse time with knee-point characteristic curve. The parameter **Max. time of the curve** determines the initial time value of the characteristic curve, and relates to the 3I0 **Threshold** value. The transition point is defined by parameter **Knee-point current** and parameter **Knee-point time**. The parameter **Min. time of the curve** indicates the lower time limit, and parameter **Current at Min. time** determines the current value at **Min. time of the curve**. The parameter **Time dial** servers as a time factor to the operate time.

[dw_loinkn, 3, en_US]

Figure 6-503 Operate Curve of the Logarithmic Inverse Time with Knee-Point Characteristic (In the Example of **Threshold** = ***0.004 A***)

6.28.8.2 Application and Setting Notes

Apart from the operate curve, this type of stage is almost identical to the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.28.6.1 Description*). The only difference is that the dynamic settings change functionality is not available.

This section only discusses the nature of the operate curve. For further functionality, refer to chapter *6.28.6.2 Application and Setting Notes*.

Parameter: Threshold

- Default setting **(_:3) Threshold** = ***1.20 A***

You can use the **Threshold** parameter to define the pickup value of the stage corresponding to the specific application.

Parameter: `Time dial`

- Default setting **`(_:6) Time dial`** = ***`0.2`***

You can use the **`Time dial`** parameter to displace the operate curve in the time direction.
General information cannot be provided. Define the value corresponding to the application.

Parameter: `Knee-point`

- Default setting **`(_:101) Knee-point current`** = ***`1.300 A`***
- Default setting **`(_:105) Knee-point time`** = ***`23.60 s`***

You use the **`Knee-point current`** parameter and the **`Knee-point time`** parameter to define the knee-point of the operate curve.
General information cannot be provided. Define the values corresponding to the application.

Parameter: Minimum Time of the Operate Curve

- Default setting **`(_:104) Min. time of the curve`** = ***`0.80 s`***
- Default setting **`(_:102) Current at Min. time`** = ***`1.500 A`***

Via the parameters **`Min. time of the curve`** and **`Current at Min. time`**, the point of the operate curve is defined where higher currents do no longer cause shorter operate times.
General information cannot be provided. Define the value corresponding to the application.

Parameter: Maximum Time of the Operate Curve

- Default setting **`(_:103) Max. time of the curve`** = ***`93.00 s`***

You can use the parameter **`Max. time of the curve`** to determine the initial value of the operate curve (for 3I0 = **`Threshold`**).
General information cannot be provided. Define the value corresponding to the application.

6.28.9 Stage with User-Defined Characteristic Curve

6.28.9.1 Description

Logic of the Stage

[lo_dirusr, 2, en_US]

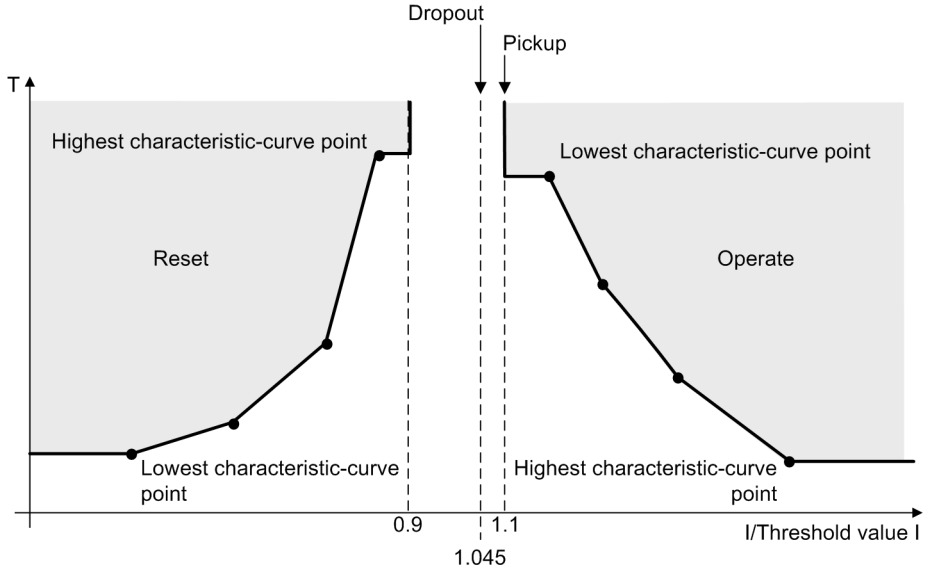
Figure 6-504 Logic Diagram of the Directional User-Defined Characteristic Curve Overcurrent Protection, Ground

This stage is structured in the same way as the **Inverse-time overcurrent protection – advanced** stage (see chapter *6.28.6.1 Description*). The only difference is that you can define the characteristic curve.

This section only discusses the nature of the operate curve. For further functionality, refer to chapter *6.28.6.1 Description*.

User-Defined Characteristic Curve

With the directional, user-defined characteristic curve, you can define the operate curve point by point using up to 30 value pairs of current and time. The device uses linear interpolation to calculate the characteristic curve from these values. You can also define a dropout characteristic curve if you wish.



Pickup and Dropout Behaviors with User-Defined Characteristic Curves

When the input variable exceeds the threshold value by 1.1 times, the characteristic curve is processed.

An integrating method of measurement totalizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls short of the threshold value by a factor of 1.045 (0.95 × 1.1× threshold value), the dropout is started. The pickup will be indicated as outgoing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is started from 0.9 of the set threshold value.

The following figure shows the pickup behavior and dropout behavior when a directional user-defined characteristic curve is used.

[dw_pidrbe, 1, en_US]

Figure 6-505 Pickup and Dropout Behaviors when Using a User-Defined Characteristic Curve

NOTE

Note that the currents that are lower than the current value of the smallest characteristic-curve point do not extend the operate time. The pickup characteristic runs in parallel to the current axis up to the smallest characteristic-curve point. Currents that are larger than the current value of the largest characteristic-curve point do not reduce the operate time. The pickup characteristic runs in parallel to the current axis from the largest characteristic-curve point.

6.28.9.2 Application and Setting Notes

This stage is structured in the same way as the **Inverse-time overcurrent protection – advanced** stage. The only difference is that you can define the characteristic curve as required. This section only provides application and setting notes for setting the characteristic curves. For guidance on the other parameters of the stage, see chapter *6.28.6.2 Application and Setting Notes*.

Parameter: `Current/time value pairs` (of the Operate Curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting follows the characteristic curve you want to realize.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **`Threshold`** parameter to ***`1.00`*** in order to obtain a simple relation. You can change the threshold setting afterwards if you want to displace the characteristic curve.

Specify the time value in seconds. The characteristic curve is displaced using the **`Time dial`** parameter.

NOTE

The value pairs must be entered in continuous order.

Parameter: `Time dial`

- Default setting **`(_:101) Time dial`** = ***`1`***

You can use the **`Time dial`** parameter to displace the characteristic curve in the time direction.

The setting value for the **`Time dial`** parameter is derived from the time-grading chart that has been prepared for the system. Where no grading and therefore no displacement of the characteristic curve is required, leave the **`Time dial`** set to ***`1`***.

Parameter: `Reset`

- Default setting **`(_:110) Reset`** = ***`disk emulation`***

The **`Reset`** parameter is used to define whether the stage drops out according to the dropout characteristic curve (behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Both operate curve and a dropout characteristic curve have to be specified with this setting. Use this setting if the device is coordinated with electromechanical devices or other devices performing dropout after disk emulation.
`instantaneous`	Use this setting if the dropout is not to be performed after disk emulation, that is, if instantaneous dropout is required.

Parameter: `Current/time value pairs` (of the Dropout Curve)

Use these settings to define the characteristic curve. Set a current/time value pair for each characteristic-curve point. The setting is determined by the characteristic curve you want to achieve.

Set the current value as a multiple of the threshold value. Siemens recommends that you set the **`Threshold`** parameter to ***`1.00`*** in order to obtain a simple relation. You can change the threshold setting afterwards if you want to displace the characteristic curve.

Specify the time value in seconds. The characteristic curve is displaced using the **`Time dial`** parameter.

NOTE

The value pairs must be entered in continuous order.

6.28.10 Influence of Other Functions via Dynamic Settings

6.24.8.1 Description and *6.24.8.2 Application and Setting Notes (Advanced Stage)* describe the influence of other functions on dynamic settings.

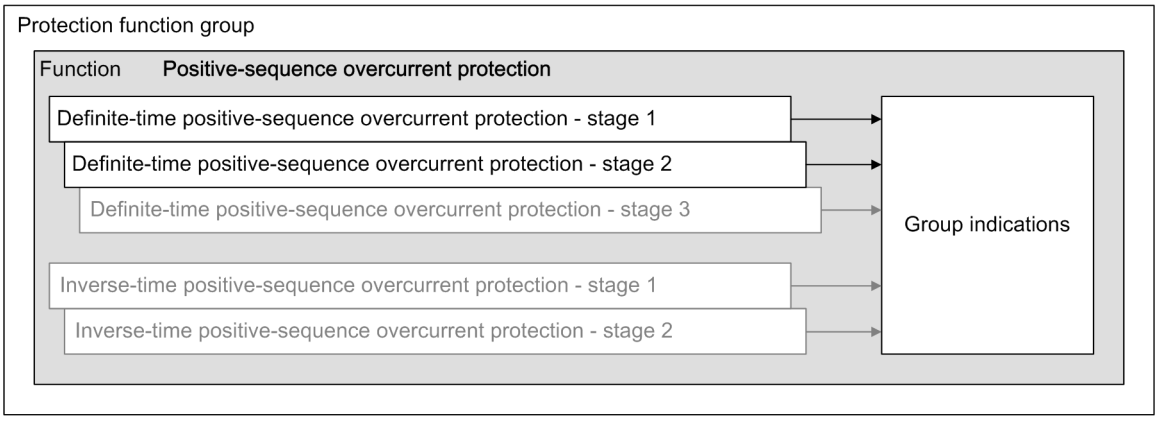
6.29 Positive-Sequence Overcurrent Protection

6.29.1 Overview of Functions

The **Positive-sequence overcurrent protection** function (ANSI 50/51):

- Detects short circuits in electric equipment
- Can be applied when the zero-sequence current or negative-sequence current should not influence the tripping, for example, on the tertiary delta winding of an auto transformer

You can find a typical application scenario in the chapter *6.29.3.2 Application and Setting Notes*.



6.29.2 Structure of the Function

The **Positive-sequence overcurrent protection** function is used in protection function groups with 3-phase current measurement.
The function comes factory-set with 2 **Definite-time positive-sequence overcurrent protection** stages.
The following stages can be operated simultaneously within the function:

- 3 stages **Definite-time positive-sequence overcurrent protection**
- 2 stages **Inverse-time positive-sequence overcurrent protection**

Stages that are not preconfigured are shown in gray in the following figure. Apart from the tripping delay characteristic, the stages are identical in structure.
The group-indication output logic generates the following group indications of the protection function by the logical OR of the stage-selective indications:

- **`Pickup`**
- **`Operate`**

[dw_PSP_structure, 1, en_US]

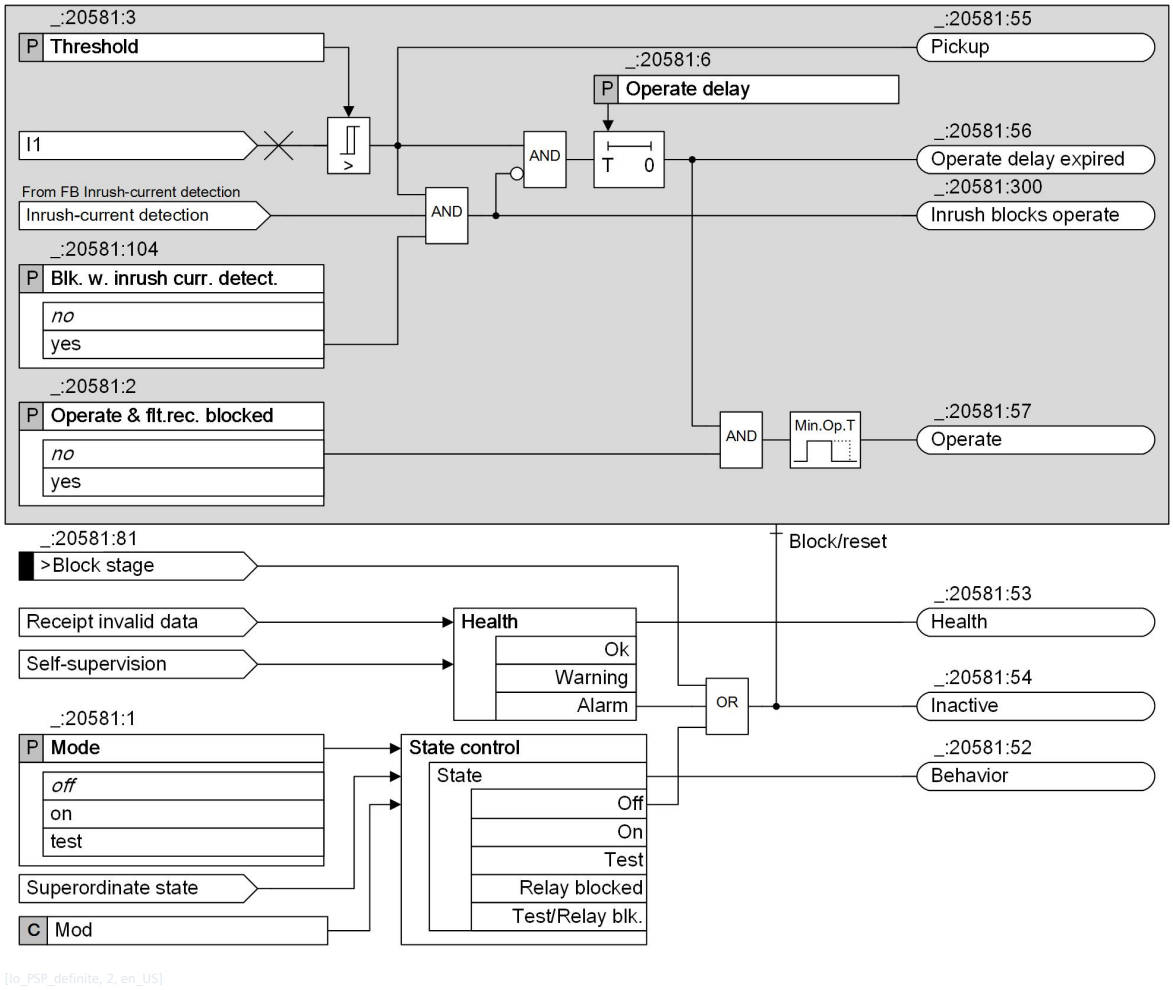


Figure 6-506 Structure/Embedding of the Function

If the device is equipped with an **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer-inrush currents.

6.29.3 Stage with Definite-Time Characteristic Curve

6.29.3.1 Description

Logic

[lo_PSP_definite, 2, en_US]

Figure 6-507 Logic Diagram of the Stage Definite-Time Positive-Sequence Overcurrent Protection

Method of Measurement

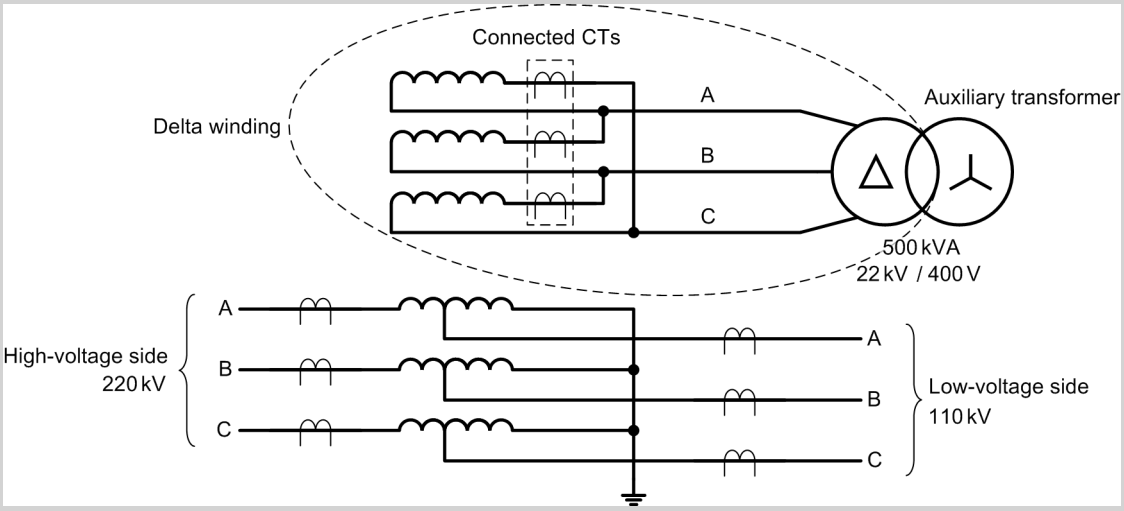
The fundamental phasors are calculated from the 3-phase phase currents. Based on this, the positive-sequence current is calculated.

Blocking of the Stage

You can block the stage externally or internally via the binary input signal **`>Block stage`**. In the event of blocking, the picked up stage is reset.

Blocking of Tripping via the Device-Internal Inrush-Current Detection Function

If the device is equipped with the additional **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer inrush currents.



With the **`Blk. w. inrush curr. detect.`** parameter, you can define whether tripping of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking, the stage picks up. The start of the time delay and tripping are however blocked. The stage signals this by way of a corresponding indication. If the blocking drops out and the threshold value of the stage is still exceeded, the tripping delay (time delay) is started. After that time, the stage operates.

6.29.3.2 Application and Setting Notes

Application Example

The **Positive-sequence overcurrent protection** function is applied to the tertiary delta winding of the auto transformer as shown in the following figure.

Short circuits on the delta winding must be detected. The stage should be as sensitive as possible but must not pick up in case of faults in the circuits connected to the low-voltage side of the auxiliary transformer. A single **Positive-sequence overcurrent protection** stage without time delay is applied and is connected with the CTs marked in the following figure. When the stage operates, both the high-voltage and low-voltage sides of the auto transformer will trip.

[dw_PSP_application_example, 1, en_US]

Figure 6-508 Auto Transformer with Tertiary Delta Winding

During ground faults on the high-voltage side (220 kV) or low-voltage side (110 kV) of the auto transformer, large currents circulate in the delta winding. This circulating current is a pure zero-sequence current. The protection function applied to the delta winding must not respond to this zero-sequence current. For this purpose, the **Positive-sequence overcurrent protection** function is applied.

In this application example, there is no circuit breaker on the delta winding, and the load on the delta winding is directly connected via the 500-kVA auxiliary transformer.

The application data in this application example is as follows:

Application Data	Value
Rated apparent power of the auto transformer	300 MVA
Rated apparent power of the auxiliary transformer ($S_{rated, aux}$)	500 kVA
Short-circuit voltage of the auxiliary transformer ($u_{k\text{-}aux}$)	12 %
Rated apparent power of the delta winding	30 MVA
Rated voltage of the delta winding ($V_{rated, delta}$)	22 kV
Connected load on the delta winding	500 kVA
Current transformer ratio in the delta winding ($Ratio_I$)	800 A/1 A

Generally, for the delta winding, the short-circuit current is substantially larger than the rated current, and the expected maximum load current is substantially smaller than the rated current. Therefore, you only need to consider the short-circuit current when determining the pickup threshold of the **Positive-sequence overcurrent protection** function.

As there is no circuit breaker between the delta winding and the connected auxiliary transformer, the pickup threshold of the **Positive-sequence overcurrent protection** function is graded against the maximum short-circuit current due to a short circuit on the low-voltage (400 V) side of the auxiliary transformer. The

maximum fault current for a fault on the low-voltage side of the auxiliary transformer must therefore be determined to establish the pickup threshold.

To determine the pickup threshold (setting of the **Threshold** parameter) of the stage, the following calculations must be carried out:

- Maximum short-circuit current ($I_{SC, max}$) on the high-voltage side of the auxiliary transformer due to a short circuit on the low-voltage (400 V) side

$$I_{SC, max} = \frac{S_{rated, aux} \cdot 100}{V_{rated, delta} \cdot \sqrt{3} \cdot u_{k\text{-}aux}} = \frac{500\ kVA \cdot 100}{22\ kV \cdot \sqrt{3} \cdot 12\ \%} = 109\ A$$

[fo_max_fault_current, 1, en_US]

- Primary-current pickup threshold ($I1_{stage1, prim}$)

  In this example, a safety margin (k_s) of 200 % is applied.

$$I1_{stage\ 1, prim} = \frac{I_{SC, max} \cdot k_s}{\sqrt{3}} = \frac{109\ A \cdot 2}{\sqrt{3}} = 126\ A$$

[fo_prim_threshold, 1, en_US]

- Secondary-current pickup threshold ($I1_{stage1, sec}$), which is the setting of the **Threshold** parameter

$$I1_{stage\ 1, sec} = I1_{stage\ 1, prim} \cdot \frac{1}{Ratio_I} = 126\ A \cdot \frac{1\ A}{800\ A} = 0.16\ A$$

[fo_sec_threshold, 1, en_US]

Parameter: Threshold, Operate delay

- Default setting **(_:20581:3) Threshold** = ***1.200 A*** (for the 1st stage)
- Default setting **(_:20581:6) Operate delay** = ***0.50 s*** (for the 1st stage)

Set the **Threshold** and **Operate delay** parameters for the specific application.

As time coordination with other protection functions is not required, you can set the **Operate delay** parameter to a rather small value of ***0.03 s***.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:20581:104) Blk. w. inrush curr. detect.** = ***no***

With the **Blk. w. inrush curr. detect.** parameter, you stabilize the stage against tripping due to transformer-inrush currents. If transformers are parts of the protection zones, set this parameter to **yes**.

When the pickup threshold is set to 2 times the maximum short-circuit current, the threshold value should be above the current flowing during an inrush to the auxiliary transformer. Consequently, the setting of the **Blk. w. inrush curr. detect.** can remain ***no***. For more sensitive pickup thresholds, the **Blk. w. inrush curr. detect.** should be set to **yes**.

Parameter: Operate & flt.rec. blocked

- Default setting **(_:20581:2) Operate & flt.rec. blocked** = ***no***

With the **Operate & flt.rec. blocked** parameter, you block the operate indication, the fault recording, and the fault log.

6.29.4 Stage with Inverse-Time Characteristic Curve

6.29.4.1 Description

Logic

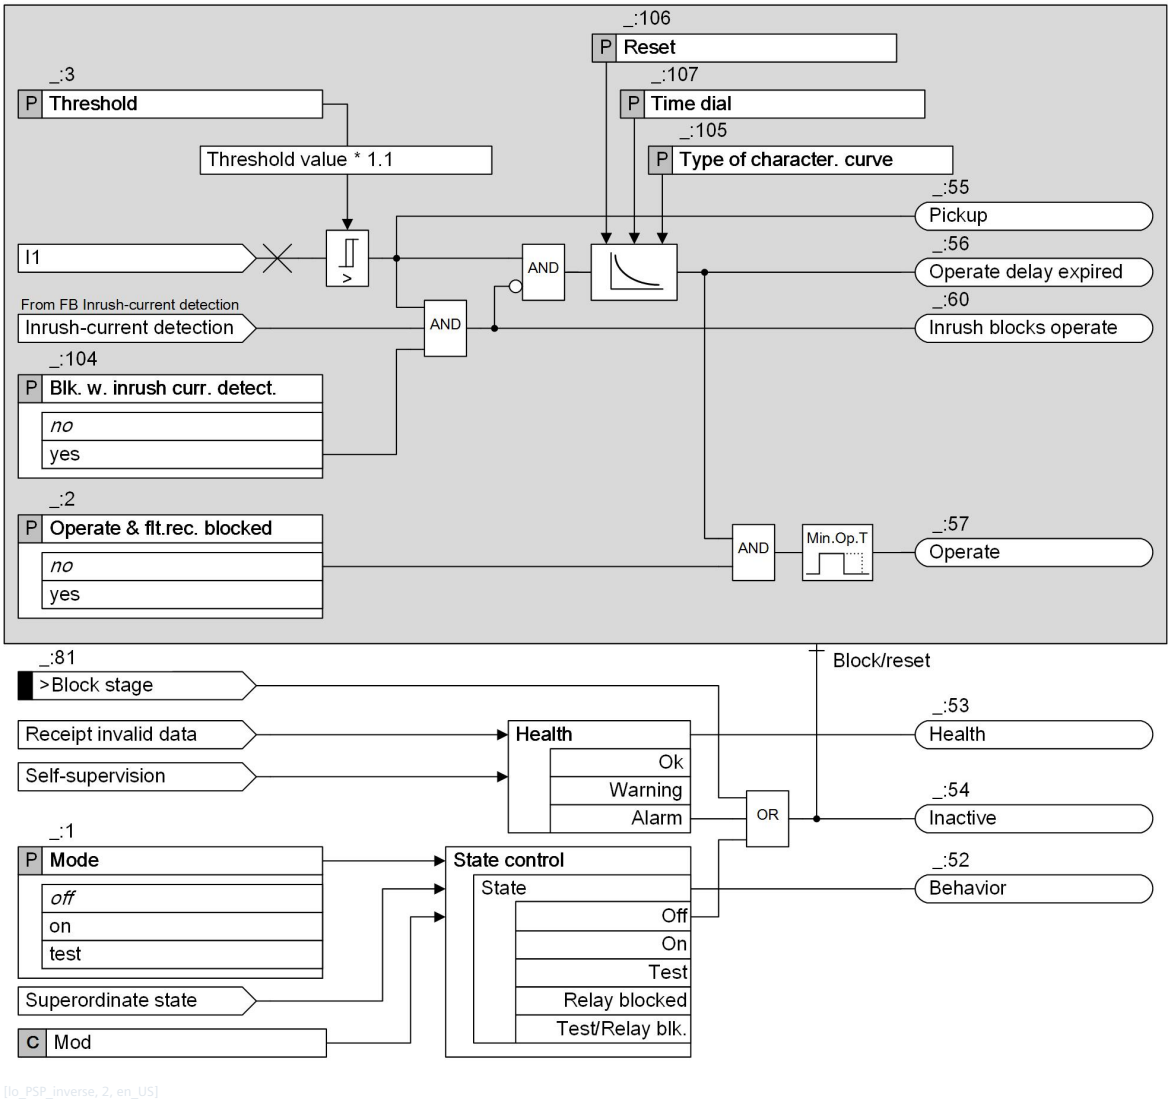

Figure 6-509 Logic Diagram of the Inverse-Time Positive-Sequence Overcurrent Protection

Method of Measurement

The fundamental phasors are calculated from the 3-phase phase currents. Based on this, the positive-sequence current is calculated.

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI

When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according

to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Blocking of the Stage

You can block the stage externally or internally via the binary input signal **>Block stage**. In the event of blocking, the picked up stage is reset.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

The **Blk. w. inrush curr. detect.** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

6.29.4.2 Application and Setting Notes

Parameter: Type of character. curve

- Default setting **(_:105) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application. For more information about the parameter **Type of character. curve**, refer to chapter *12.25.2 Stage with Inverse-Time Characteristic Curve*.

Parameter: Threshold

- Default setting **(_:3) Threshold** = ***1.200 A***

Set the **Threshold** and **Type of character. curve** parameters for the specific application.

Note that a safety margin is set between the pickup value and the threshold value. The stage only picks up at approx. 10 % above the **Threshold**.

Parameter: Time dial

- Default setting **(_:107) Time dial** = ***1.00***

With the **Time dial** parameter, you displace the characteristic curve in the time direction.

The set value for the **Time dial** parameter is derived from the time-grading schedule that has been prepared for the electrical power system.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the parameter **Time dial** at ***1.00*** (default setting).

Parameter: Reset

- Default setting **(_:106) Reset** = ***disk emulation***

With the **Reset** parameter, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
disk emulation	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
instantaneous	Select this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

Parameter: Blk. w. inrush curr. detect.

- Default setting **(_:104) Blk. w. inrush curr. detect.** = ***no***

With the **Blk. w. inrush curr. detect.** parameter, you stabilize the stage against tripping due to transformer-inrush currents. If transformers are parts of the protection zones, set this parameter to **yes**.

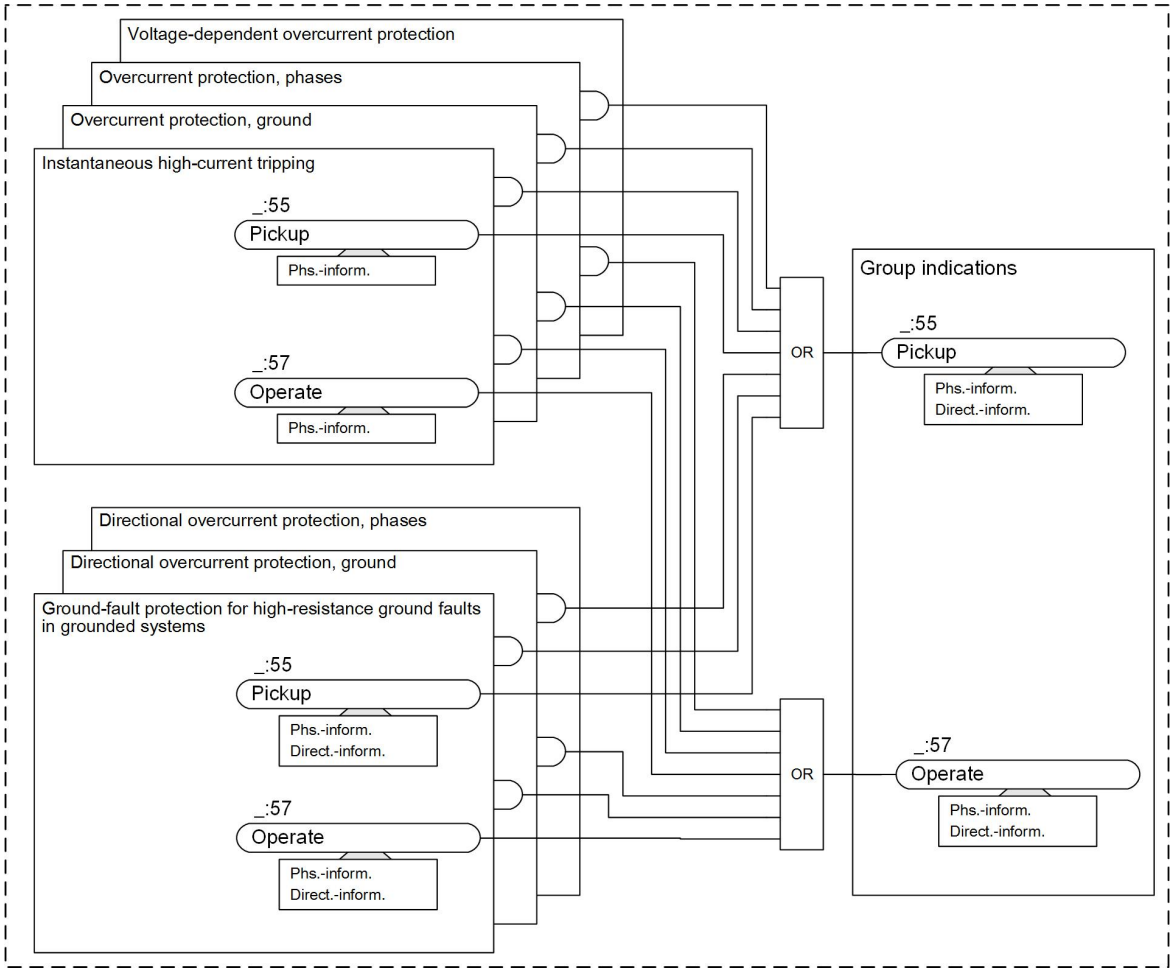
6.30 Group Indications of Overcurrent Protection Functions

6.30.1 Description



The function block **Group indications of the overcurrent protection functions** uses the pickup and operate indications of the following functions:

- Overcurrent protection, phases
- Overcurrent protection, ground
- Voltage-dependent overcurrent protection
- Directional overcurrent protection, phases
- Directional overcurrent protection, ground
- Ground-fault protection for high-impedance ground faults in grounded systems
- Instantaneous high-current tripping

The group indications of the overcurrent protection are generated by a logical OR of the stage-selective pickup and operate indications of the functions listed above (see also *Figure 6-510*):

- **`Pickup`**
- **`Operate`**

The pickup and operate indications are output, where present, with direction information.

[lo_oc_grin, 4, en_US]

Figure 6-510 Logic Diagram of the Overcurrent Protection Group Indications

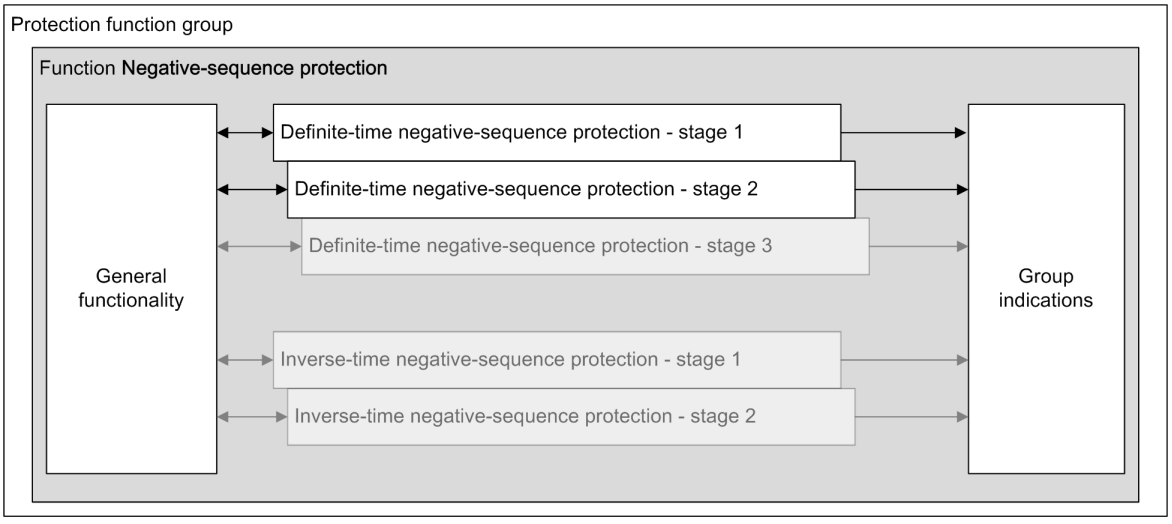
6.31 Negative-Sequence Protection

6.31.1 Overview of Functions

The function **Negative-sequence protection** (ANSI 46):

- Detects 1-phase or 2-phase short circuits in the electrical power system with clearly increased sensitivity compared to the classical overcurrent protection
- Protects electric machines during excessive unbalanced load
- Reports unbalanced load conditions in the electricity supply system
- Detects phase interruptions in the primary system
- Locates short circuits or inversions in the connections to the current transformers

6.31.2 Structure of the Function



The **Negative-sequence protection** function is used in protection function groups with current measurement.

The function is preconfigured by the manufacturer with 2 **Definite-time negative-sequence protection** stages.

In the function **Negative-sequence protection**, the following stages can be operated simultaneously:

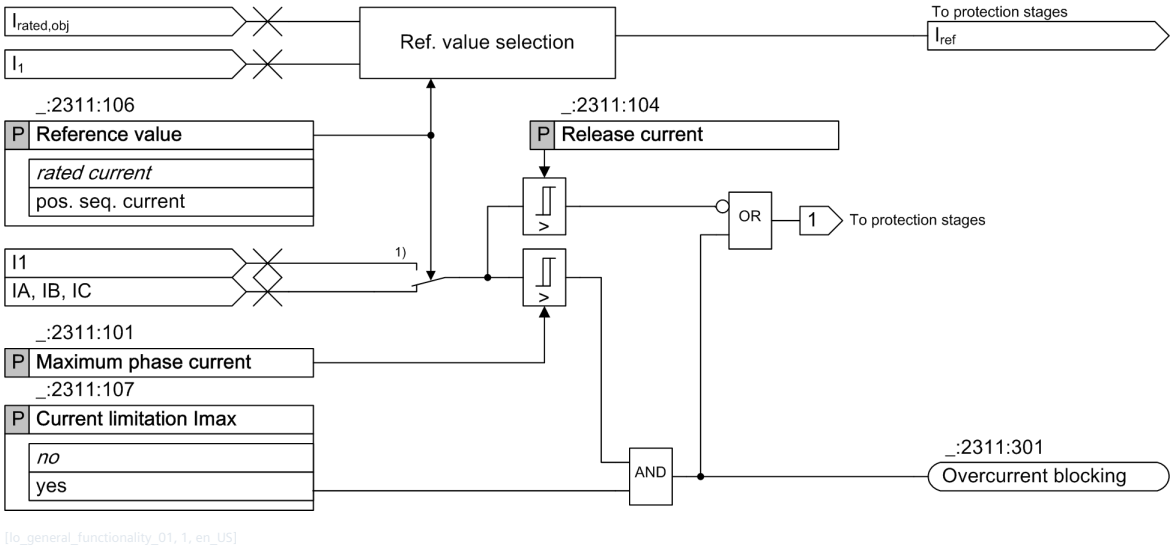
- 3 stages **Definite-time negative-sequence protection**
- 2 stages **Inverse-time negative-sequence protection**

The stages have an identical structure. Stages that are not preconfigured are shown in gray in the following figure.

[dw_nsp_str, 3, en_US]

Figure 6-511 Structure/Embedding of the Function

If the device is equipped with the **Inrush-current detection** function, the stages can be stabilized against operate due to transformer-inrush currents.



6.31.3 General Functionality

6.31.3.1 Description

Logic

The following figure represents the logic of the general functionality which applies across all configured stages. It contains:

- Selection of the reference value
- Current-release criterion

[lo_general_functionality_01, 1, en_US]

Figure 6-512 Logic Diagram of the General Functionality

(1) Switchover to I_1 with **(_:2311:106) Reference value** = ***pos. seq. current***

Reference Value

With the parameter **Reference value**, the negative-sequence current I_2 is normalized to the rated object current $I_{rated, obj}$ or to the positive-sequence current I_1. When I_2 is normalized to I_1, the sensitivity of the function for low short-circuit currents is increased.

Current Limitation and Maximum Phase Current

With the parameters **Current limitation Imax** and **Maximum phase current**, you restrict the operating range of the function. When the limiting is activated, pickup of the stages is blocked as soon as the maximum phase-current threshold value is exceeded. For more information, refer to the stage description.

Release Current

The threshold value of the **Release current** serves to release the negative-sequence protection.

6.31.3.2 Application and Setting Notes

Parameter: Reference value

- Default setting **(_:2311:106) Reference value** = ***rated current***

With the parameter **Reference value**, you define the normalization of the negative-sequence current I_2 to the rated object current $I_{rated, obj}$ ($I_2/I_{rated, obj}$) or to the positive-sequence current I_1 (I_2/I_1).

Parameter Value	Description
$I_2/I_{rated, obj}$	The negative-sequence current is referred to the rated current of the protected object. This is a preferred normalization for electrical machines, because the permissible limiting values are indicated exclusively referred to the machine rated current. You can also use this normalization for other applications.
I_2/I_1	The normalization of the negative-sequence system to the positive-sequence system yields a higher sensitivity. Use this normalization when detecting interruptions in the primary system.

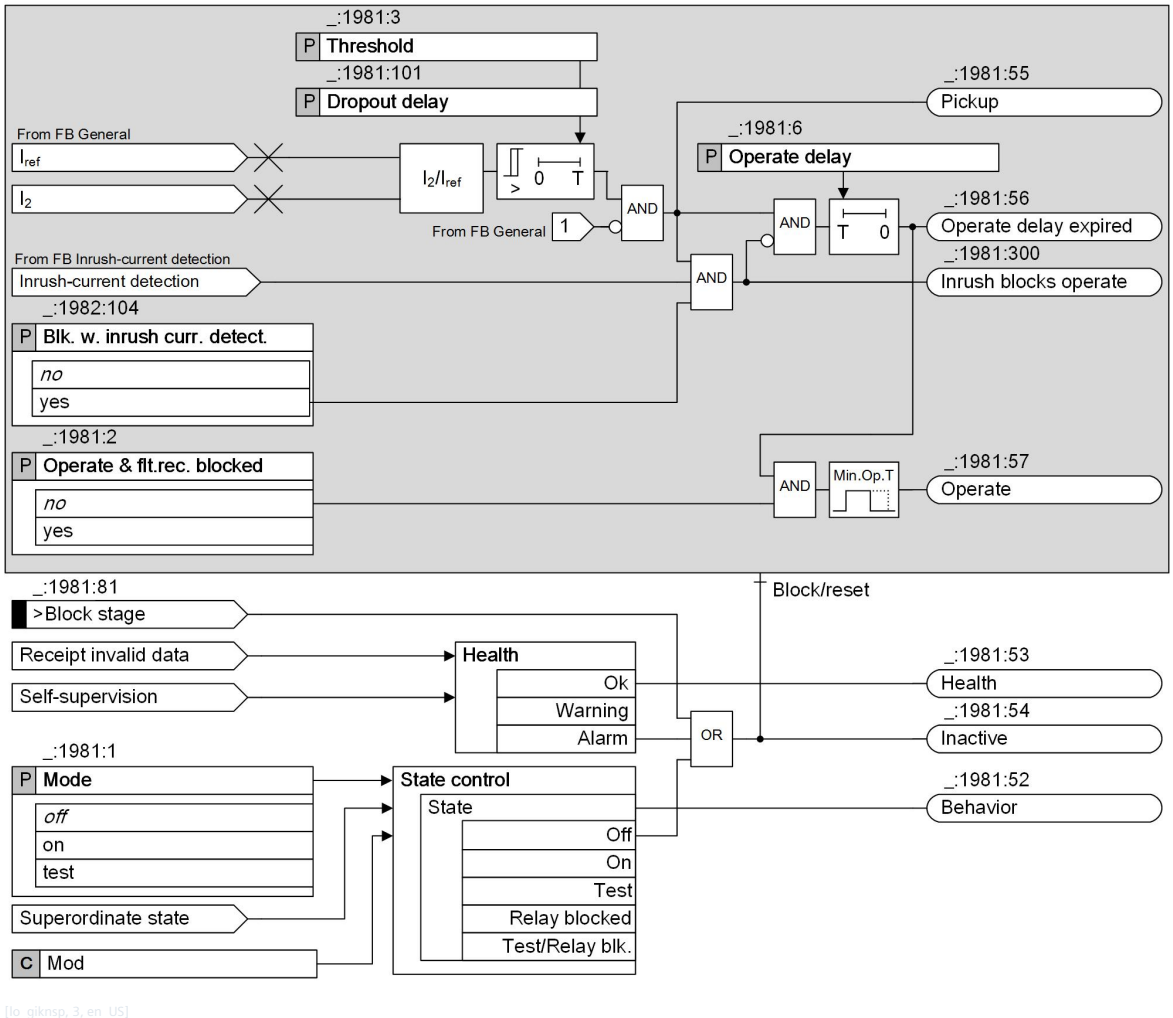
Set the parameter depending on the application.

Parameter: **Current limitation Imax,Maximum phase current**

- Default setting **(_:2311:107) Current limitation Imax** = ***no***
- Recommended setting value **(_:2311:101) Maximum phase current** = ***10.0 A at 1 A***

If the protection function needs a maximum current limitation, set the value of the **Current limitation Imax** parameter from ***no*** to ***yes***. With the parameter **Maximum phase current**, you set the upper limit of the phase current. CT saturation will cause negative-sequence current in the secondary system. To avoid overfunction due to the CT saturation, a suitable phase-current limit value is 10 times of the rated protection-object current.

Parameter: **Release current**



- Recommended setting value **(_:2311:104) Release current** = ***0.05 A at 1 A***

For the safe calculation of negative-sequence currents, the current in at least one phase must be greater than 5 % of the secondary rated device current. For a 1-A device, the value of **Release current** is 0.05 A (0.25 A for a 5-A device).

6.31.4 Stage with Definite-Time Characteristic Curve

6.31.4.1 Stage Description

Logic of a Stage

[lo_giknsp, 3, en_US]

Figure 6-513 Logic Diagram of the Stage Negative-Sequence Protection with Definite-Time Characteristic Curve

Method of Measurement

The fundamental phasors are calculated from the 3-phase phase currents. Based on this, the negative-sequence system and the positive-sequence system are calculated. Following this, the negative-sequence current is normalized to the reference current. The selection of the reference current is made in the **FB General**.

Blocking of the Stage

When blocked, the picked-up stage will drop out.

Blocking the stage is possible externally or internally via the binary input signal **`>Block stage`**.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

The **`Blk. w. inrush curr. detect.`** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking

and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

6.31.4.2 Application and Setting Notes

Parameter: `Threshold`

- Recommended setting value **`(_:1981:3) Threshold`** = ***`10 %`***

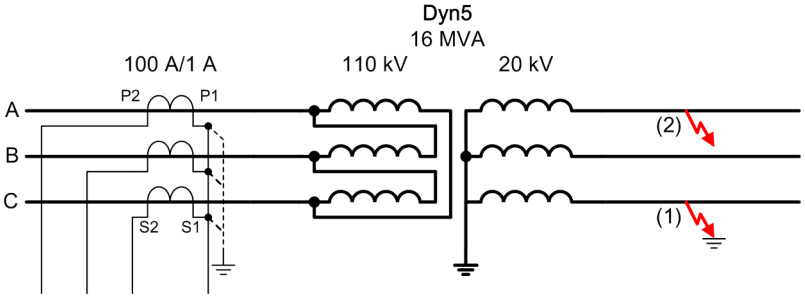
The setting of the parameter **`Threshold`** depends on the respective application. A threshold value of 10 % is a practicable value for fault indications of electrical machines.

Parameter: `Operate delay`

- Recommended setting value **`(_:1981:6) Operate delay`** = ***`1500 ms`***

The setting of the **`Operate delay`** depends on the application. Observe the time grading in the power-system protection and do not set the time for monitoring too short. The default setting is practicable. For motors, the time depends on the permissible time period for the set unbalanced load.

Parameter: `Blk. w. inrush curr. detect.`



- Default setting **`(_:1981:104) Blk. w. inrush curr. detect.`** = ***`no`***

With the parameter **`Blk. w. inrush curr. detect.`**, the stage can be stabilized against tripping on transformer-inrush currents. If transformers are parts of the protection zones, set this parameter to **`yes`**.

Backup Protection with a Three-Winding Transformer

The function **Negative-sequence protection** can be used for a transformer as a responsive backup protection on the supply side. It aims to acquire weak current from the 1-phase and 2-phase short circuits. Also on the low-voltage side, 1-phase short circuits can be used, which do not create a zero-sequence system in the current on the upper-voltage side (for example in vector group Dyn).

The following example explains the achieved sensitivity. *Figure 6-514* shows the example with the relevant technical data.

[dw_1p2pku, 1, en_US]

Figure 6-514 1- Phase and 2-Phase Short Circuit on Transformer

(1) 1-phase ground fault
(2) 2-phase short circuit

The standardization is based on the transformer rated object current (**`Reference value`** = ***`rated current`***).

If the pickup value on the upper-voltage side is 12 % (**`Threshold`** = ***`12 %`***) of the transformer rated current, this corresponds to 0.1 A on the secondary side. With this the following currents and sensitivities are reached.

- 1-phase short circuit

$$I_{F;ph-gnd} = 3 \cdot \frac{V_{US}}{V_{LS}} \cdot \frac{I_{CT,prim}}{I_{CT,S}} \cdot I_2 = 3 \cdot \frac{110\,kV}{20\,kV} \cdot \frac{100\,A}{1\,A} \cdot 0.1\,A = 165\,A$$

[fo_einpk1, 3, en_US]

Sensitivity:

$$\frac{I_{F,ph-gnd}}{I_{rated,transf.-LS}}[\%] = \frac{I_{F,ph-gnd}}{\frac{S_{rated,transf.}}{\sqrt{3} \cdot V_{LS}}} \cdot 100\,\% = \frac{165\,A}{\frac{16\,MVA}{\sqrt{3} \cdot 20\,kV}} \cdot 100\,\% = 36\,\%$$

[fo_einpk2, 2, en_US]

- 2-phase short circuit

$$I_{F;ph-ph} = \sqrt{3} \cdot \frac{V_{HS}}{V_{LS}} \cdot \frac{I_{P,CT}}{I_{S,CT}} \cdot I_2 = \sqrt{3} \cdot \frac{110\,kV}{20\,kV} \cdot \frac{100\,A}{1\,A} \cdot 0.1A = 95\,A$$

[fo_zwpok3, 2, en_US]

Sensitivity:

$$\frac{I_{F,ph-ph}}{I_{rated,transf.-LS}}[\%] = \frac{I_{F,ph-ph}}{\frac{S_{rated,transf.}}{\sqrt{3} \cdot V_{LS}}} \cdot 100\,\% = \frac{95\,A}{\frac{16\,MVA}{\sqrt{3} \cdot 20\,kV}} \cdot 100\,\% = 21\%$$

[fo_zwepk4, 2, en_US]

Since this is the short circuit on the low-voltage side, the time delay must be coordinated with the times of subordinate protection devices.

Line or Cable Networks

In line or cable networks, the function **Negative-sequence protection** is used to detect weak current caused by unbalanced faults. In the unbalanced fault, the pickup values of the overcurrent protection are not reached.

The current is based on the rated object current (**`Reference value` = *`rated current`***).

Therefore:

The 2-phase short circuit with the current I leads to a negative-sequence current:

$$I_2 = \frac{1}{\sqrt{3}} \cdot I = 0.58 \cdot I$$

[fo_zwepk5, 2, en_US]

The 1-phase short circuit with the current I leads to a negative-sequence current:

$$I_2 = \frac{1}{3} \cdot I = 0.33 \cdot I$$

[fo_einpk6, 2, en_US]

If the protection works exclusively with short circuits, the protection must be set via the value for 2-phase operation. Then a 2-phase short circuit can be assumed with more than 60 % of the rated object current. Set the standardization on the rated object current. To avoid over-function with overload, Siemens recommends a pickup value of approx. 65 %. Coordinate the time delays with the network grading for phase short circuits.

Break in Primary System

To record breaks in the primary system, set standardization on I_2/I_1 (**`Reference value` = *`pos. seq. current`***) to achieve a higher sensitivity (independence of load current). For a 1-phase break, the ratio of the negative-sequence current and the positive-sequence current can be described according to the following equation with the negative-sequence and zero-sequence impedance (Z_2, Z_0).

$$\frac{I_2}{I_1} = \frac{1}{1 + \frac{\sum Z_2}{\sum Z_0}}$$

[fo_untpk7, 2, en_US]

In the isolated system or with one-sided ground, the zero-sequence impedance is infinity and thus the ratio is always 1. Observe a two-sided grounded network and set the zero-sequence impedance equal to the negative-sequence impedance, then the ratio is 0.5. If a wire break occurs in the secondary circuit, value of 1 or 0.5 is also possible.

For a 2-phase break, current can only flow with a two-sided grounded network. In this case, the ratio $I_2/I_1 = 1$. If a partial 1-phase load is expected, the ratio is also set. The setting value is dependent on the maximum 1-phase load. For a setting value of 10 %, the phase current can be 30 %.

If you want to prevent an indication with short circuits, activate the current limiting to, for example, 1.2 $I_{rated,obj}$ (**Current limitation Imax** = ***yes***; **Maximum phase current** = ***1.2 A at 1 A*** transformer and ideal adaptation to the protected object). Here calculate the current with the current transformer ratio to the secondary circuit.

The setting of the protection stage is aligned to the network type. A setting value of 25 % (**Threshold** = ***25 %***) offers a sufficiently high sensitivity. If errors occur in the current transformer circuit, there can be, however, also be a tripping. To prevent over-functions during the AREC cycles, the time delay for the tripping must be set long. A time of 60 s (**Operate delay** = ***60.00 s***) offers sufficient reliability.

6.31.5 Stage with Inverse-Time Characteristic Curve

6.31.5.1 Description

Logic of a Stage

[lo_nsp_inverse, 2, en_US]

Figure 6-515 Logic Diagram of the Negative-Sequence Protection with Inverse-Time Characteristic Curve

Method of Measurement

The fundamental phasors are calculated from the 3-phase phase currents. Based on this, the negative-sequence system and the positive-sequence system are calculated. Following this, the negative-sequence current is normalized to the reference current. The selection of the reference current is made in the **FB General**.

Pickup and Dropout Behaviors of the Inverse-Time Characteristic Curve According to IEC and ANSI

When the input variable exceeds the threshold value by a factor of 1.1, the inverse-time characteristic curve is processed. An integrating method of measurement summarizes the weighted time. The weighted time results from the characteristic curve. For this, the time that is associated with the present current value is determined from the characteristic curve. Once the weighted time exceeds the value 1, the stage operates.

When the measured value falls below the pickup value by a factor of 1.045 (0.95 · 1.1 · threshold value), the dropout is started. The pickup will be indicated as clearing. You can influence the dropout behavior via setting parameters. You can select between instantaneous dropout (totalized time is deleted) or dropout according to the characteristic curve (reduction of totalized time depending on the characteristic curve). The dropout according to characteristic curve (disk emulation) is the same as turning back a rotor disk. The weighted reduction of the time is initiated from 0.9 of the set threshold value.

The characteristic curve and associated formulas are shown in the Technical Data.

Blocking of the Stage

When blocked, the picked-up protection stage will drop out.

Blocking the stage is possible externally or internally via the binary input signal **>Block stage**.

Blocking of the Tripping by Device-Internal Inrush-Current Detection

The **Blk. w. inrush curr. detect.** parameter allows you to define whether the operate indication of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking and fulfilled pickup conditions, the stage picks up. The start of the time delay and the operate indication are blocked. The function indicates this through a corresponding indication. If the blocking drops out and the pickup conditions are still met, the time delay is started. After that time, the stage operates.

6.31.5.2 Application and Settings Notes

Parameter: Type of character. curve

- Default setting **(_:105) Type of character. curve** = ***IEC normal inverse***

The device offers all the usual inverse-time characteristic curves according to IEC and ANSI. Select the **Type of character. curve** required for your specific application. For more information about the parameter **Type of character. curve**, refer to chapter *12.26.2 Stage with Inverse-Time Characteristic Curve*.

Parameter: Threshold

- Recommended setting value **(_:3) Threshold** = ***10.0 %***

The setting of the parameter **Threshold** depends on the respective application. A threshold value of 10 % is a practicable value for fault detection for different applications.

Parameter: Time dial

- Recommended setting value **(_:107) Time dial** = ***1.00***

With the parameter **Time dial**, you displace the characteristic curve in the time direction.

The set value for the parameter **Time dial** is derived from the time-grading schedule that has been prepared for the electrical power system.

Where no time grading and therefore no displacement of the characteristic curve is required, leave the **Time dial** parameter at 1.00 (default setting).

Parameter: `Reset`

- Default setting **`(_:106) Reset`** = ***`disk emulation`***

With the parameter **`Reset`**, you define whether the stage drops out according to the dropout characteristic curve (in accordance with the behavior of a disk emulation = rotor disk) or instantaneously.

Parameter Value	Description
`disk emulation`	Select this setting if the device is coordinated with electromechanical devices or other devices which perform a dropout after a disk emulation.
`instantaneous`	Use this setting if the dropout is not to be performed after disk emulation and an instantaneous dropout is desired instead.

Parameter: `Blk. w. inrush curr. detect.`

- Default setting **`(_:104) Blk. w. inrush curr. detect.`** = ***`no`***

With the parameter **`Blk. w. inrush curr. detect.`**, the stage can be stabilized against tripping on transformer-inrush currents. If transformers are parts of the protection zones, set this parameter to ***`yes`***.

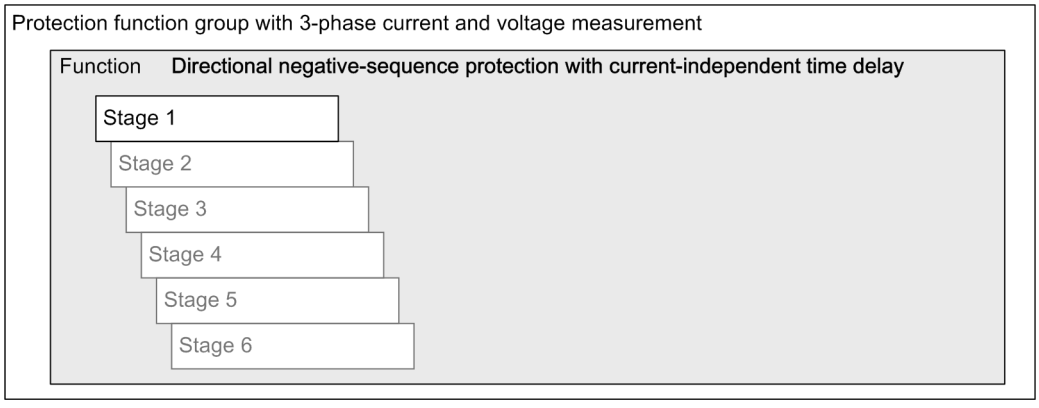
6.32 Directional Negative-Sequence Protection

6.32.1 Overview of Functions

The function **Directional negative-sequence protection with current-independent time delay** (ANSI 46) serves as the backup short-circuit protection for unbalanced faults.



With the negative-sequence system, various supervision and protection tasks can be realized, for example:

- Recording of 1 or 2-phase short circuits in the system with a higher sensitivity than in classic overcurrent protection. The pickup value can be set under the rated object current.
- Recording of phase conductor interruptions in the primary system and in the current-transformer secondary circuits
- Location of short circuits or reversals in the connections to the current transformers
- Indication of unbalanced states in the energy system
- Protection of electrical machines following unbalanced loads that are caused by unbalanced voltages or conductor interruptions (for example, through a defective fuse)

6.32.2 Structure of the Function

The **Directional negative-sequence protection with definite time delay** function can be used in protection function groups with 3-phase current and voltage measurement.

The function comes factory-set with 1 stage. A maximum of 6 tripping stages can be operated simultaneously in the function.

[dw_nsp_dir, 1, en_US]

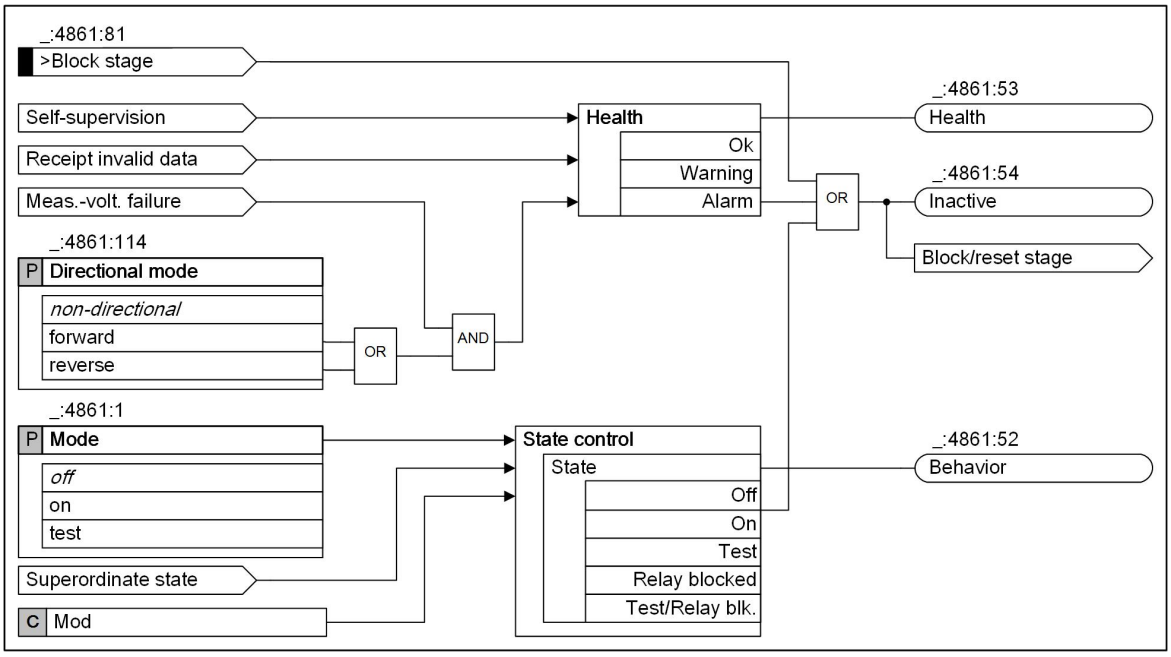


Figure 6-516 Structure/Embedding of the Function

If the device is equipped with the **Inrush-current detection** function, the tripping stages can be stabilized against tripping due to transformer-inrush currents.

6.32.3 Function Description

Stage Control

The following figure shows a stage control. It is available separately for each stage.

[lo_stensp, 2, en_US]

Figure 6-517 Stage Control of the Directional Negative-Sequence Protection

In addition to the generally valid stage control, the stage is blocked in the event of a measuring-voltage failure, provided the stage is working directionally.

Logic of the Stage

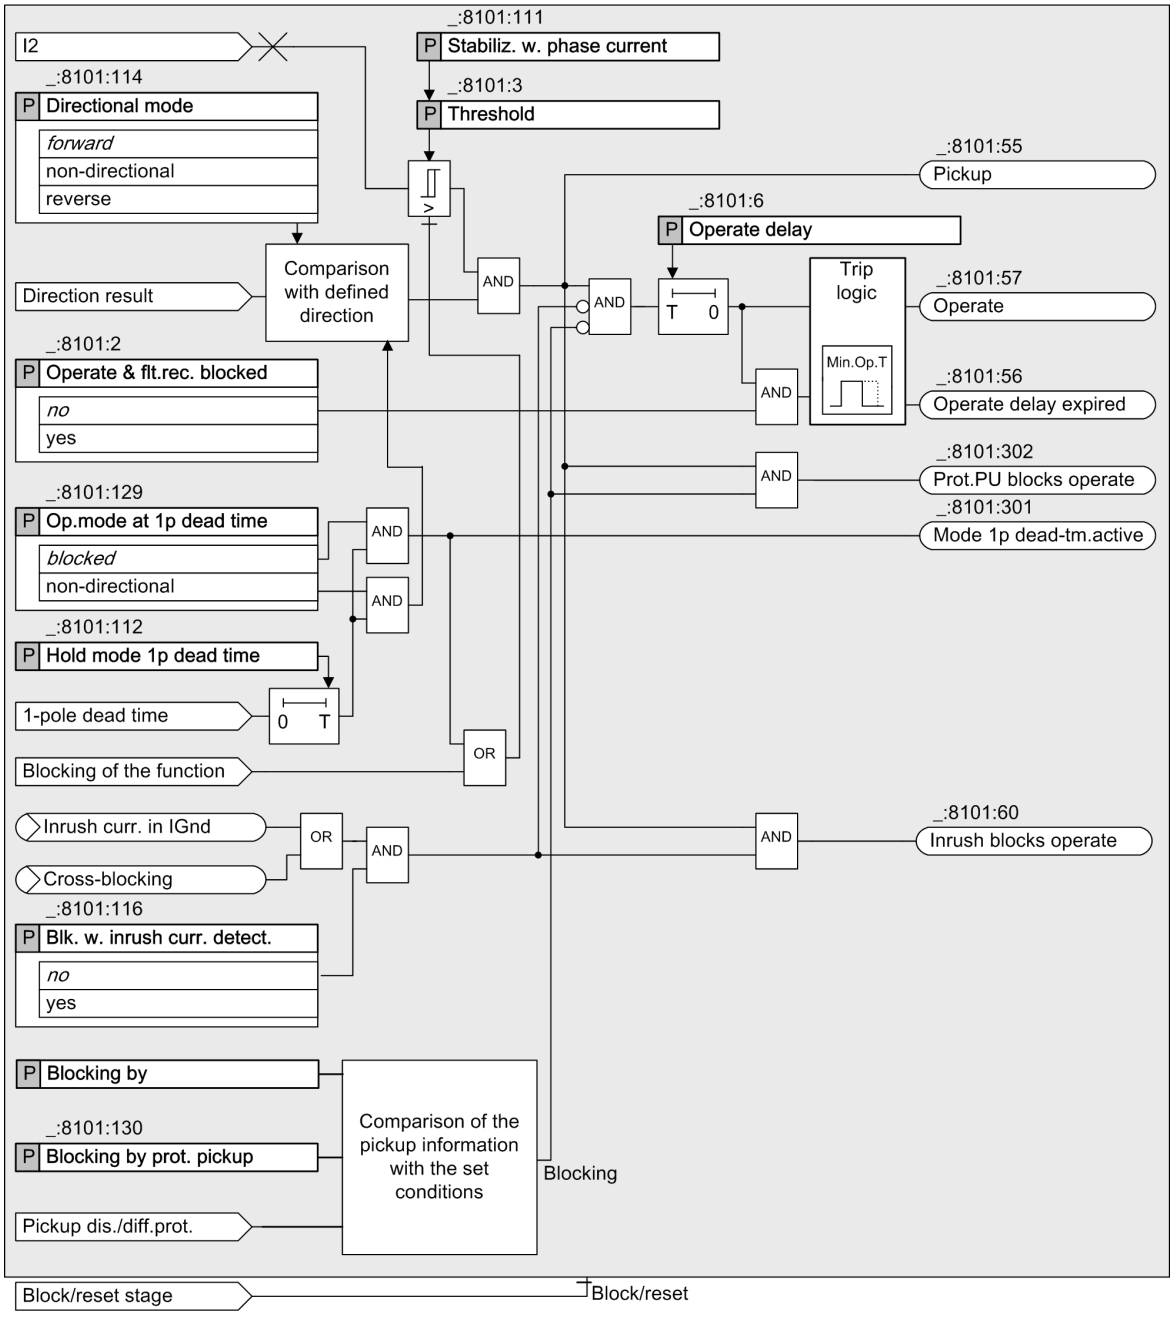

Figure 6-518 Logic Diagram of the Function Directional Negative-Sequence System Protection with Current-Independent Time Delay

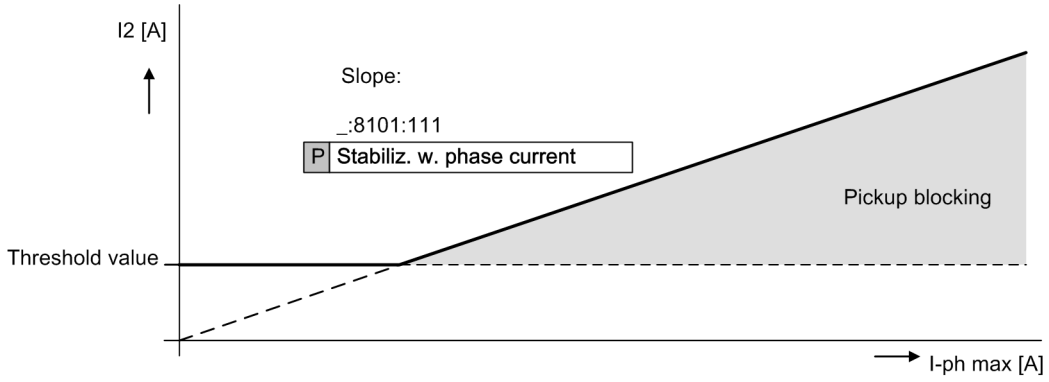
Measurand

The negative-sequence current I2 is used as a measurand. From the 3-phase currents, the fundamental phasors are determined via a 1-cycle filter and, corresponding with the definition equation of the symmetrical components, the negative-sequence system is calculated from this.



Functioning

The stage picks up if the negative-sequence system current exceeds the set threshold value and the parameterized direction agrees with the measured direction. The pickup drops out if the negative-sequence system current falls below 95 % of the set threshold.

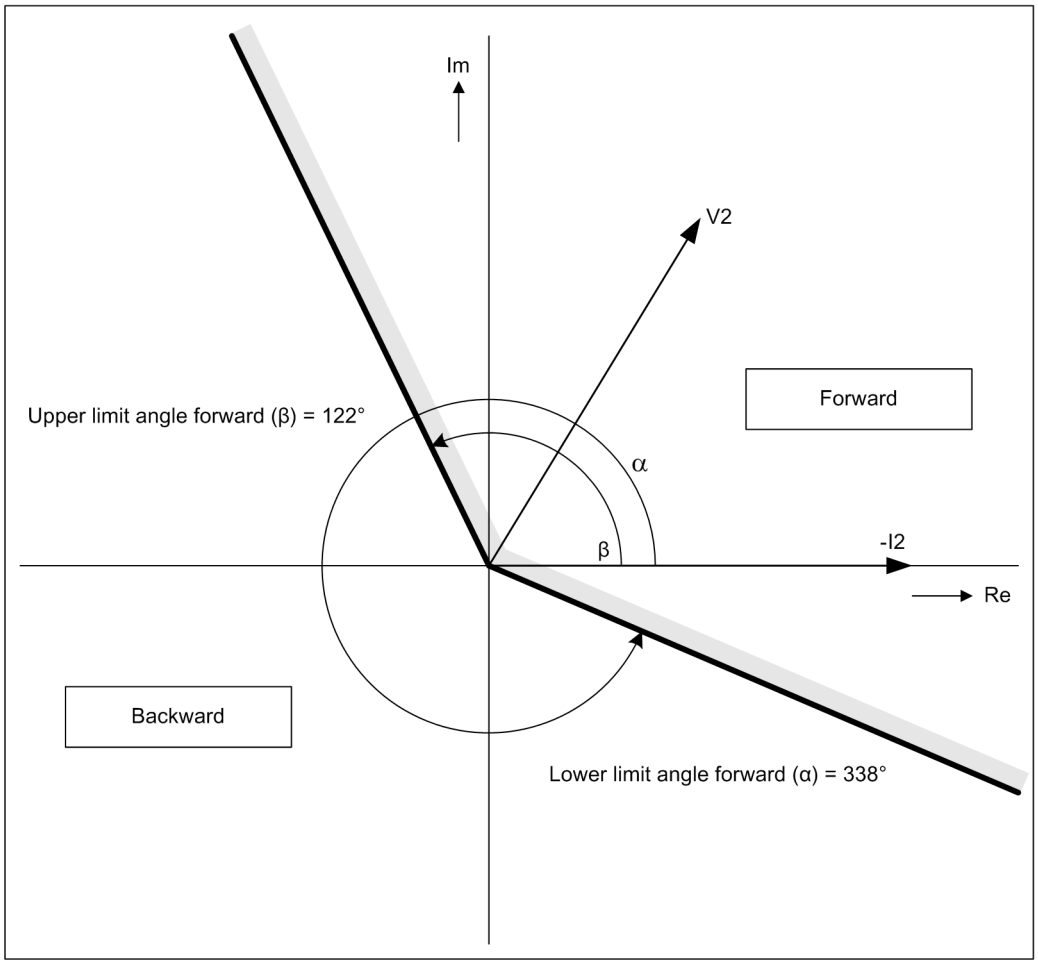
Stabilization with Phase Current

Unbalance in operation and unbalanced transformer ratios can lead to spurious pickups and incorrect tripping. In order to avoid this, the directional negative-sequence system stage is stabilized with the phase currents. The threshold value increases with rising phase currents (see next image).

You can change the stabilization factor (= gradient) via the **Stabiliz. w. phase current** parameter.

[dw_stabil, 1, en_US]

Figure 6-519 Stabilization with Phase Currents

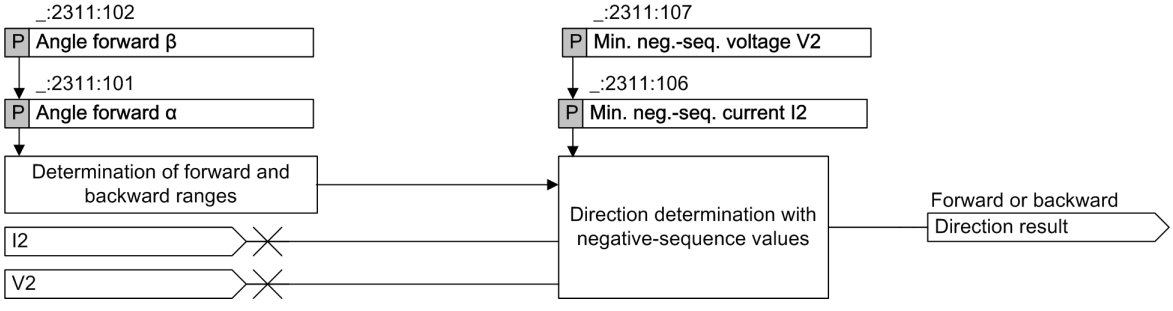


Direction Determination

The direction determination takes place with the negative-sequence system measurements I2 and V2.

The forward and reverse region is defined through the parameters **Angle forward α** and **Angle forward β** (see next figure). The reference for the 2 angles that must be set is the positive real axis. The angles are positively defined in a mathematical sense (counter-clockwise). The region between the limit angle α and the limit angle β - counted from the former in a positive direction - is the forward region. The remaining region is the reverse region.

For determining of the direction, the function places the measuring current I2 on the real axis. If the phasor of the negative-sequence system voltage V2 is located within the defined forward region, the function determines the direction as *forward*. In the other case, the function determines the direction as *reverse*.



The requirement for determining the direction is that the adjustable minimum variables have been exceeded for the negative-sequence system current and negative-sequence system voltage (parameters **Min. neg.-seq. current I2** and **Min. neg.-seq. voltage V2**).

[dw_phasor, 1, en_US]

Figure 6-520 Phasor Diagram for Direction Determination with Negative-Sequence System Values

If the device determines a fault in the voltage-transformer secondary circuit (through the binary input *voltage transformer circuit-breaker dropout* or through **measuring-voltage failure detection**), direction determination will be disabled and every directionally set stage will be blocked. Non-directionally set stages become active again if there are faults in the voltage-transformer secondary circuit.

[lo_richtu, 1, en_US]

Figure 6-521 Logic of Direction Determination

Directional Mode

You use the **`Directional mode`** parameter to define whether the stage works in a forward or reverse direction. Non-directional operation is also possible.

Operating Mode upon 1-Pole Interruption

With the parameter **Op.mode at 1p dead time**, you determine if the stage is blocked during a 1-pole dead time, or if it works in a non-directional manner, even if it is set for directional operation. When the 1-pole dead time is complete, the corresponding device-internal signal is extended by the time of the parameter **Hold mode 1p dead time**.

NOTE

The **Op.mode at 1p dead time** parameter is only available in devices with 1-/3-pole tripping. In devices with 3-pole tripping, this setting does not apply.

Blocking the Tripping by Pickup of the Main Protection Functions

The pickup and type of pickup for the main protection functions can block the tripping of the stage. You can perform this setting via 2 parameters:

- **Blocking by**
  This setting is used to select the zone or stage at which blocking is to occur in the event of pickup.
- **Blocking by prot. pickup**
  The pickup type at which the blocking is to occur is defined with this parameter. The blocking can occur at any pickup or only at 1-pole or only at multipole pickups.
  This parameter is also used to set that no blocking should occur when the main protection has picked up.

Blocking of Tripping via the Device-Internal Inrush-Current Detection Function

If the device is equipped with the additional **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer inrush currents.
With the **Blk. w. inrush curr. detect.** parameter, you can define whether tripping of the stage should be blocked when a threshold value is exceeded due to an inrush current. In case of a blocking, the stage picks up. The start of the time delay and tripping are however blocked. The stage signals this by way of a corresponding indication. If the blocking drops out and the threshold value of the stage is still exceeded, the tripping delay (time delay) is started. After that time, the stage operates.

6.32.4 Application and Setting Notes for Direction Determination

Parameter: Limit Angle Region Forward

- Recommended setting value **(_:2311:101) Angle forward α** = ***338°***
- Recommended setting value **(_:2311:102) Angle forward β** = ***122°***

With the parameters **Angle forward α** and **Angle forward β**, you can change the location of the directional characteristic curve.
Siemens recommends using the defaults, because the function with these settings reliably determines the direction.

Parameter: Minimum Negative-Sequence System Variables V2 and I2

- Default setting **(_:2311:107) Min. neg.-seq. voltage V2** = ***0.7 V***
- Default setting **(_:2311:106) Min. neg.-seq. current I2** = ***0.05 A***

With the parameters **Min. neg.-seq. voltage V2** and **Min. neg.-seq. current I2**, you can specify the minimum negative-sequence system values for direction determination with V2 and I2. The set limiting values must not be exceeded by operational unbalances.

6.32.5 Application and Setting Notes for Stages

Parameter: Directional mode

- Default setting **(_:8101:114) Directional mode** = ***forward***

You use the **Directional mode** parameter to define the directional mode of the stage.

Parameter Value	Description
non-directional	If the stage is to work in the forward and reverse direction (in the direction of the line and busbar), then select this setting. The stage will work with this setting even if no direction measurement is possible, for example due to insufficient polarization voltage (or none at all), or due to failure of the measuring voltage.
forward	Select these settings if the stage is only to work in a forward direction (in direction of the line).
reverse	Select this setting if the level is only to work in the reverse direction (in the direction of the busbar).

Parameter: Blk. w. inrush curr. detect.

If the device is equipped with the additional **Inrush-current detection** function, the stages can be stabilized against tripping due to transformer inrush currents.

- Default setting **(_:8101:116) Blk. w. inrush curr. detect.** = ***no***

Parameter Value	Description
no	The transformer inrush current detection does not affect the stage. Select this setting in the following cases: 1) In cases where the device is not used on transformers. 2) In cases where the device is used on transformers and the threshold value of the stage is set above the maximum inrush current of the transformer.
yes	When the transformer inrush current detection detects an inrush current that can lead to a tripping of the stage, the start of the time delay and tripping of the stage are blocked. Select this setting if the device is used on transformers and the threshold value of the stage is set below the maximum inrush current of the transformer.

Parameter: Blocking by the main Protection

- Recommended setting value **(_:8101:140) Blocking by** =

If you wish to give selective fault clarification through the main protection function precedence over tripping through the directional negative-sequence protection, you can define this via the 2 parameters **Blocking by** and **Blocking by prot. pickup**. The **Blocking by** parameter is used to select the zones or tripping stages of the main protection function(s), upon whose pickup the negative-sequence protection is to be blocked.

Parameter: Blocking by prot. pickup

- Default setting **(_:8101:130) Blocking by prot. pickup** = ***every pickup***

The **Blocking by prot. pickup** parameter can be used to define the type of pickup, which leads to the blocking.

Parameter Value	Description
every pickup	Blocking at every pickup
1-phase pickup	Blocking only at 1-pole pickup

Parameter Value	Description
multi-phase pickup	Blocking only at multipole pickup
no pickup	If the pickup of the main protection function should not lead to blocking of the negative-sequence protection, select this setting.

Parameter: Op.mode at 1p dead time

- Default setting **(_:8101:129) Op.mode at 1p dead time** = ***blocked***

The **Op.mode at 1p dead time** parameter is used to define the behavior of the stage in the event of a 1-pole interruption.

Parameter Value	Description
blocked	The energy-transmission system is unbalanced in the 1-pole dead time. A mode-dependent negative-sequence system results from this, which can lead to an undesired pickup of the directional negative-sequence protection. That is why blocking with this setting makes sense if the pickup threshold of the stage is lower than/equal to the maximum mode-dependent negative-sequence current in the 1-pole dead time.
non-directional	If the directional negative-sequence protection is to continue to work in the 1-pole dead time, select this setting. The directional measurement works in a non-directional manner, because a reliable direction dead time measurement is not possible due to load current in the zero and negative-sequence system with the circuit breaker open on one pole. Set the pickup threshold of the stage higher than the maximum mode-dependent negative-sequence current in the 1-pole dead time.

NOTE

The **Op.mode at 1p dead time** parameter is only available in devices with 1-/3-pole tripping. In devices with 3-pole tripping, this setting does not apply.

Parameter: Hold mode 1-p dead time

- Default setting **(_:8101:112) Hold mode 1p dead time** = ***0.040 s***

The parameter **Hold mode 1p dead time** is used to define the time by which the device-internal signal for the 1-pole interruption is extended after the end of the 1-pole interruption.

At all line ends, there is no simultaneous switch-in after a 1-pole dead time. Thus, the parameterized operating mode for a 1-pole dead time must be retained for a certain time after the switch-in (end of the 1-pole dead time) until the other end or ends have securely switched in. The time to be set here corresponds to the maximum time between the switch-in of the 1st circuit breaker and the switch-in of the last circuit breaker at all ends of the feeder after a 1-pole dead time.

NOTE

The **Hold mode 1p dead time** parameter is only available in devices with 1-/3-pole tripping. In devices with 3-pole tripping, this setting does not apply.

Parameter: Stabiliz. w. phase current

- Recommended setting value **(_:8101:111) Stabiliz. w. phase current** = ***10 %***

In order to avoid unwanted pickups and tripping, the negative-sequence system current stage is stabilized with the phase currents.

More information can be found in chapter *6.32.3 Function Description*.

The threshold value increases as the phase currents increase.

You can change the stabilization factor (= gradient) via the **Stabiliz. w. phase current** parameter.

Siemens recommends a default setting of 10 % under normal operations.

Parameter: Threshold

- Default setting **(_:8101:3) Threshold** = ***1.5 A***

Define the pickup value corresponding to the application. In doing so, for the time-graded stages, the setting for the superordinate and subordinate stages must be taken into account in the grading chart.

With a very sensitive setting, you must make sure that the negative-sequence system current does not lead to undesired response of the stage due to unbalance (for example non-twisted line).

Parameter: Operate delay

- Default setting **(_:8101:6) Operate delay** = ***0.30 s***

The tripping delay (time delay) to be set is derived from the time-grading schedule that has been prepared for the system.

When selecting the current and time setting, pay attention to whether the stage must work dependent on the direction.

6.32.6 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General				
_:2311:101	General:Angle forward α		0 ° to 360 °	338 °

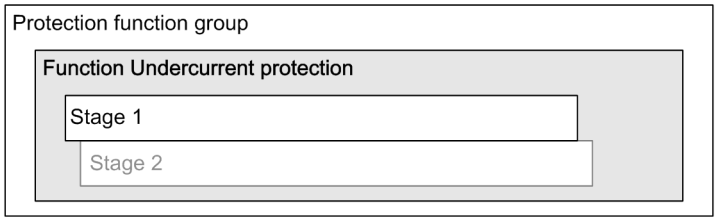
6.33 Undercurrent Protection

6.33.1 Overview of Functions



The **Undercurrent protection** function (ANSI 37):

- Detects the going current in a feeder after the opening of the infeed circuit breaker
- Detects the loss of loads
- Detects and protects pumps from running idle

6.33.2 Structure of the Function

The **Undercurrent protection** function is used in protection function groups with current measurement.

The **Undercurrent protection** function comes with 1 protection stage preconfigured at the factory. A maximum of 2 protection stages can be operated simultaneously in this function. The protection stages are structured identically.

[lo_stuundcu, 2, en_US]

Figure 6-522 Structure/Embedding of the Function

6.33.3 Stage Description

Logic of the Stage

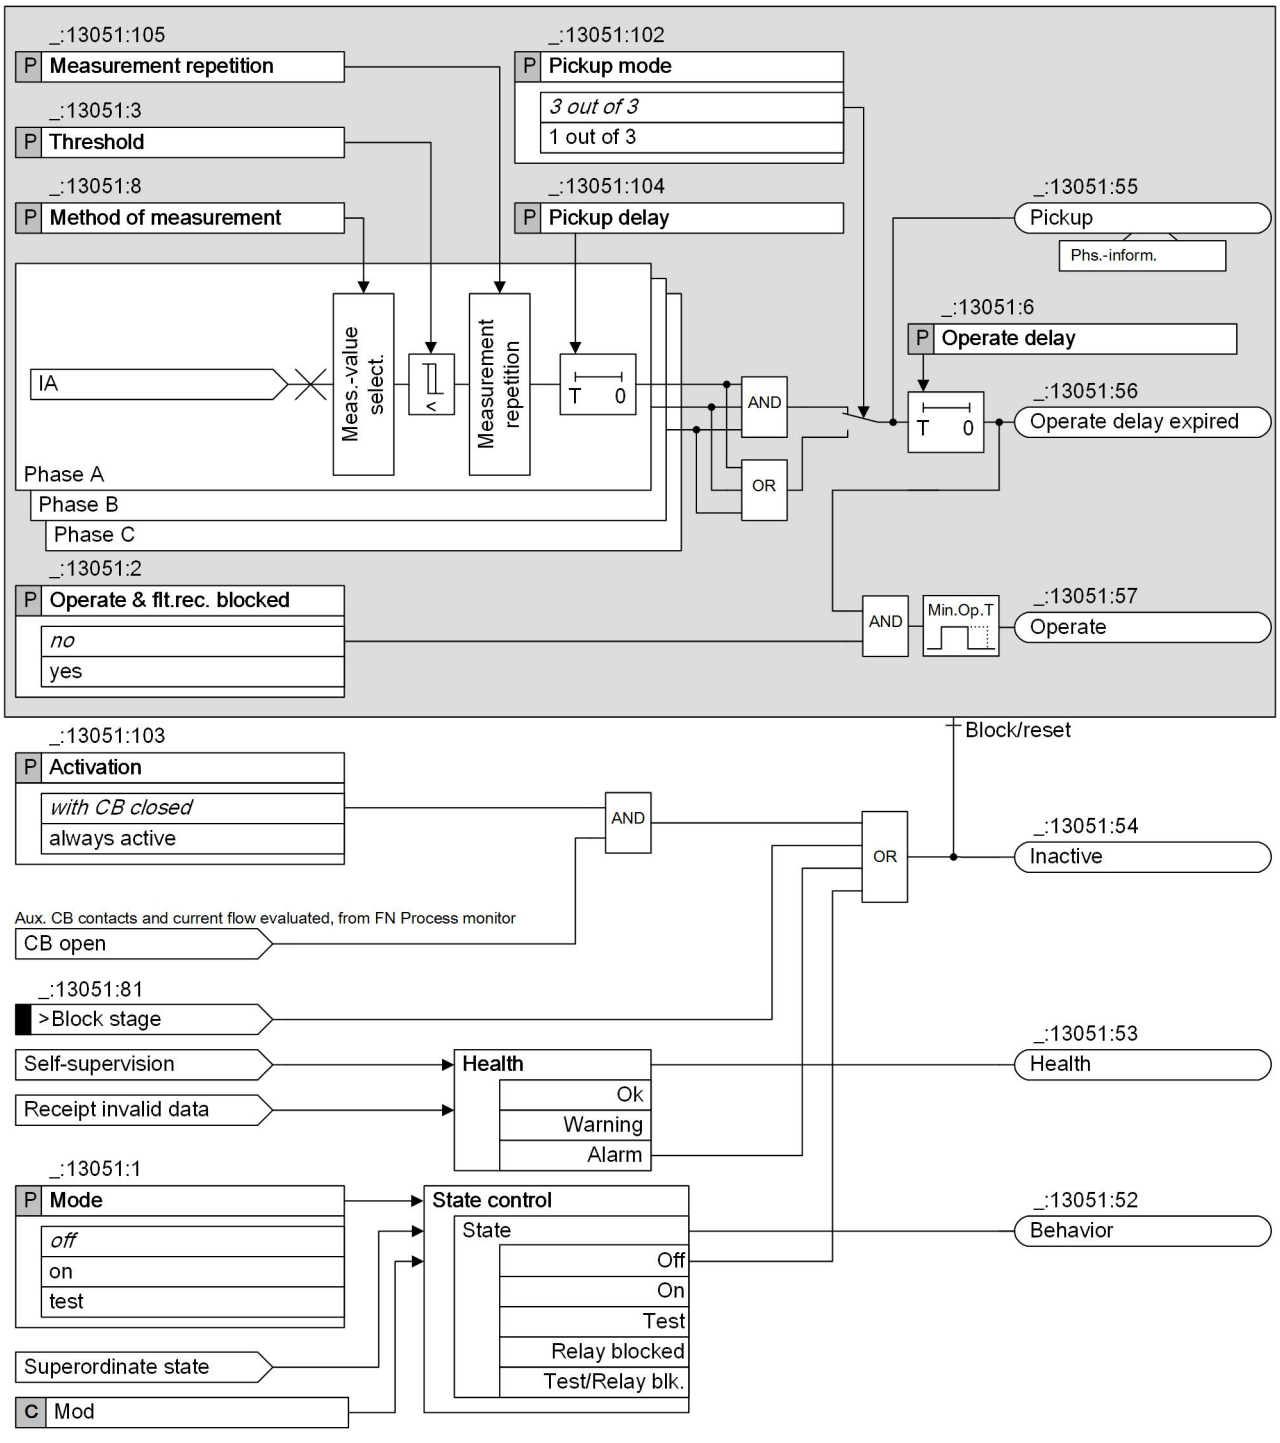


Figure 6-523 Logic Diagram of the Undercurrent Protection

Method of Measurement

You use the parameter **Method of measurement** to define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

- Measurement of the fundamental comp.:
  This measurement method processes the sampled current values and numerically filters out the fundamental component.
- Measurement of the parameter value RMS value:
  This measurement method determines the current amplitude from the sampled values according to the definition equation of the RMS value. Harmonics are included in the analysis.

Measurement Repetition

To enable the pickup stabilization, you set the parameter **Measurement repetition** to a value other than 0. Then, if the input current keeps below the **Threshold** for a specified number (**Measurement repetition** value) of successive measuring cycles, the stage picks up. For 50 Hz, the measuring cycle time is 5 ms (**Method of measurement** = ***fundamental comp.***) or 10 ms (**Method of measurement** = ***RMS value***).

If you set this parameter to ***0*** (default value), the stabilization is not applied. The pickup signal is issued immediately after the input current falls below the parameter **Threshold**.

Pickup Mode

The parameter **Pickup mode** defines whether the protection stage picks up if all 3 measuring elements detect the undercurrent condition (***3 out of 3***) or if only 1 measuring element has to detect the undercurrent condition (***1 out of 3***).

Blocking the Stage

When blocked, the picked-up protection stage will drop out. Blocking the stage is possible externally or internally via the binary input signal *>Block stage*.

Activation and Blocking of the Stage Depending On the Circuit-Breaker Condition

With the parameter **Activation**, you define if the stage **Undercurrent protection** is always active or only active if the circuit breaker is indicating **closed**.

If the parameter **Activation** is set to ***with CB closed*** and the local circuit breaker is not **closed**, the function **Undercurrent protection** is blocked and no pickup is generated.

The circuit-breaker position is detected as **closed** if one of the following conditions is met:

- The binary inputs are connected to the auxiliary contacts of the circuit breaker. The circuit-breaker switch position is detected as **closed** via the related binary inputs of the indication *Position*. This is also true under the condition that no phase current is flowing.
- The current-flow criterion indicates that the circuit breaker is **closed**. This is also true under the condition that the auxiliary contacts indicate the circuit breaker as **open**.

Behavior on Leaving the Operating Range

The sampling frequency tracking makes a wide frequency operating range possible. If the stage has picked up before leaving the frequency operating range, the pickup is maintained. The signal **Pickup** is reset when a blocking condition becomes active.

6.33.4 Application and Setting Notes

Parameter: Activation

- Default setting **(_:13051:103) Activation** = ***with CB closed***

Parameter Value	Description
with CB closed	The **Undercurrent protection** is active only when the circuit-breaker position is detected as **closed**. A precondition is, that the **Position** indication is routed to binary inputs to obtain the CB position information via the CB auxiliary contacts. If this is not the case, the function will always be inactive.
always active	The **Undercurrent protection** stage is always active independent of the position of the circuit breaker.

Parameter: **Method of measurement**

- Recommended setting value **(_:13051:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** (standard method) or the calculated ***RMS value***.

Parameter Value	Description
fundamental comp.	Select this method of measurement if harmonics or transient current peaks are to be suppressed. Siemens recommends using this method as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Consider that aperiodic DC components present in the secondary circuit are measured and can cause an overfunction. For this method of measurement, do not set the **threshold value** of the stage to less than 0.1 $I_{rated,sec}$. If currents from more than one measuring point are added up in the current interface of a function group, the setting value should not be set lower than 0.1 $I_{rated,sec}$ multiplied by the number of added currents.

Parameter: **Pickup mode**

- Default setting **(_:13051:102) Pickup mode** = ***3 out of 3***

Use the **Pickup mode** parameter to define whether the protection stage picks up if all 3 measuring elements detect the undercurrent condition (***3 out of 3***) or if only 1 measuring element has to detect the undercurrent condition (***1 out of 3***).

Parameter: **Pickup delay**

- Default setting **(_:13051:104) Pickup delay** = ***0.00 s***

For special applications, it could be desirable that a short falling below the current threshold does not lead to the pickup of the stage and to the start of fault logging and recording.

With the **Pickup delay** parameter, you define a time interval during which a pickup is not triggered if the current falls below the threshold.

Parameter: **Threshold**

- Default setting **(_:13051:3) Threshold** = ***0.050 A***

Specify the **Threshold** (pickup threshold) for the specific application.

Parameter: **Measurement repetition**

- Default setting **(_:13051:105) Measurement repetition** = ***0***

For special applications, it could be desirable that a short falling of the input current below the pickup value does not lead to the pickup of the stage, which starts fault logging and recording. This is achieved by setting the parameter **Measurement repetition** to a value other than 0.

For example, if you set this parameter to ***2***, the pickup signal is issued when the current keeps being below the **Threshold** for 2 additional measuring cycles. For 50 Hz, the measuring cycle time is 5 ms (**Method of measurement** = ***fundamental comp.***) or 10 ms (**Method of measurement** = ***RMS value***).

Parameter: **Operate delay**

- Default setting **(_:13051:6) Operate delay** = ***0.05 s***

Operate delay must be set according to the specific application. No general application notes can be given.

6.34 Overexcitation Protection

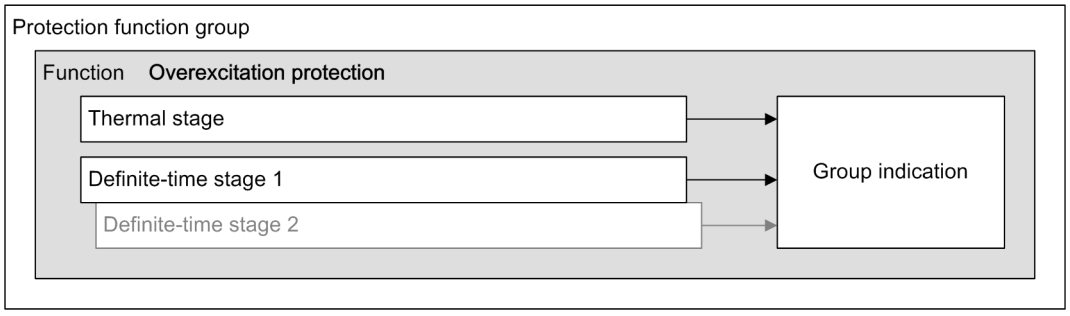
6.34.1 Overview of Functions

The **Overexcitation protection** (ANSI 24) is used for detecting high induction values in generators and transformers. It protects the equipment from excessive thermal loads.

The induction is recorded indirectly by analyzing the V/f ratio (also referred to as Volt per Hertz protection). Overvoltage leads to excessive magnetizing currents, while underfrequency leads to higher losses when resetting the magnetization.

If the power system is disconnected and the voltage and frequency control function in the remaining system does not react quickly or the power imbalance is excessive, there is a risk of overexcitation.

6.34.2 Structure of the Function



The **Overexcitation protection** function is used within protection function groups that have a 3-phase voltage input. The function comes with the following factory-set stages:

- Thermal stage adjustable with a user-defined characteristic curve
- Definite-time stage which can be delayed using a time component

Within this function, the following maximum number of stages can be operated simultaneously: one stage with a user-defined characteristic curve and 2 definite-time stages.

The group-indication output logic (see following figure) uses the logical OR function from the stage-selective indications to generate the following group indications of the entire **Overexcitation protection** function:

- Pickup
- Operate Indication

[dw_ovexuf, 3, en_US]

6.34.3 Stage with Dependent Characteristic Curve (Thermal Stage)

6.34.3.1 Function Description

Logic

[lo_therm-char_V-f, 2, en_US]

Figure 6-525 Logic of the Overexcitation Protection with Thermal Characteristic Curve

(1) Heating
(2) Cooling

V/f Method of Measurement

The input values of the protection function are the continuously measured voltage and the frequency. The phase-to-phase voltage is used to process the voltage. The angle difference method (see *6.51 Overfrequency Protection*) is used to determine the frequency. Both values form the V/f ratio. In order to arrive at an absolute value, standardized data is applied.

Thus, the ratio is derived from:

$$\frac{V/V_{rated,obj.}}{f/f_{rated}}$$

[fo_verufn, 1, en_US]

with

V	Measured voltage (maximum phase-to-phase voltage)
$V_{rated, obj.}$	Adjusted rated voltage of the protected object
f	Measured frequency
f_{rated}	Adjusted rated frequency

Based on the definition above, the protection function refers exclusively to primary values of the protected object. A deviation between the primary rated voltage of the voltage transformer and the protected object is corrected automatically.

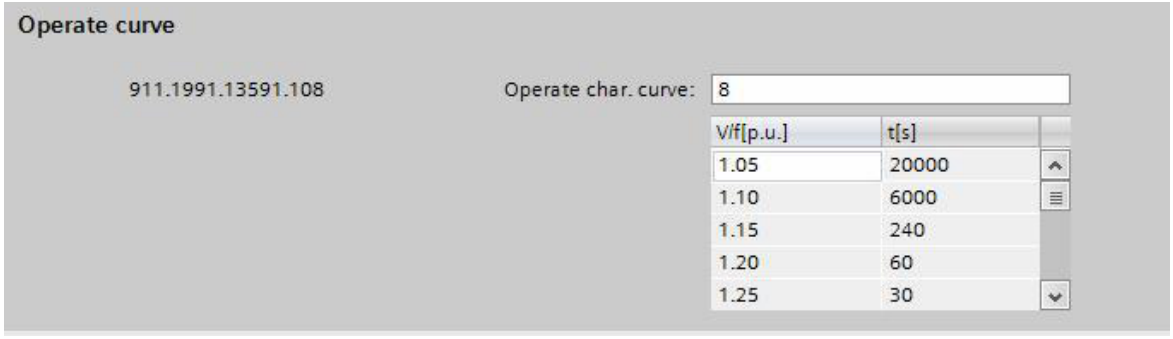
NOTE

This fact must be considered during a secondary test.

More information can be found in chapter *11.13 Functional Test for Overexcitation Protection* .

The function compares the calculated value of the measured V/f ratio with the threshold value and the user-defined thermal characteristic curve.

Depending on the characteristic curve, a **thermal** trip signal is triggered after a pre-determined duration.



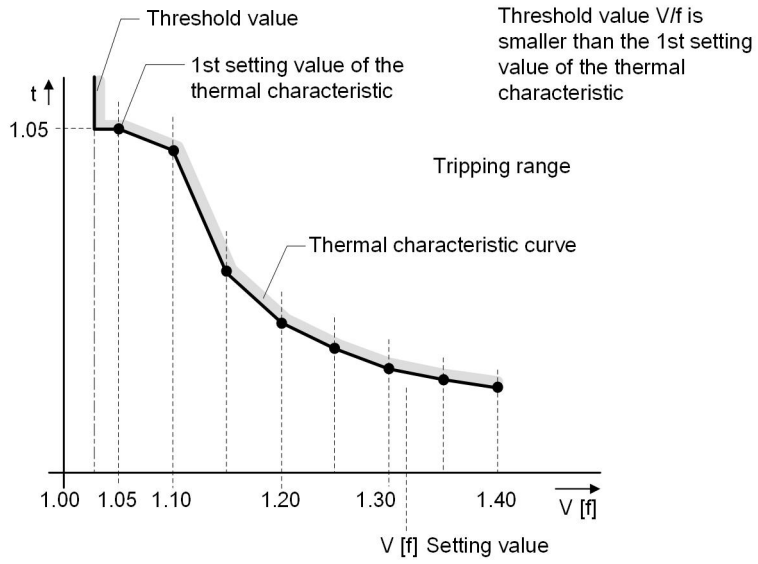
Characteristic Curve

You can freely configure the thermal characteristic curve with the user-defined values. This provides a flexible adjustment to the specified characteristics of the protected object. If the set threshold value (parameter **(_:13591:3) Threshold**) is exceeded, the evaluation of the characteristic curve is initiated. Exceeding the threshold value triggers an indication (*(_:13591:55) Pickup*). In addition, a definite-time stage may be used to generate a delayed indication output as (*(_:13591:301) warning*).

The pickup is used to start the integration process (weighted counting) of the thermal characteristic curve. If the time as a factor of V/f is reached, the pickup is triggered. Based on the replica of the thermal behavior, the trigger value is always 100 % (see *Thermal Behavior, Page 1439*).

If the value drops below the pickup threshold, the trip command is rescinded and the **internal counter** of the parameterized cooling time (parameter **(_:13591:102) Cooling time therm.replica**) is reduced. The dropout threshold of the pickup threshold is fixed to 0.98 * **Threshold**.

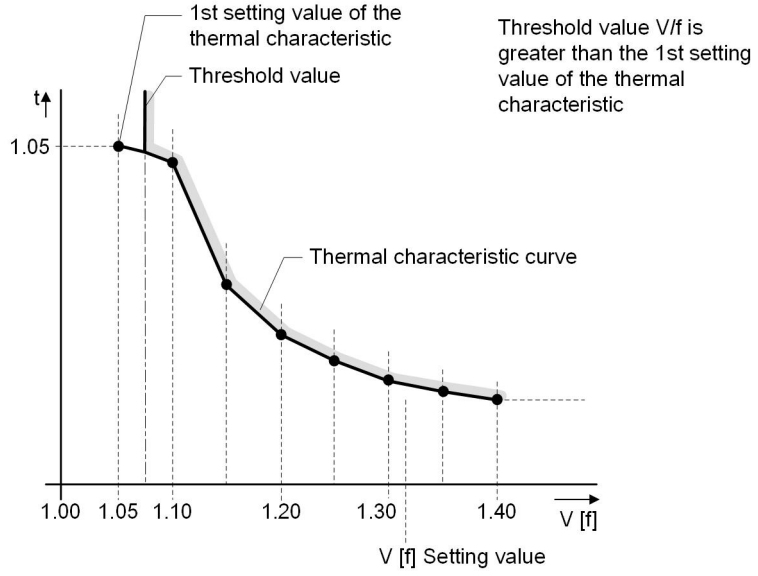
The thermal characteristic curve can be set through a maximum of 30 overexcitation value pairs V/f (referring to the rated values) and the operate time t can be set. The default characteristic curve refers to a standard transformer.



[sc_aulskn, 1, en_US]

Figure 6-526 Data Sheet for Adjustment of Thermal Characteristic Curve

The parameter **Threshold** (pickup threshold) affects the evaluation of the characteristic curve as follows:



If the **Threshold** is smaller than the first characteristic pair, the set time will be extended (see *Figure 6-527*).

[dw_ovexak, 1, en_US]

Figure 6-527 Tripping Zone of the Thermal Characteristic Curve (I)

If the **Threshold** is greater, then a cutoff occurs (see *Figure 6-528*).

[dw_ovexab, 1, en_US]

Figure 6-528 Tripping Zone of the Thermal Characteristic Curve (II)

Warning Threshold

If the **Threshold** is exceeded, the time delay (parameter **(_:13591:101) Warning delay**) is started. If the time delay has elapsed, the indication (*(_:13591:301) Warning*) will be displayed.

Thermal Behavior

The time derived from the characteristic curve and associated with the V/f value is set to 100 %. With each function call, the time will be increased according to the respective weighted invocation interval. If the 100 % value is exceeded, tripping is initiated. If the V/f value is changed, the associated time from the characteristic curve is added as a new 100 % value.

In order to prevent excessive cooling times, the thermal storage has been limited internally to 150 %. The *fill level* of the thermal storage will be provided as functional measured value.

Measured Value	Description
(_:13591:321) V/f th.	Thermal tripping of the overexcitation protection. If the value reaches 100 %, the tripping occurs.

Cooling Time

If the value drops below the threshold value (**(_:13591:3) Threshold**), tripping of the thermal characteristic curve (dependent characteristic curve) is reverted. However, the parameterized cooling time (**Cooling time therm.replica**) reduces the thermal storage (counter content) to 0. This parameter is defined as time. It is required by the thermal replica in order to cool down from 100 % to 0 %.

Resetting the Thermal Map

The binary input indication *(_:13591:501) >Reset thermal replica* can be applied to reset the thermal replica. The thermal replica will then have a value of 0. A reparameterization will also lead to resetting the thermal replica.

Blocking the Stage

The function can be blocked externally or internally by the binary input signal *(_:13591:81) >Block stage*. Blocking will cause a picked up function to be reset.

6.34.3.2 Application and Setting Notes

Thermal overloads extended over a longer period will jeopardize electric equipment, for example, synchronous motors, generators, or transformers and may cause damage. When using the thermal, user-defined characteristic curve, the overexcitation protection is ideally suited for adjusting the specified limits of the protection equipment.

The following provides the recommended settings:

NOTE

One requirement for the correct mode of operation of the function is based on the proper setting of the power-system data.

You can find more detailed information on this in *6.1 Power-System Data*.

For additional setting recommendations, verity the following parameter in the power-system data:

- Adjusted rated frequency
- Adjusted rated voltage of the protected object
- Adjusted rated voltage of the voltage transformer of the applicable measuring point

Parameter: Threshold Value

- Default setting **(_:13591:3) Threshold** = *1.10*

  The **Threshold** parameter is used to describe the value for the permissible continuous overexcitation. The default value is a practical value used for transformers. The value may be less for generator applications. These values can be found in the manufacturer's information.

Parameter: Time Delayed Warning

- Default setting **(_:13591:101) Warning delay** = *10.00 s*

  When using the **Warning delay** parameter, the time can be determined by which the warning indication of the stage should be delayed after the pickup. This time delay depends on the specific application. This time must clearly exceed the reaction time of the regulators. 10 seconds is a feasible value.

Parameter: `Cooling Time Therm. Replica`

- Default setting **`(_:13591:102) Cooling time therm.replica`** = ***`3600 s`***

The **`Cooling time therm.replica`** parameter is used to define the cooling characteristics of the thermal replica. If concrete specifications are not given, the default value can be retained.

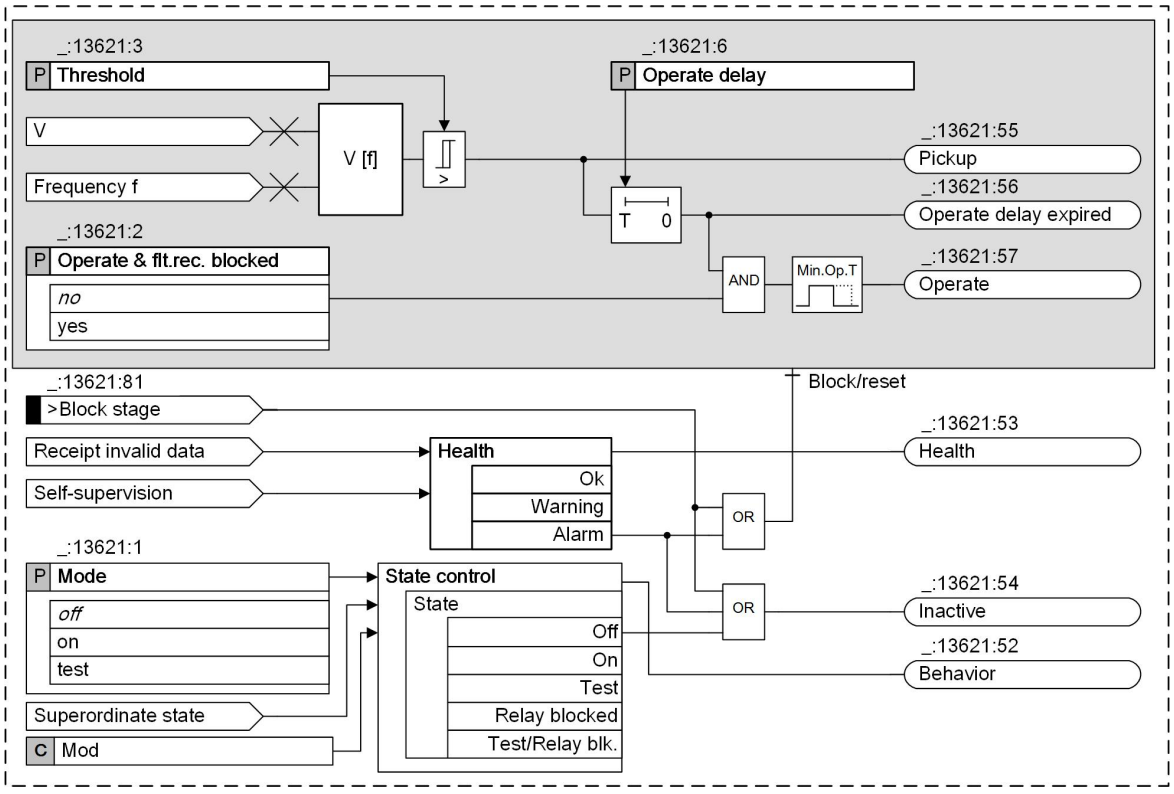
Parameter: `V/f/time value pairs` (operate curve)

With this parameter, the number of potting points along the thermal operate curve are defined. This is required for the calculation. The number of points defines the accuracy of the image of the specified characteristic curve. Adjust the value individually.

Set a V/f/time value pair for each characteristic-curve point. The setting depends on the characteristic curve you want to realize. The default settings refer to a Siemens standard transformer.

NOTE

The value pairs must be entered in continuous order.



NOTE

Note that the V/f values that are lower than the V/f values of the smallest characteristic-curve point do not extend the operate time. Up to the smallest characteristic-curve point, the characteristic curves runs parallel to the V/f axis. V/f values that are larger than the V/f value of the largest characteristic-curve point do not reduce the operate time. From the largest characteristic-curve point, the pickup characteristic runs parallel to the V/f axis (see*Characteristic Curve, Page 1438*).

6.34.4 Stage with Definite-Time Characteristic Curve (Time Stage)

6.34.4.1 Function Description

Logic

{lo_dtchuf, 2, en_US}

Figure 6-529 Logic of the Overexcitation Protection with Independent Characteristic Curve (Definite-Time Stage)

Method of Measurement

This stage also evaluates the V/f value that is identical to the input value of the thermal stage.

For measurement-relevant details, see also *6.34.3 Stage with Dependent Characteristic Curve (Thermal Stage)*.

Operating Principle of the Definite-Time Stage

The stage comprises a threshold value and a time-delay stage. If the V/f value is greater than the set threshold value (**(_:13621:3) Threshold**), then the stage is tripped after an adjustable time delay has elapsed. You can set the time delay with the parameter **(_:13621:6) Operate delay**.

The dropout ratio for the **Threshold** is fixed to 98 %.

6.34.4.2 Application and Setting Notes

The definite-time stage can be applied when fast tripping is required in the presence of high V/f values. In this case, the stage acts superimposed on the thermal, dependent stage.

Parameter: Threshold Value

- Default setting **(_:13621:3) Threshold** = ***1.40***

  The **Threshold** parameter is used to describe the overexcitation value that causes the tripping function. The default value matches a feasible upper limit.

Parameter: `Tripping delay`

- Default setting **`(_:13621:6) Operate delay`** = ***`1.00 s`***

  The **`Operate delay`** parameter is used to determine the time by which the stage is delayed after the pickup. This time delay depends on the specific application. The default value is practical for the application described in the previous chapter.

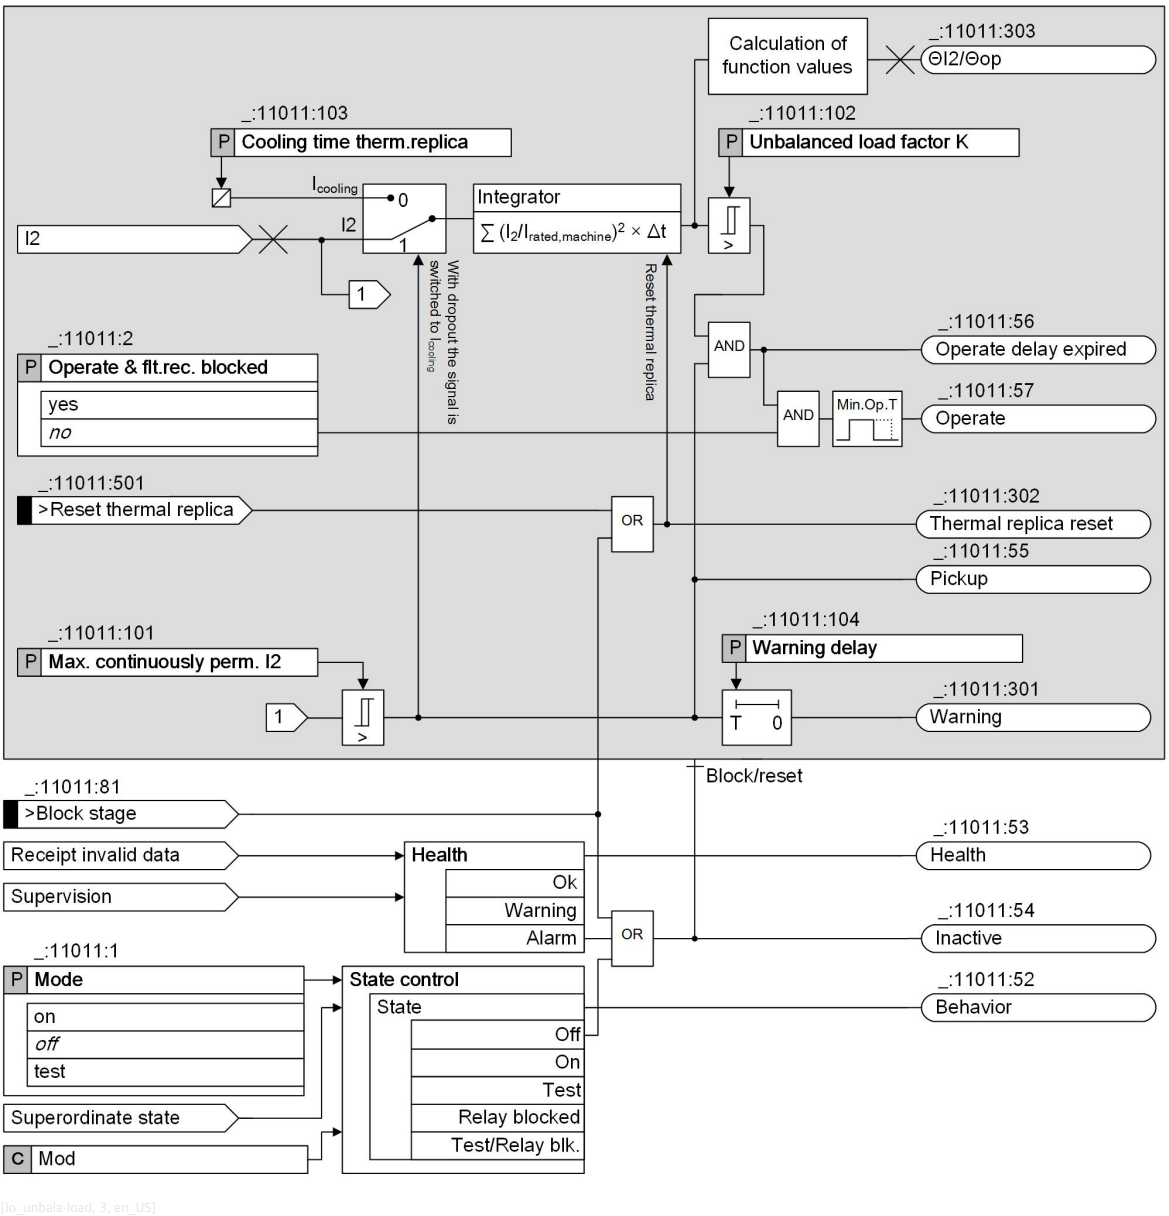
6.35 Unbalanced-Load Protection

6.35.1 Overview of Functions

The **Unbalanced-load protection** function detects unbalanced loads or line interruptions of electrical machines (generators and motors). Unbalanced loads create a counter-rotating magnetic field at double frequency in the rotor. The skin effect leads to local overheating on the surface of the rotor bars in the transition between the slot wedges and the winding bundles. Another effect of unbalanced loads is the overheating of the damper winding.

6.35.2 Structure of the Function

The **Unbalanced-load protection** function is used in the protection function group. The **Unbalanced-load protection** function is preconfigured with 1 stage. A maximum of 2 stages can operate simultaneously in the function.



[dw_unbla, 1, en_US]

Figure 6-530 Structure/Embedding of the Function

6.35.3 Function Description

Logic of the Stage

[lo_unbala-load, 3, en_US]

Figure 6-531 Logic Diagram of the Unbalanced-Load Protection Function

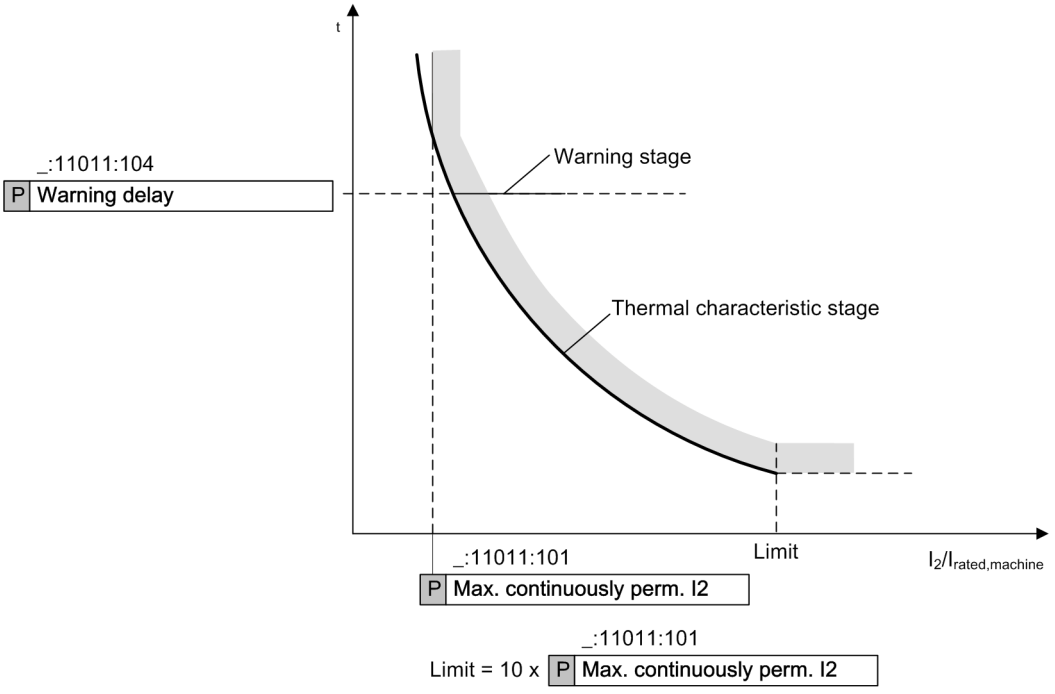
Method of Measurement

The stage uses the negative-sequence current I_2 as a measurand. The negative-sequence current is calculated from the measured 3-phase currents according to the defining equation of symmetrical components.

Warning Stage

If the negative-sequence current I_2 continuously exceeds the parameter **`Max. continuously perm. I2`**, the ***`Warning`*** indication is given after expiry of a set time **`Warning delay`**.

Thermal Characteristic Stage



The machine manufacturers indicate the permissible unbalanced load using the following formula:

$$t_{I2\,Perm} = \frac{K}{\left(I_2 / I_{rated,machine}\right)^2}$$

[fo_rbanl, 1, en_US]

With:

t_{I2Perm}	Permissible time of the negative-sequence current
K	Unbalanced-load factor of the machine (parameter **Unbalanced load factor K**)
$I_2/I_{rated,machine}$	Actual unbalanced-load current as a per unit value(negative-sequence current/rated current of the machine)

[dw_unbalo, 2, en_US]

Figure 6-532 Operate Curve of the Unbalanced-Load Protection

The parameter **Unbalanced load factor K** depends on the machine. It also represents the time in seconds during which the machine can be loaded with a 100 % unbalanced load. This factor is typical in a range from 5 s to 40 s. The heating of the protected object starts to calculate as soon as the negative-sequence current I_2 exceeds the parameter **Max. continuously perm. I2**. The operate time is calculated from the flowing negative-sequence current I_2 with an integrating method of measurement depending on the thermal characteristic. As soon as the integrate result reaches the parameter **Unbalanced load factor K**, the thermal characteristic stage operates.

Limitation of Operate Curve

To avoid an overfunction of the thermal characteristic stage in the situation of unbalanced short circuits (for example, 2-phase short circuit), the input current I_2 is restricted to an upper limit. The limiting value is 10 times of **Max. continuously perm. I2**. If I_2 exceeds the limit, the operate time of the function is constant.

In addition, the thermal memory is limited to 200 % of **Unbalanced load factor K**. The limitation avoids a too long cooling after a delayed short-circuit tripping (for example, of external power-system faults).

Cooling Time Thermal Replica

The thermal replica starts to cool down as soon as the negative-sequence current I_2 is lower than **Max. continuously perm. I2**. The thermal replica decreases according to the parameter **Cooling time therm.replica**. The parameter **Cooling time therm.replica** is the time required by the thermal replica to cool down from 100 % to 0 %. If the parameter **Cooling time therm.replica** is set to 0, the thermal replica is reset immediately.

The parameter **Cooling time therm.replica** depends on the construction type of the machine, especially of the damper winding. Preloading is considered when unbalanced loading occurs again during the cooling time. The protection device thus operates in a shorter time.

Functional Measured Values

The following formula is used to calculate the functional measured value ΘI2/Θop:

$$\Theta I2/\Theta op = \frac{\sum_{0}^{t}\left(I_2/I_{rated,machine}\right)^2 \cdot \Delta t}{K} 100\ \%$$

[fo_runbl2, 1, en_US]

With

ΘI2/Θop	Functional measured value indicating the thermal replica of the unbalanced load
$\sum_{0}^{t}\left(I_2/I_{rated,\ machine}\right)^2 \cdot \Delta t$	Integrating method of measurement of the thermal replica of the negative-sequence system
K	Unbalanced-load factor of the machine (parameter **Unbalanced load factor K**)
$I_2/I_{rated,machine}$	Unbalanced-load as a per unit value (negative-sequence current/rated current of the machine)

If the functional measured value reaches 100 %, the operate of the function is initiated.

6.35.4 Application and Setting Notes

The function is used in the applications of machines. You can get the necessary settings from the technical data of the synchronous generators and motors. The setting example is applied for a generator application.

Parameter: Max. continuously perm. I2, Warning delay

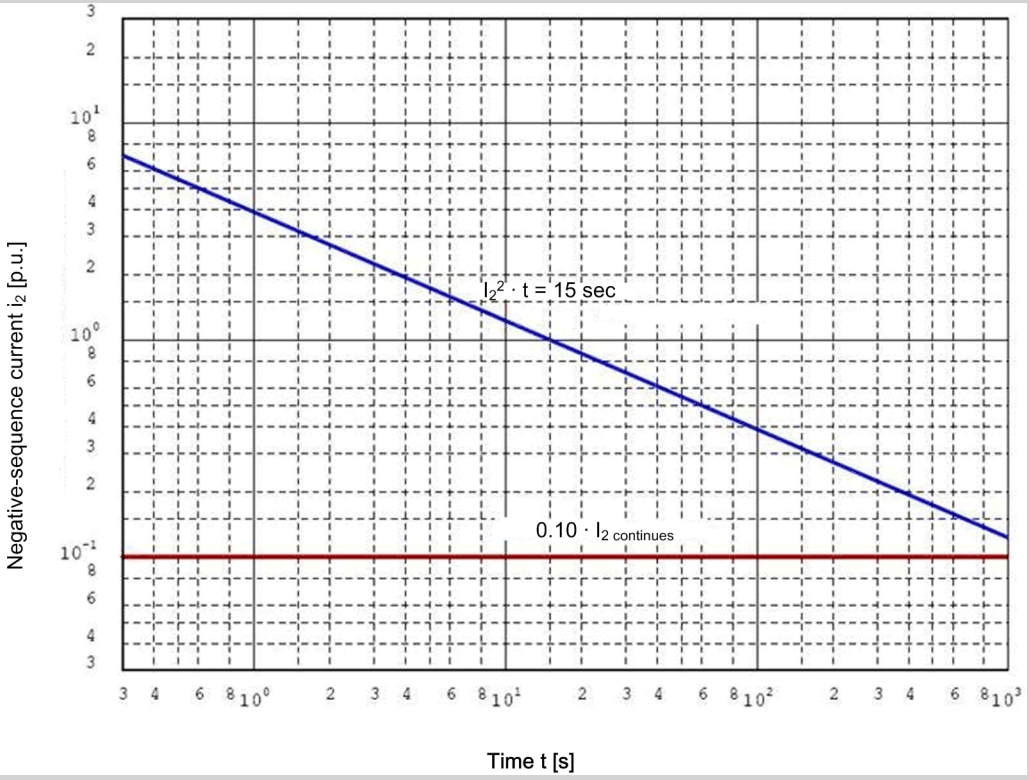
- Default setting **(_:11011:101) Max. continuously perm. I2** = ***10.0 %***
- Default setting **(_:11011:104) Warning delay** = ***15 s***

If the negative-sequence current I_2 exceeds **Max. continuously perm. I2** , the stage picks up and a warning indication is given after the set time delay **Warning delay** .

The parameter **Max. continuously perm. I2** is given in percentage of the rated current of the protected object.

The setting value of the parameter **Max. continuously perm. I2** depends on following parts:

- Design of the machine (salient pole or non-salient pole rotor synchronous machine)
- Cooling system (directly or indirectly cooled)
- Size of the machine



Depending on the standards IEEE C50.12 and IEC 60034-1, the parameter is given in the range between 5 % and 12 %. To set the parameter **Max. continuously perm. I2** , technical data of the machine

is required. The technical data of the machine is provided in the Technical Data Sheet of the machine manufacturer.

EXAMPLE

The following example shows the setting of the parameter **Max. continuously perm. I2** . The value 10 % is selected in the example.

To avoid issuing the *Warning* indication too fast, Siemens recommends a longer delay. Setting the parameter **Warning delay** in the range of 10 s to 20 s is practicable. 15 s is selected in the example.

[dw_unbloc, 1, en_US]

Figure 6-533 Example of an Unbalanced-Load Characteristic Specified by the Machine Manufacturer

Parameter: Unbalanced load factor K

- Default setting **(_:11011:102) Unbalanced load factor K** = ***15 s***

Unbalanced load factor K can be derived from the unbalanced-load characteristic according to *Figure 6-533*. You can read the time corresponding to **Unbalanced load factor K** at the point I_2 / $I_{rated,machine}$= 1. In the example, this is the p.u. value 10° which corresponds to a time of 15 s. As the example shows, the time is often written directly on the characteristic curve.

Parameter: Cooling time therm.replica

- Default setting **(_:11011:103) Cooling time therm.replica** = ***1500 s***

The parameter **Cooling time therm.replica** establishes the time required by the protected object to cool down the thermal replica to the initial value. If the machine manufacturer does not provide this information, the setting value of **Cooling time therm.replica** can be calculated from the setting values of **Unbalanced load factor K** and **Max. continuously perm. I2** by the formula in the following example.

EXAMPLE

$$\text{Cooling time therm. replica} = \frac{\text{Unbalanced load factor K}}{(\text{Max. continuously perm. I 2})^2}$$

[fo_rbala2_02, 1, en_US]

Max. continuously perm. I_2	= 10.0 % (corresponds to 0.1)
Unbalanced load factor K	= 15 s
Cooling time therm. replica	= 1500 s

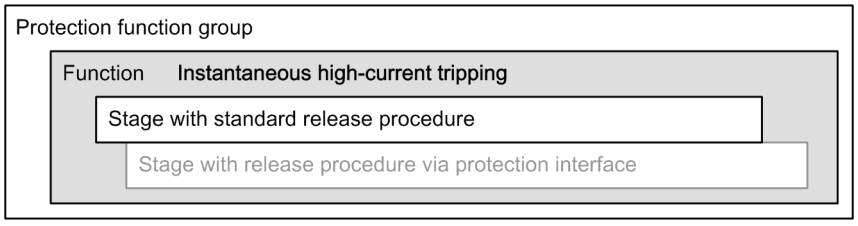
6.36 Instantaneous High-Current Tripping

6.36.1 Overview of Functions

The function **Instantaneous high-current tripping** (ANSI 50) has the following tasks:



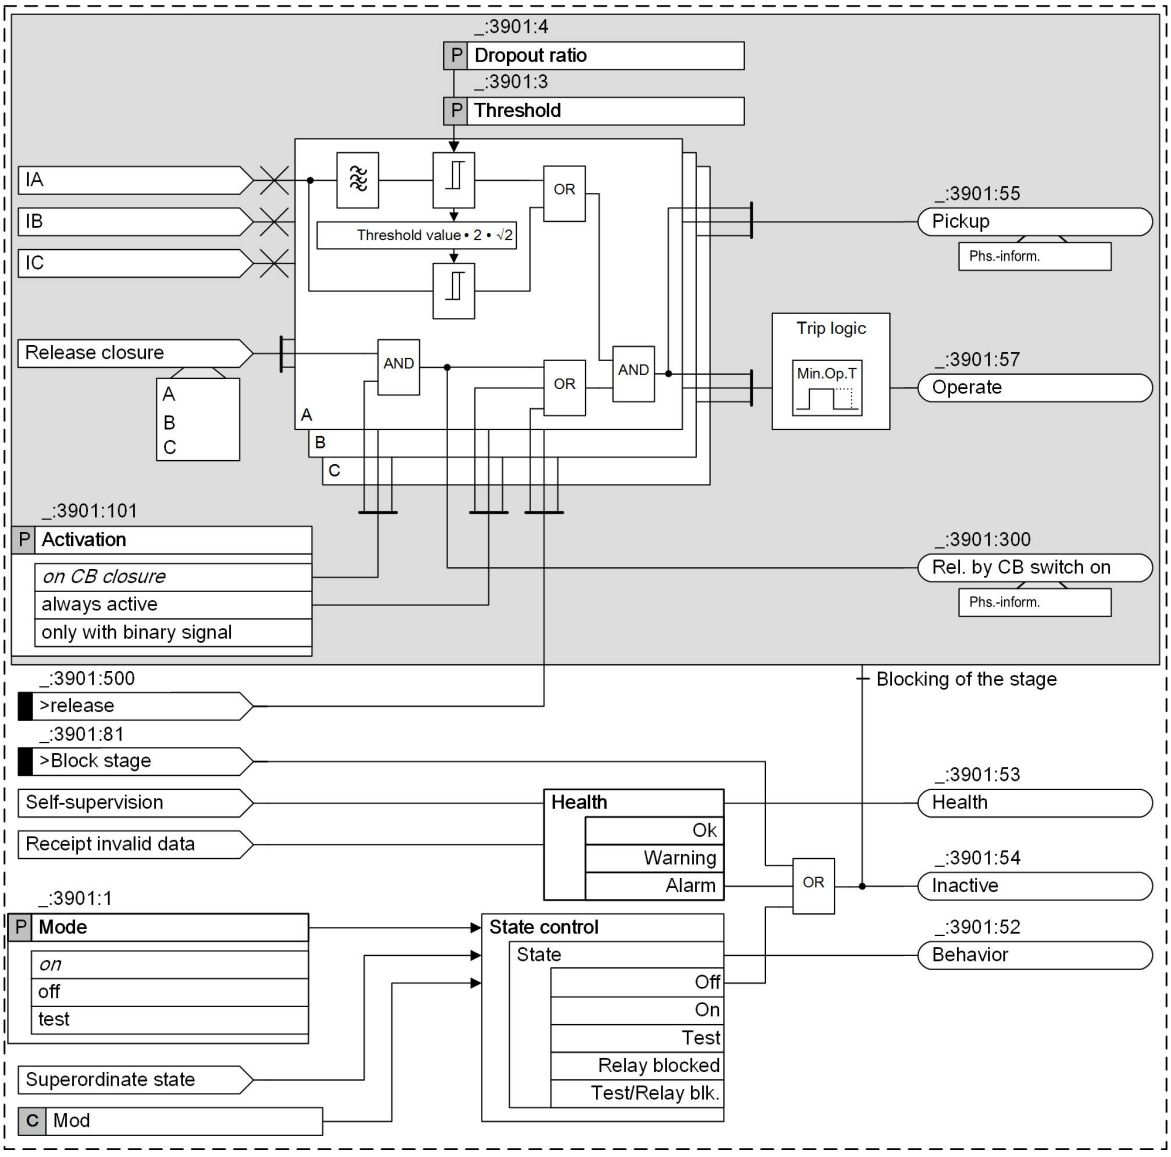
- Instantaneous tripping when switching onto an existing fault, for example, if a grounding switch is closed.
- Instantaneous disconnection of high currents above the highest overcurrent-protection stage.
- The function works independently of other functions.

6.36.2 Structure of the Function

The **Instantaneous high-current tripping** function offers 2 different increment types:

- Stage with standard release method
- Stage with release method via protection interface (only applicable if the device is equipped with a protection interface)

The function with the stage for the standard release procedure is factory-set.



[dw_ihc_str, 1, en_US]

Figure 6-534 Structure/Embedding of the Function

6.36.3 Standard Release Procedure

Logic

[lo_hlore3_3_en_US]

Figure 6-535 Logic Diagram of Instantaneous High-Current Tripping with Standard Release Method

Activation

Using the **Activation** parameter, you set the conditions under which the stage is released.

- ***on CB closure***

  With this procedure, the stage is released only if the circuit breaker is about to be closed (the CB is open) or if the circuit breaker is being closed or the binary input signal *>release* is active. The way the *Rel. by CB switch on* signal is generated is described in chapter *5.9.8 Circuit-Breaker Position Recognition for Protection-Related Auxiliary Functions*.

- ***always active***

  The stage is always released and is thus independent of the closing of the circuit breaker switch and of the binary input signal*>release*.

- ***only with binary signal***
  The stage is released only if the binary input signal *>release* is active.

Method of Measurement, Threshold Value

The stage works with 2 different methods of measurement:

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically. A DC component is thus eliminated. The RMS value of the fundamental component is compared with the set threshold value.
- Evaluation of the unfiltered measurand:
  The stage also works with unfiltered sampled values. Thus, very short operate times are possible. The current sampling values are compared with the threshold value of 2 · √2 of the preset threshold value.

6.36.4 Application and Setting Notes

Parameter: Activation

- Default setting **(_:3901:101) Activation** = ***on CB closure***

With the parameter **Activation**, you define the conditions under which the stage is released.

Parameter Value	Description
on CB closure	Select this setting to activate the stage only when the circuit breaker is closed.
always active	Select this setting to release the stage statically.
only with binary signal	Select this setting to release the stage via an external signal.

Parameter: Threshold

- Default setting **(_:3901:3) Threshold** = ***10.0 A*** for I_{rated} = 1 A or ***50.0 A*** for I_{rated} = 5 A

The stage works independently of the position of the remote circuit breakers. For this reason, set the **Threshold** so that the fault current flowing through does not trigger the stage. Thus, use this stage only if current grading over the protected object is possible, that is, for transformers, shunt reactors or long lines with low source impedance. In other cases, deactivate the stage.

EXAMPLE

Calculation example for current grading of a 110-kV overhead line measuring 150 mm²

s (length) = 100 km;

R_1/s = 0.21 Ω/km;

X_1/s = 0.43 Ω/km

Since the stage is non-directional, the calculation must consider the maximum short-circuit power at the start of the line or at the opposite end:

Ssc" = 3.5 GVA (subtransient, because the function can respond to the 1st peak value)

Current transformer: 600 A/5 A

The line impedance Z_L and the minimum source impedance Z_S are calculated on this basis:

Line impedance Z_L and Source impedance Z_S:

$$Z_1/s = \sqrt{0.21^2 + 0.43^2}\ \Omega/km = 0.479\ \Omega/km$$

$$Z_L = 0.479\ \Omega/km \cdot 100\ km = 47.9\ \Omega$$

$$Z_S = \frac{110\ kV^2}{3500\ MVA} = 3.46\ \Omega$$

[fo_glchzv, 1, en_US]

The maximum 3-phase short-circuit current I''_{sc} flowing through is (at a source voltage of 1.1 V_N):

$$I''_{sc} = \frac{1.1 \cdot V_{net}}{\sqrt{3} \cdot (Z_S + Z_L)} + \frac{1.1 \cdot 110\,kV}{\sqrt{3} \cdot (3.46\,\Omega + 47.9\,\Omega)} = 1360\,A$$

[fo_glchik, 1, en_US]

With a safety margin of 10 %, the following setting value results:

- **Threshold value** (primary) = 1.1 · 1360 A = 1496 A
- **Threshold value** (secondary) = $1.1 \cdot \frac{1360\,A}{600\,A} \cdot 5\,A = 12.5\,A$

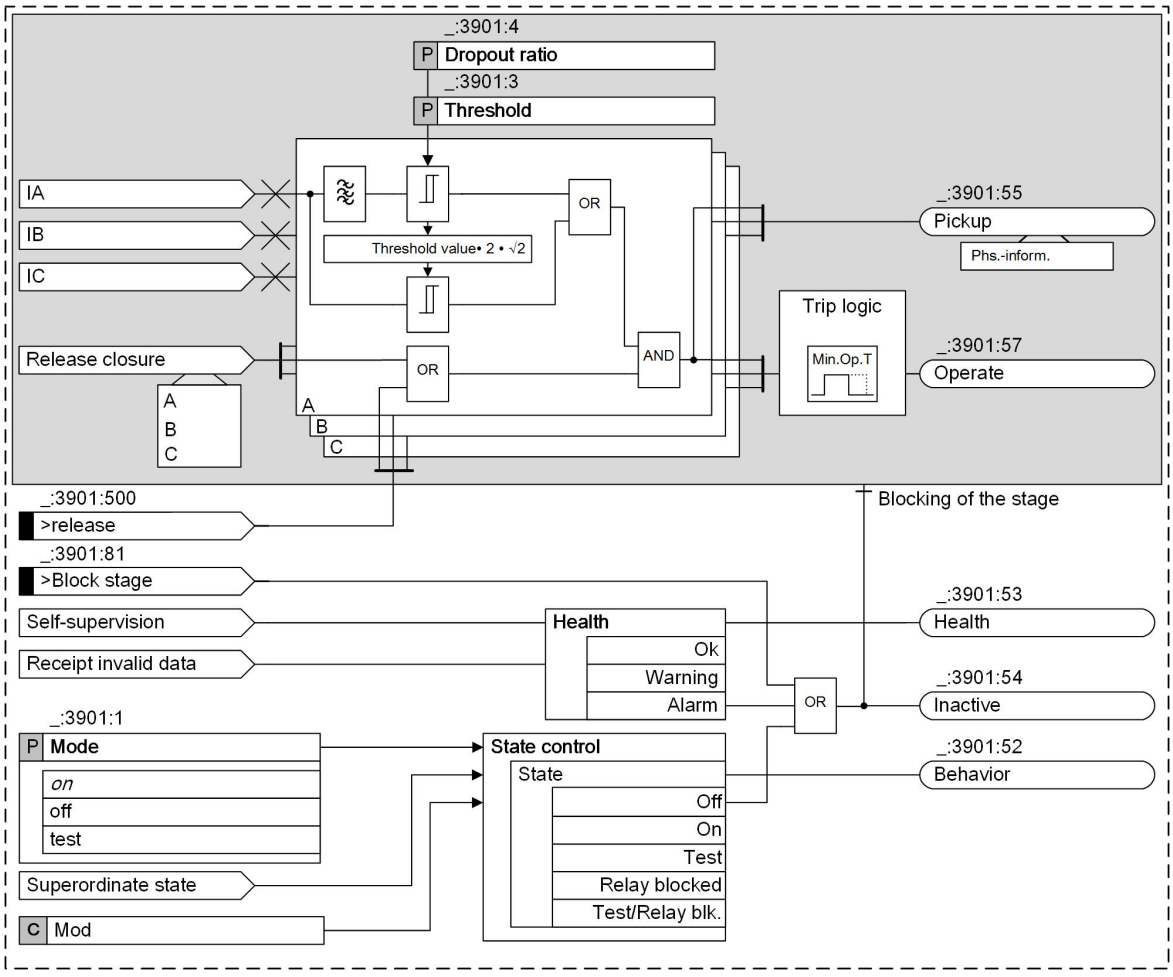
[fo_glnste, 1, en_US]

If short-circuit currents exceed 1496 A (primary) or 12.5 A (secondary), there is a short circuit on the line to be protected. It can be disconnected immediately.

NOTE

The calculation was performed with absolute values, which is accurate enough for overhead lines. A complex calculation is required only if the source impedance and the line impedance have extremely different angles.

Parameter: `Dropout ratio`



- Recommended setting value **`(_:3901:4) Dropout ratio`** = ***`0.90`***

The recommended setting value of ***`0.90`*** is sufficient for many applications. To obtain high-precision measurements, the **`Dropout ratio`** can be reduced. If you expect highly fluctuating measurands at the pickup threshold, you can increase the setting value of the parameter **`Dropout ratio`**. This avoids chattering of the tripping stage.

6.36.5 Release Procedure via Protection Interface

This stage can be applied only if the device is equipped with a protection interface.

Logic

[lo_hinre3, 2, en_US]

Figure 6-536 Logic Diagram of Instantaneous High-Current Tripping with Release Procedure via Protection Interface

Release

If one of the following conditions is fulfilled, the stage is released (the internal **Release** signal is present) (for further information, refer to *5.5.4 Process Monitor (FG Line)*):

- No voltage has yet been applied to the protected object, which means that the remote circuit breakers are open, or
- Switching to the local circuit breaker is imminent.

These conditions are recognized internally if a circuit breaker is open or just closed

Furthermore, the stage can be activated externally via the **`>release`** binary input signal.

NOTE

To enable internal release of the stage, the devices at all ends of the protected object must be informed of the circuit-breaker position (the circuit-breaker auxiliary contacts must be connected to the devices; the respective binary input signals must be routed).

Method of Measurement, Threshold Value

The stage works with 2 different methods of measurement:

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically. A DC component is thus eliminated. The RMS value of the fundamental component is compared with the set threshold value.
- Evaluation of the unfiltered measurand:
  If the current exceeds a preset threshold value by the
  current ≥ 2·√2·threshold value
  this stage will use unfiltered measurands in addition. Thus, very short operate times are possible.

6.36.6 Application and Setting Notes

Parameter: `Threshold`

- Default setting **`(_:3901:3) Threshold`** = ***`2.5 A`*** for I_{rated} = 1 A or ***`12.5 A`*** for I_{rated} = 5 A

Select the value high enough for the protection not to pick up on the RMS value of the inrush current that occurs when the local circuit breaker is closed. You do not have to consider short-circuit currents flowing through, because the stage is released only if the circuit breakers are opened at all remote ends of the protected object or the release was caused by the binary input *`>release`*.

Parameter: `Dropout ratio`

- Recommended setting value **`(_:3901:4) Dropout ratio`** = ***`0.90`***

The recommended setting value of ***`0.90`*** is sufficient for many applications. To obtain extremely accurate measurements, the dropout ratio can be reduced. If you expect highly fluctuating measurands at the pickup threshold, you can increase the dropout ratio. This avoids chattering of the tripping stage.

6.37 Overvoltage Protection with 3-Phase Voltage

6.37.1 Overview of Functions

The function **Overvoltage protection with 3-phase voltage** (ANSI 59) is used to:

- Monitor the permissible voltage range
- Protect equipment (for example, plant components, machines, etc.) against damages caused by overvoltage
- Decouple systems (for example, wind power supply)

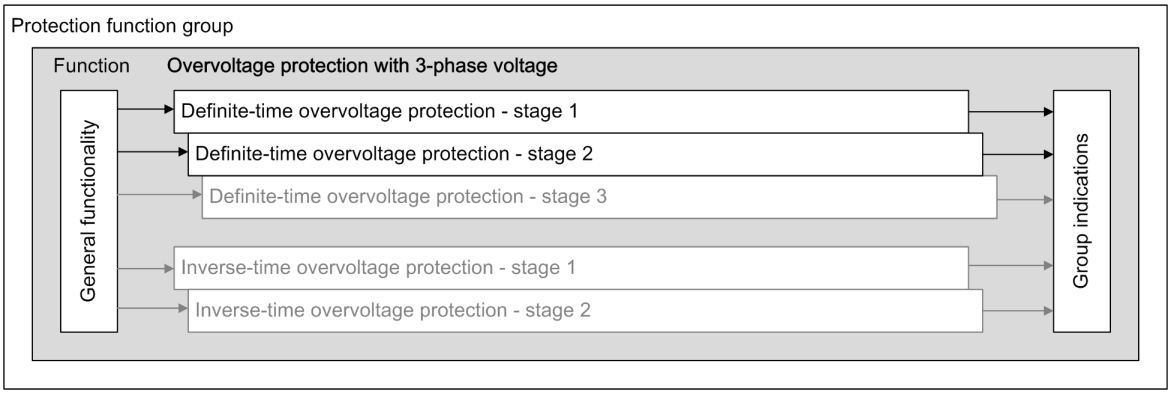
Abnormally high voltages in power systems are caused by voltage controller failure at the transformer or on long transmission lines under low-load conditions.

When using common-mode reactors in the protected power system, the device must shut down the line quickly if the reactors fail (for example, due to fault clearance). The insulation is endangered by the overvoltage condition.

Overvoltages at capacitor banks can be caused by resonances with line or transformer inductances.

In power plants increased voltage levels can be due to one of these factors:

- Incorrect operation when controlling the excitation system manually
- Failure of the automatic voltage controller
- After full load shedding of a generator
- Generators which are disconnected from the network or in island mode



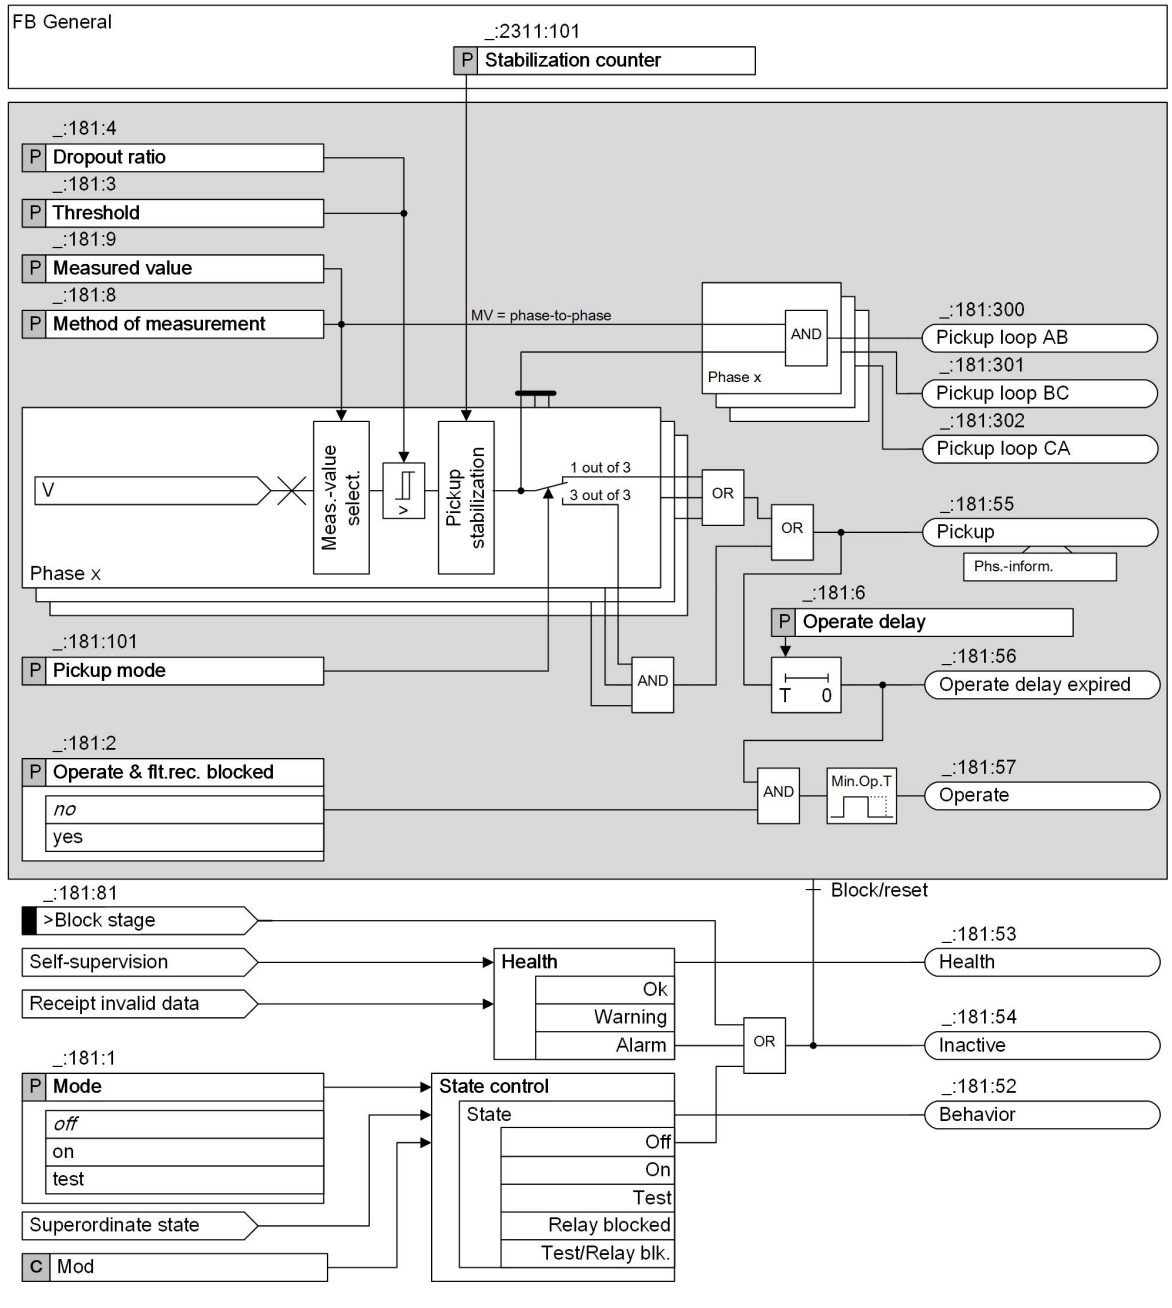
6.37.2 Structure of the Function

The **Overvoltage protection with 3-phase voltage** function is used in protection function groups with voltage measurement.

The **Overvoltage protection with 3-phase voltage** function comes factory-set with 2 **Definite-time overvoltage protection** stages. In this function, the following stages can operate simultaneously:

- 3 stages **Definite-time overvoltage protection**
- 2 stages **Inverse-time overvoltage protection**

Stages that are not preconfigured are shown in gray in the following figure.



[dw_3-phase_ovp, 5, en_US]

Figure 6-537 Structure/Embedding of the Function

6.37.3 Stage with Definite-Time Characteristic Curve

6.37.3.1 Description

Logic of the Stage

[lo_3phas_i_5, en_US]

Figure 6-538 Logic Diagram of the Definite-Time Overvoltage Protection with 3-Phase Voltage

Method of Measurement

Use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the ***RMS value***.

- Measurement ***fundamental comp.***:
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- Measurement ***RMS value***:
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Pickup Stabilization

To enable the pickup stabilization, you set the **Stabilization counter** parameter to a value other than zero. Then, if the input voltage keeps exceeding the **Threshold** for a specified number (1 + **Stabilization counter** value) of successive measuring cycles, the stage picks up. For 50 Hz, the measuring cycle time is 10 ms.

If you set this parameter to ***0*** (default value), the stabilization is not applied. The pickup signal is issued immediately after the input voltage exceeds the **Threshold**.

Pickup Mode

The **Pickup mode** parameter defines whether the protection stage picks up if all 3 measuring elements detect the overvoltage condition (***3 out of 3***) or if only 1 measuring element detects the overvoltage condition (***1 out of 3***).

Measured Value

Use the **Measured value** parameter to define whether the tripping stage analyzes the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C.

If the measured value is set to phase-to-phase, the function reports those measuring elements that have picked up.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking is possible externally or internally via the binary input signal *>Block stage*.

6.37.3.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:181:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends this method of measurement as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Do not set the **threshold value** of the stage under 10 V for this method of measurement.

Parameter: Measured value

- Default setting **(_:181:9) Measured value** = ***phase-to-phase***

With the **Measured value** parameter, you define whether the stage monitors the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA} or the phase-to-ground voltages V_A, V_B, and V_C.

Parameter Value	Description
phase-to-phase	If you want to monitor the voltage range, keep ***phase-to-phase*** as the default setting. In this case, the function will not pick up on ground faults. Siemens recommends the measured value ***phase-to-phase*** as the default setting.
phase-to-ground	Select the ***phase-to-ground*** setting if you want to detect voltage unbalances and overvoltage conditions caused by ground faults.

Parameter: Threshold

- Default setting **(_:181:3) Threshold** = ***110 V***

Depending on the **Measured value**, the **Threshold** is set either as phase-to-phase quantity or as phase-to-ground quantity. The default setting assumes that the voltage range is monitored on long-distance transmission lines under low-load conditions.

Specify the **Threshold** (pickup threshold) for the specific application.

Parameter: Stabilization counter

- Default setting **(_:2311:101) Stabilization counter** = ***0***

You can configure the **Stabilization counter** parameter in the function block **General**.

For special applications, it could be desirable that a short exceeding of the input voltage above the pickup value does not lead to the pickup of the stage, which starts fault logging and recording. This is achieved by setting the **Stabilization counter** parameter to a value other than zero.

For example, if you set this parameter to ***1***, the pickup signal is issued when the voltage keeps exceeding the **Threshold** for 2 successive measuring cycles. For 50 Hz, the measuring cycle time is 10 ms.

Parameter: Operate delay

- Default setting **(_:181:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:181:4) Dropout ratio** = ***0.95***

The recommended set value of ***0.95*** is appropriate for most applications. To achieve high measurement precision, the **Dropout ratio** can be reduced, to 0.98, for example.

Parameter: Pickup mode

- Recommended setting value **(_:181:101) Pickup mode** = ***1 out of 3***

With the **Pickup mode** parameter, you define whether the protection stage picks up if all 3 measuring elements detect the overvoltage condition (***3 out of 3***) or if only 1 measuring element detects the overvoltage condition (***1 out of 3***).

Parameter Value	Description
1 out of 3	Select the setting for protection applications or for monitoring the voltage range. Siemens recommends ***1 out of 3*** as the default setting. This reflects how the function behaved in previous generations (SIPROTEC 4, SIPROTEC 3).
3 out of 3	Select this setting when using the stage to disconnect from the power system (in the case of wind farms, for example).

Operation as Supervision Function

If you want the stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

EXAMPLE

Example for 2-stage overvoltage protection

The example describes the possible settings for a 2-stage overvoltage protection function. We will look at the settings of the parameters **Threshold** and **Operate delay**.

- 1. Stage:
  To detect stationary overvoltages, set the threshold value of the first overvoltage-protection element at least 10 % above the max. stationary phase-to-phase voltage anticipated during normal operation. When setting the parameter **Measured value** to phase-to-phase voltage and a secondary rated voltage of 100 V, the secondary setting value of the first overvoltage-protection element is calculated as follows:

Threshold value: 10 % above V_{rated}

$V_{threshold, sec} = 1.1\ V_{rated, sec} = 1.1 \times 100\ V = 110\ V$

This requires that the primary rated voltages of protected object and voltage transformer are identical. If they are different, you have to adjust the pickup value.

For the **Operate delay** set a value of 3 s.

- 2. Stage:
  The second overvoltage-protection stage is intended for high overvoltages with short duration. A high pickup value is selected here, for example, 1.5 times the rated voltage. A time delay setting of 0.1 s to 0.2 s is sufficient then.

Stage	Setting Values	
	Threshold value	Time delay
1	1.1 V_{rated}	3 s
2	1.5 V_{rated}	0.1 s to 0.2 s

6.37.4 Stage with Inverse-Time Characteristic Curve

6.37.4.1 Description

Logic of the Stage

[lo_3ph_inv, 4, en_US]

Figure 6-539 Logic Diagram of the Inverse-Time Overvoltage Protection with 3-Phase Voltage

Method of Measurement

Use the **Method of measurement** parameter to define whether the stage uses the ***fundamental comp.*** or the ***RMS value*** .

- Measurement ***fundamental comp.*** :
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- Measurement ***RMS value*** :
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Pickup Stabilization

To enable the pickup stabilization, you set the **Stabilization counter** parameter to a value other than zero. Then, if the input voltage keeps exceeding the pickup value for a specified number (1 + **Stabilization counter** value) of successive measuring cycles, the stage picks up. For 50 Hz, the measuring cycle time is 10 ms.

If you set this parameter to ***0*** (default value), the stabilization is not applied. The pickup signal is issued immediately after the input voltage exceeds the pickup value.

Pickup Mode

With the **Pickup mode** parameter, you define whether the protection stage picks up if all 3 measuring elements detect the overvoltage condition (***3 out of 3***) or if only 1 measuring element detects the overvoltage condition (***1 out of 3***).

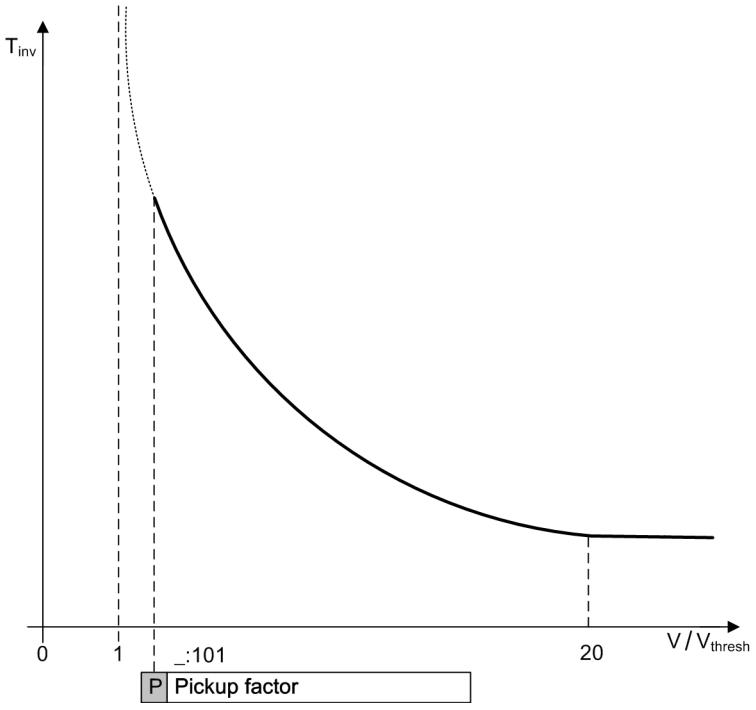
Measured Value

Use the **Measured value** parameter to define whether the stage analyzes the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C.

If the measured value is set to phase-to-phase, the function reports those measuring elements that have picked up.

Pickup and Operate Curve

When the input voltage exceeds the threshold value by a settable value **Pickup factor** , the stage picks up and the inverse-time characteristic curve is processed. Operate delay starts. The operate delay is the sum of inverse-time delay and additional time delay.



$$T_{op} = T_{inv} + T_{add}$$

Where

T_{op}	Operate delay
T_{inv}	Inverse-time delay
T_{add}	Additional time delay (parameter **Additional time delay**)

After pickup, the time value T_{inv} is calculated for every input voltage that exceeds the threshold. An integrator accumulates the value $1/T_{inv}$. Once the accumulated integral reaches the fixed value 1, the inverse-time delay expires. The additional time delay T_{add} starts. The stage operates after the additional time delay expires.

The inverse-time characteristic is shown in the following figure.

[dw_ovp_inv, 2, en_US]

Figure 6-540 Operate Curve of Inverse-Time Characteristic

The inverse-time delay is calculated with the following formula:

$$T_{inv} = T_p \left(\frac{k}{\left(\frac{V}{V_{thresh}} \right)^{\alpha} - 1} + c \right) [s]$$

Where

T_{inv}	Inverse-time delay
T_p	Time multiplier (parameter **Time dial**)
V	Measured voltage
V_{thresh}	Threshold value (parameter **Threshold**)
k	Curve constant k (parameter **Charact. constant k**)
α	Curve constant α (parameter **Charact. constant α**)
c	Curve constant c (parameter **Charact. constant c**)

When V/V_{thresh} is equal to or greater than 20, the inverse-time delay does not decrease any further.

Dropout Behavior

When the voltage falls below the dropout threshold (0.95 × pickup factor × threshold value), the pickup signal is going and the dropout is started. You can define the dropout behavior via parameter **Reset time** . Instantaneous reset takes place by setting **Reset time** to 0 s. A delayed reset takes place by setting the desired delay time.

During the **Reset time** (> 0 s), the elapsed operate delay is frozen. If the pickup value is exceeded again within this period, the stage operates when the rest of operate delay expires.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking is possible externally or internally via the binary input signal *>Block stage* .

6.37.4.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the tripping stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends this method of measurement as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Do not set the **threshold value** of the tripping stage under 10 V for this method of measurement.

Parameter: Measured value

- Default setting **(_:9) Measured value** = ***phase-to-phase***

With the **Measured value** parameter, you define whether the tripping stage monitors the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA} or the phase-to-ground voltages V_A, V_B, and V_C.

Parameter Value	Description
phase-to-phase	If you want to monitor the voltage range, keep ***phase-to-phase*** as the default setting. In this case, the function will not pick up on ground faults. Siemens recommends the measured value ***phase-to-phase*** as the default setting.
phase-to-ground	Select the ***phase-to-ground*** setting if you want to detect voltage unbalances and overvoltage conditions caused by ground faults.

Parameter: Threshold, Pickup factor

- Default setting **(_:3) Threshold** = ***110.000 V***
- Default setting **(_:101) Pickup factor** = ***1.10***

The stage picks up when the measured voltage value exceeds the pickup value **Threshold** × **Pickup factor**.

Depending on the **Measured value**, the **Threshold** is set either as phase-to-phase quantity or as phase-to-ground quantity.

With the **Pickup factor** parameter, you modify the pickup value. To avoid a long-time operate delay after pickup when the measured value is slightly over the threshold, Siemens recommends using the default setting.

Specify the **Threshold** (pickup threshold) and **Pickup factor** for the specific application.

Parameter: Stabilization counter

- Default setting **(_:2311:101) Stabilization counter** = ***0***

You can configure the **Stabilization counter** parameter in the function block **General**.

For special applications, it could be desirable that a short exceeding of the input voltage above the pickup value does not lead to the pickup of the stage, which starts fault logging and recording. This is achieved by setting the **Stabilization counter** parameter to a value other than zero.

For example, if you set this parameter to ***1***, the pickup signal is issued when the voltage keeps exceeding the pickup value for 2 successive measuring cycles. For 50 Hz, the measuring cycle time is 10 ms.

Parameter: `Pickup mode`

- Recommended setting value **`(_:182:101) Pickup mode`** = ***`1 out of 3`***

With the **`Pickup mode`** parameter, you define whether the protection stage picks up if all 3 measuring elements detect the overvoltage condition (***`3 out of 3`***) or if only 1 measuring element detects the overvoltage condition (***`1 out of 3`***).

Parameter Value	Description
`1 out of 3`	Select the setting for protection applications or for monitoring the voltage range. Siemens recommends ***`1 out of 3`*** as the default setting. This reflects how the function behaved in previous generations (SIPROTEC 4, SIPROTEC 3).
`3 out of 3`	Select this setting when using the stage to disconnect from the power system (in the case of wind farms, for example).

Parameter: `Charact. constant k`, `Charact. constant α`, `Charact. constant c`

- Default setting **`(_:102) Charact. constant k`** = ***`1.00`***
- Default setting **`(_:103) Charact. constant α`** = ***`1.000`***
- Default setting **`(_:104) Charact. constant c`** = ***`0.000`***

With the parameters **`Charact. constant k`**, **`Charact. constant α`**, and **`Charact. constant c`**, you define the required inverse-time characteristic curve.

Parameter: `Time dial`

- Default setting **`(_:105) Time dial`** = ***`1.00`***

With the **`Time dial`** parameter, you displace the characteristic curve in the time direction.

As usually, there is no time grading for voltage protection and therefore no displacement of the characteristic curve, Siemens recommends leaving the **`Time dial`** parameter at ***`1.00`*** (default setting).

Parameter: `Additional time delay`

- Default setting **`(_:106) Additional time delay`** = ***`0.00 s`***

With the **`Additional time delay`** parameter, you define a definite-time delay in addition to the inverse-time delay.

If the setting is left on its default value of 0 s, only the inverse-time delay is operative.

Parameter: `Reset time`

- Default setting **`(_:107) Reset time`** = ***`0.00 s`***

With the **`Reset time`** parameter, you define the reset time delay which is started when the voltage falls below the dropout threshold. Set the parameter **`Reset time`** to 0 s when instantaneous reset is desired.

Under network conditions of intermittent faults or faults which occur in rapid succession, Siemens recommends setting the **`Reset time`** to an appropriate value (> 0 s) to ensure the operation. Otherwise Siemens recommends keeping the default value to ensure a fast reset of the function.

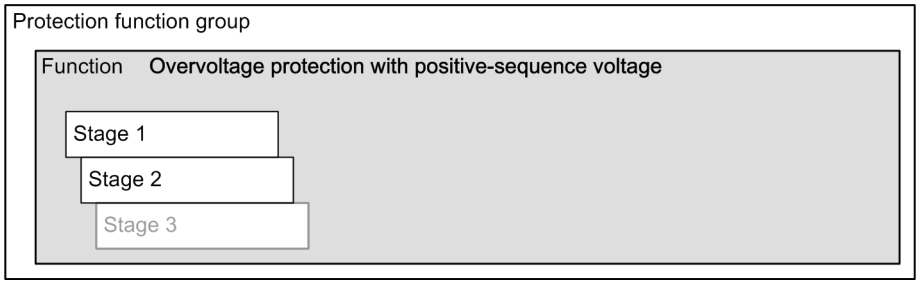
6.38 Overvoltage Protection with Positive-Sequence Voltage

6.38.1 Overview of Functions



The function **Overvoltage protection with positive-sequence voltage** (ANSI 59) is used to:

- Detect symmetric stationary overvoltages
- Supervise the voltage range if the positive-sequence voltage is the decisive quantity

Unbalanced overvoltages, for example, caused by ground faults and unbalanced faults, are not detected due to the evaluation of the positive-sequence voltage.

6.38.2 Structure of the Function

The **Overvoltage protection with positive-sequence voltage** function is used in protection function groups, which are based on voltage measurement.
The function **Overvoltage protection with positive-sequence voltage** comes factory-set with 2 stages. A maximum of 3 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.

[dw_ovp_u1s, 1, en_US]
Figure 6-541 Structure/Embedding of the Function

6.38.3 Stage Description

Logic of a Stage

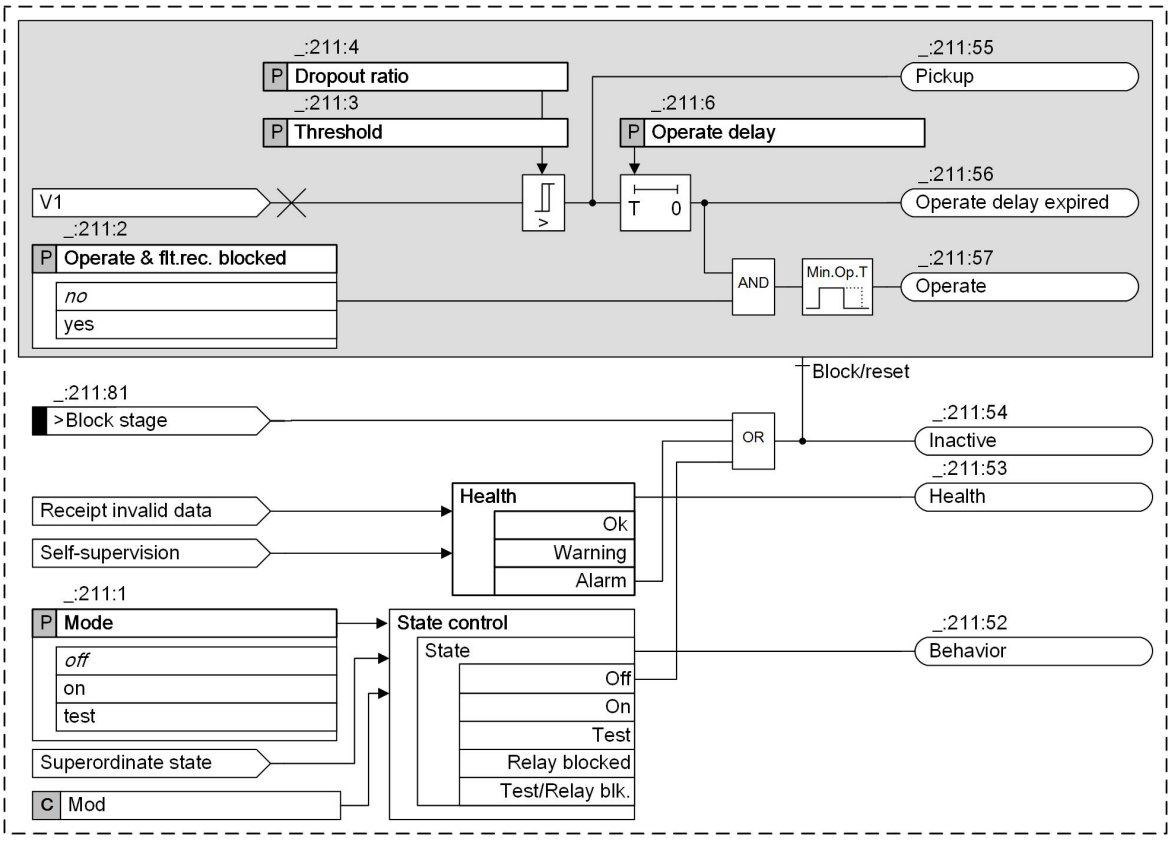


Figure 6-542 Logic Diagram of a Stage: Overvoltage Protection with Positive-Sequence Voltage

Method of Measurement

The stage uses the positive-sequence voltage. The positive-sequence voltage is calculated from the measured phase-to-ground voltages according to the defining equation.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking is possible externally or internally via the binary input signal **>Block stage**.

6.38.4 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:211:3) Threshold** = ***65 V***

The Threshold is set according to the definition of the positive-sequence system.

Specify the Threshold (pickup threshold) for the specific application.

Parameter: Operate delay

- Default **(_:211:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:211:4) Dropout ratio** = ***0.95***

The default value of ***0.95*** is appropriate for most applications. To achieve high measurement precision, the **Dropout ratio** can be reduced, to 0.98, for example.

General Notes

If the overvoltage is high, the first stage can trip with a short time delay. If overvoltages are lower, the second stage can either only signal the threshold value violation (see *Operation as monitoring function*) or trip with a longer delay to allow the voltage controller to regulate the voltage back into the nominal range.

Operation as Supervision Function

If you want the tripping stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

6.39 Overvoltage Protection with Negative-Sequence Voltage

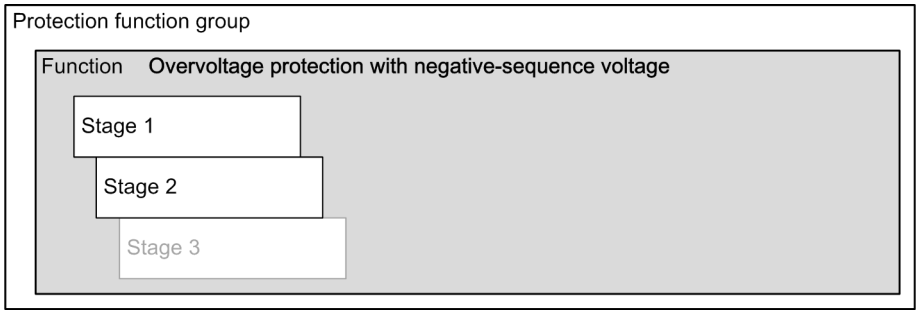
6.39.1 Overview of Functions

The function **Overvoltage protection with negative-sequence voltage** (ANSI 47) is used to:

- Monitor the power system and electric machines for voltage unbalances
- Establish a release criterion of overcurrent protection for unbalanced faults

Voltage unbalances can be caused by various factors:

- The most common cause is unbalanced load, caused by different consumers in the individual phases, for example.
- Voltage unbalance can also be caused by phase failure, for example due to a tripped 1-phase fuse, a broken conductor, etc.
- Other causes can include faults in the primary system, for example, at the transformer or in installations for reactive-power compensation.



6.39.2 Structure of the Function

The **Overvoltage protection with negative-sequence voltage** function is used in protection function groups, which are based on voltage measurement.

The **Overvoltage protection with negative-sequence voltage** function comes factory-set with 2 stages.

A maximum of 3 stages can be operated simultaneously in the function.

The stages have an identical structure.

[dw_uZovps_ext, 2, en_US]

Figure 6-543 Structure/Embedding of the Function

6.39.3 General Functionality

6.39.3.1 Description

Logic

The following figure represents the logic of the average-value calculation of the negative-sequence voltage. The average value is forwarded to all subordinate stages.

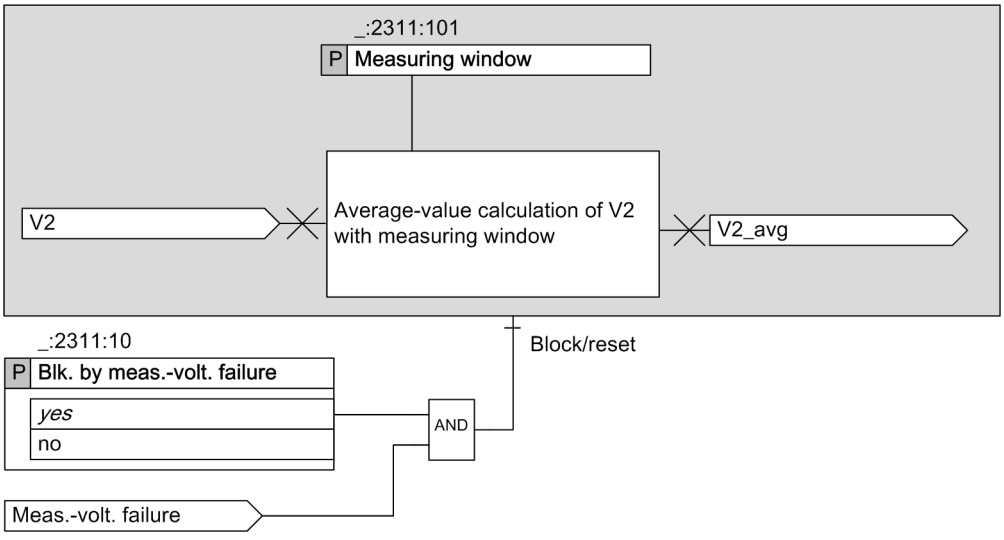


Figure 6-544 Logic Diagram of the General Functionality

Measurand

The average value of negative-sequence voltage is determined by a settable time interval (parameter: **Measuring window**). With the parameter **Measuring window**, you can adapt this function to all power-system conditions.

You can set the parameter **Measuring window** with a large value to get a more accurate calculated result, which leads to a longer pickup time however.

Blocking the Function with Measuring-Voltage Failure Detection

In case of blocking, the picked up function is reset. The following blocking options is available for the function:

- From inside on pick up of the **Measuring-voltage failure detection** function (see section *8.3.2.1 Overview of Functions*).
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker.

The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the function or does not block it.

6.39.3.2 Application and Setting Notes

Parameter: Measuring window

- Default setting **(_:2311:101) Measuring window** = ***1 cycle***

  With the parameter **Measuring window**, you can optimize the measuring accuracy or the pickup time of this function.

  For sensitive settings of the parameter **Threshold**, for example, lower than 10 % of the rated voltage, Siemens recommends using a higher number of cycles. Siemens recommends ***10 cycles***, and in this case, the pickup time is increased.

  For further information, refer to chapter *12.34 Overvoltage Protection with Negative-Sequence Voltage* .

Parameter: Blk. by meas.-volt. failure

- Recommended setting value **(_:2311:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the function when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see chapter *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection function is blocked (= default setting). Siemens recommends using the default setting.
no	The protection function is not blocked.

6.39.4 Stage with Negative-Sequence Voltage

6.39.4.1 Description

Logic of a Stage

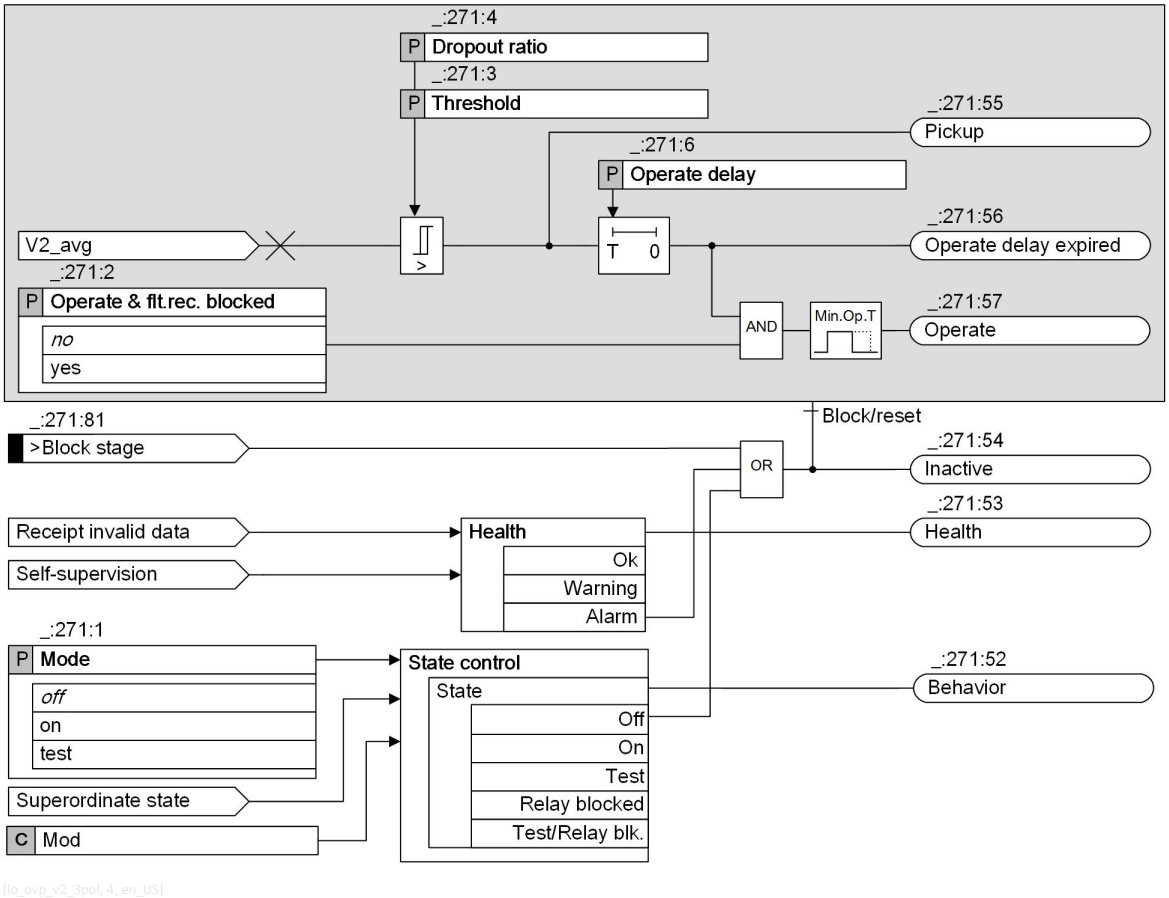

Figure 6-545 Logic Diagram of the Stage: Overvoltage Protection with Negative-Sequence Voltage

Method of Measurement

The stage uses the average value of the negative-sequence voltage, which is calculated from the function block **General Functionality**. For more information, refer to chapter *6.39.3.1 Description*.

Blocking the Stage

In case of blocking, the picked up function is reset. The following blocking option is available for the function:

- From an external or internal source via the binary input signal *>Block stage*

6.39.4.2 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:271:3) Threshold** = ***5.800 V***

The parameter **Threshold** is set according to the definition of the negative-sequence system.

Specify the **Threshold** (pickup threshold) for the specific application.

The secondary voltage of the voltage transformer can be used if the voltage transformer is adapted to the rated voltage. The value of the 10 % negative-sequence voltage at a 100 V rated secondary voltage is:

100 V / 1.73 * 0.1 = 5.77 V

Parameter: Dropout ratio

- Default setting **(_:271:4) Dropout ratio** = ***0.95***

The default setting of ***0.95*** is appropriate for most applications.

You can decrease the dropout ratio to avoid chattering of the stage if the threshold value is low. For example, for the stage with a 2 % setting, you can use a dropout ratio of 0.90.

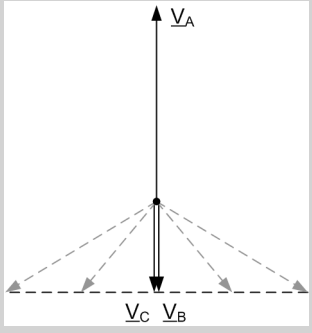
Parameter: Operate delay

- Default setting **(_:271:6) Operate delay** = ***3.00 s***

Specify the **Operate delay** for the specific application. 3.00 s is a practicable value.

For a higher threshold value, a shorter tripping delay is required.

Operation as Supervision Function



If you want the stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

Example 1:

Releasing an overcurrent protection stage for unbalanced faults

The following section describes how to set the function to release an **Overcurrent-protection** stage when unbalanced faults occur. Set the **Overcurrent-protection** stage only slightly higher than the load current, that is very sensitive. To prevent the **Overcurrent-protection** stage from picking up inadvertently, the **Overcurrent-protection** stage is released when the **Negative-sequence voltage** stage picks up. The **Overcurrent-protection** stage remains blocked as long as the **Negative-sequence voltage** stage has not picked up.

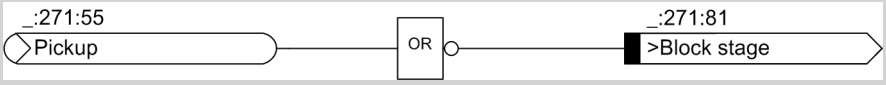
Figure 6-546 shows the voltage phasors during a 2-phase local fault between phases B and C. The phase-to-phase voltage V_{BC} is virtually 0.

[dw_ua_zeig, 1, en_US]

Figure 6-546 Voltage Phasors during a 2-Phase Local Fault

A 2-phase local fault generates a relatively large negative-sequence voltage of up to 50 % referred to the phase-to-ground voltage. The portion of the negative-sequence decreases in case of a remote fault. The lower setting limit results from the possible unbalance at full load. If you assume for example 5 % negative-sequence voltage, the pickup value must be higher. A setting value of 10 % warrants sufficient stability during unbalanced operating states and sufficient sensitivity to release the **Overcurrent-protection** stage when a fault occurs.

For a secondary rated voltage of 100 V, set the following secondary threshold value:



$$V2_{sec} = \frac{V_{rated}\ 100\ V}{\sqrt{3}} \times\ 10\ \% = \frac{100\ V}{\sqrt{3}} \times\ 0.1 \approx 5.8\ V$$

[fo_ovp_v2_secondary threshold, 1, en_US]

You can keep the default setting of 0.95 for the dropout ratio. This avoids chattering of the stage.

Set the **Negative-sequence voltage** stage so that it does not generate a fault when it picks up and does not initiate tripping. The **Overcurrent-protection** stage generates a fault indication. The pickup of the **Negative-sequence voltage** stage is used as the release criterion because the **Short-circuit** function must be released immediately when the **Negative-sequence voltage** stage has picked up. The time delay is thus not relevant and can be left at the default setting.

You implement the release of the **Overcurrent-protection** stage using a logic block chart. An inverter links the pickup of the **Negative-sequence voltage** stage with the **Overcurrent-protection** stage blocking.

[lo_invert, 1, en_US]

Figure 6-547 Linking the Pickup of the Negative-Sequence Voltage Stage

Stage	Setting Values		
	Secondary Threshold Value	Time Delay	Dropout Ratio
1	5.800 V	3.00 s	0.95

The second stage is not needed. It is deleted or remains off.

Example 2:

A negative-sequence voltage in the auxiliary system of the power plant causes negative-sequence currents on motors. This leads to a thermal overload of the rotors. The following estimation can be used as a basis: 1 % negative-sequence voltage can lead to approximately 5 % or 6 % negative-sequence current.

A negative-sequence voltage can be caused by a broken conductor on the high-voltage side. If a negative-sequence voltage occurs, this can, for example, initiate a switching of the infeed in order to prevent a protection trip of an unbalanced-load protection of the motors.

Siemens recommends using multiple stages for a better grading, whereby a sensitive setting of the threshold permits an increased tripping delay.

For a reference, only 2 stages are discussed.

The first stage has a pickup threshold of 10 % with a time delay of 1.5 s. The second stage has a pickup threshold of 3 % with a time delay of 8 s, see *Table 6-18*. Further, it is assumed that the voltage transformer is well adapted to the rated voltage.

$$V2_{sec} = \frac{100\ V}{1.73} \times \frac{V2\ [\%]}{100\%}$$

[fo_ovp_v2_secondary_threshold2, 1, en_US]

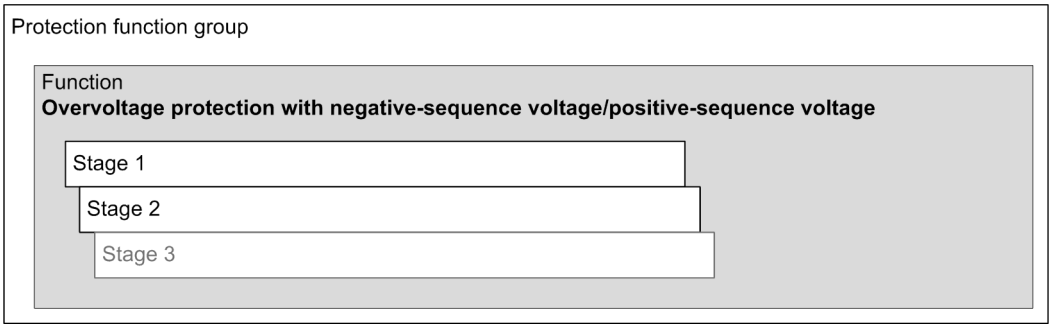
6.40 Overvoltage Protection with Negative-Sequence Voltage/Positive-Sequence Voltage

6.40.1 Overview of Functions

The function **Overvoltage protection with negative-sequence voltage/positive-sequence voltage** is used to:



- Monitor the power system and electric machines for voltage unbalances
- Establish a release criterion of overcurrent protection for unbalanced faults

Voltage unbalances can be caused by various factors:

- The most common cause is unbalanced load, caused by different consumers in the individual phases, for example.
- Voltage unbalance can also be caused by phase failure, for example due to a tripped 1-phase fuse, a broken conductor, etc.
- Other causes can include faults in the primary system, for example, at the transformer or in installations for reactive-power compensation.

6.40.2 Structure of the Function

The **Overvoltage protection with negative-sequence voltage/positive-sequence voltage** function is used in protection function groups, which are based on voltage measurement.
The **Overvoltage protection with negative-sequence voltage/positive-sequence voltage** function comes factory-set with 2 stages. A maximum of 3 stages can be operated simultaneously in the function. The stages have an identical structure.

[lo_structure_V2_V1, 2, en_US]

Figure 6-548 Structure/Embedding of the Function

6.40.3 General Functionality

6.40.3.1 Description

Logic

The following figure represents the logic of the average-value calculation of the ratio of negative-sequence voltage to positive-sequence voltage. The average value is forwarded to all subordinate stages.

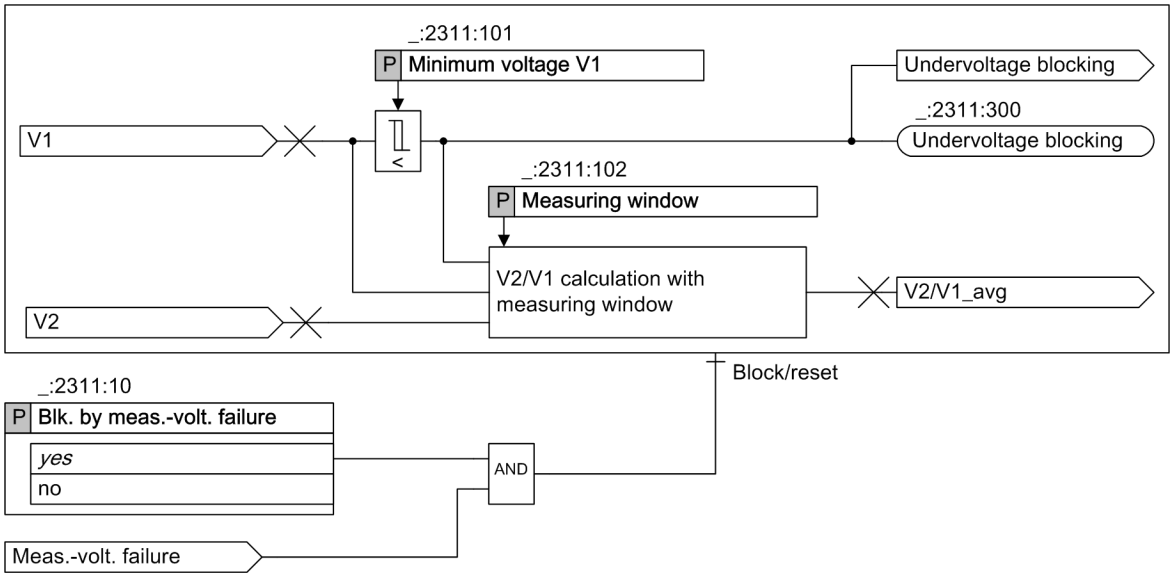


Figure 6-549 Logic Diagram of the General Functionality

Measurand

The average value of the ratio of negative-sequence voltage to positive-sequence voltage is determined by a settable time interval (parameter: **Measuring window**). With the parameter **Measuring window**, you can adapt this function to all power-system conditions.

You can set the parameter **Measuring window** with a large value to get a more accurate calculated result, which leads to a longer pickup time however.

Blocking the Function with Measuring-Voltage Failure Detection

In case of blocking, the picked up function is reset. The following blocking options is available for the function:

- From inside on pick up of the **Measuring-voltage failure detection** function (see section *8.3.2.1 Overview of Functions*).
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker.

The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the function or does not block it.

6.40.3.2 Application and Setting Notes

Parameter: Measuring window

- Default setting **(_:2311:102) Measuring window** = ***1 cycle***

  With the parameter **Measuring window**, you can optimize the measuring accuracy or the pickup time of this function.

  For sensitive settings of the parameter **Threshold**, for example, lower than 10 % of the rated voltage, Siemens recommends using a higher number of cycles. Siemens recommends ***10 cycles***, and in this case, the pickup time is increased.

  For further information, refer to chapter *12.35 Overvoltage Protection with Negative-Sequence Voltage/ Positive-Sequence Voltage* .

Parameter: Blk. by meas.-volt. failure

- Recommended setting value **(_:2311:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the function when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see chapter *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection function is blocked (= default setting). Siemens recommends using the default setting.
no	The protection function is not blocked.

6.40.4 Stage with Negative-Sequence Voltage/Positive-Sequence Voltage

6.40.4.1 Description

Logic of a Stage

[lo_V2_V1_Prov, 2, en_US]

Figure 6-550 Logic Diagram of the Stage: Overvoltage Protection with Negative-Sequence Voltage/Positive-Sequence Voltage

Method of Measurement

The stage uses the average value of the negative-sequence voltage/positive-sequence voltage, which is calculated from the function block **General Functionality**. For more information, refer to chapter *6.40.3.1 Description*.

Blocking the Stage

In case of blocking, the picked up function is reset. The following blocking option is available for the function:

- From an external or internal source via the binary input signal *>Block stage*

6.40.4.2 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:17071:3) Threshold** = *10.00 %*

The parameter **Threshold** is set in percentage according to the definition of the symmetrical compents. It is the ratio of the negative-sequence voltage to positive-sequence voltage.

Specify the **Threshold** (pickup threshold) for the specific application.

In the application with a lower threshold setting of about 2.00 %, there is a risk of an overfunction due to the measuring errors with small values as well as an influence via disturbances.

Parameter: Dropout ratio

- Default setting **(_:17071:4) Dropout ratio** = ***0.95***

The default setting of ***0.95*** is appropriate for most applications if a higher threshold is used.

You can decrease the dropout ratio to avoid chattering of the stage if the threshold value is low. For example, for the stage with a 2 % setting, you can use a dropout ratio of 0.90.

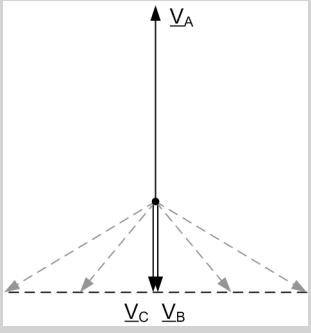
Parameter: Operate delay

- Default setting **(_:17071:6) Operate delay** = ***3.00 s***

Specify the **Operate delay** for the specific application. When using the sensitive setting of the threshold value that is described in this chapter, the function can be delayed by 3.00 s.

For a higher threshold value, a shorter tripping delay is required.

Operation as Supervision Function



If you want the stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

Example 1:

Releasing an overcurrent protection stage for unbalanced faults

The following section describes how to set the function to release an **Overcurrent-protection** stage when unbalanced faults occur. Set the **Overcurrent-protection** stage only slightly higher than the load current, that is very sensitive. To prevent the **Overcurrent-protection** stage from picking up inadvertently, the **Overcurrent-protection** stage is released when the **Negative-sequence voltage** stage picks up. The **Overcurrent-Protection** stage remains blocked as long as the **Negative-sequence voltage** stage has not picked up.

Figure 6-551 shows the voltage phasors during a 2-phase local fault between phases B and C. The phase-to-phase voltage V_{BC} is virtually 0.

[dw_ua_zeig, 1, en_US]

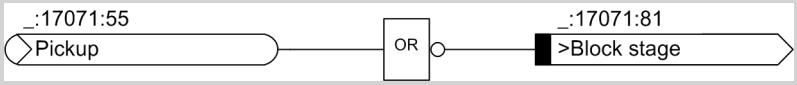


Figure 6-551 Voltage Phasors during a 2-Phase Local Fault

A 2-phase local fault generates a relatively large negative-sequence voltage of up to 100 % referred to the positive-sequence voltage. The portion of the negative-sequence decreases in case of a remote fault. The lower setting limit results from the possible unbalance at full load. If you assume for example 5 % of the negative-sequence voltage to positive-sequence voltage, the pickup value must be higher. A setting value of 10 % warrants sufficient stability during unbalanced operating states and sufficient sensitivity to release the **Overcurrent-protection** stage when a fault occurs.

You can keep the default setting of 0.95 for the dropout ratio. This avoids chattering of the stage.

Set the **Negative-sequence voltage** stage so that it does not generate a fault when it picks up and does not initiate tripping. The **Overcurrent-protection** stage generates a fault indication. The pickup of the **Negative-sequence voltage** stage is used as the release criterion because the **Short-circuit** function must be released immediately when the **Negative-sequence voltage** stage has picked up. The time delay is thus not relevant and can be left at the default setting.

You implement the release of the **Overcurrent-protection** stage using a logic block chart. An inverter links the pickup of the **Negative-sequence voltage** stage with the **Overcurrent-protection** stage blocking.

[lo_pickup V2, 1, en_US]

Figure 6-552 Linking the Pickup of the Negative-Sequence Voltage Stage

Stage	Setting Values		
	Percentage of the Negative-Sequence Voltage to Positive-Sequence Voltage	Time Delay	Dropout Ratio
1	10.00 %	3.00 s	0.95

The second stage is not needed. It is deleted or remains off.

Example 2:

A negative-sequence voltage in the auxiliary system of the power plant causes negative-sequence currents on motors. This leads to a thermal overload of the rotors. The following estimation can be used as a basis: 1 % negative-sequence voltage can lead to approximately 5 % or 6 % negative-sequence current.

A negative-sequence voltage can be caused by a broken conductor on the high-voltage side. If a negative-sequence voltage occurs, this can, for example, initiate a switching of the infeed in order to prevent a protection trip of an unbalanced-load protection of the motors.

Siemens recommends using multiple stages for a better grading, whereby a sensitive setting of the threshold permits an increased tripping delay.

For a reference, only 2 stages are discussed.

The first stage has a pickup threshold of 10 % with a time delay of 1.5 s. The second stage has a pickup threshold of 3 % with a time delay of 8 s, see*Table 6-19*.

Table 6-19 Recommended Settings

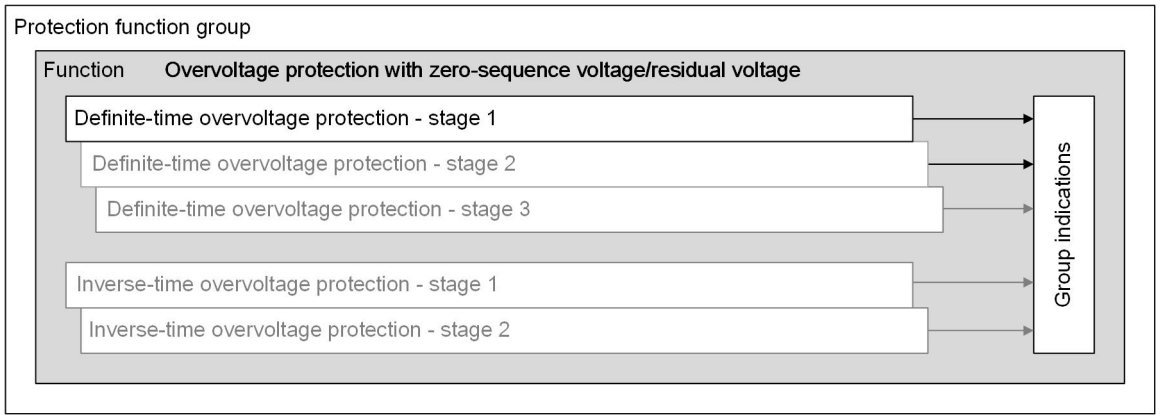
6.41 Overvoltage Protection with Zero-Sequence Voltage/Residual Voltage

6.41.1 Overview of Functions

The function **Overvoltage protection with zero-sequence voltage/residual voltage** (ANSI 59N):

- Detects ground faults in isolated or arc-suppression-coil-grounded systems
- Determines the phase affected by the ground fault
- Works with electrical machines to detect ground faults in the stator winding



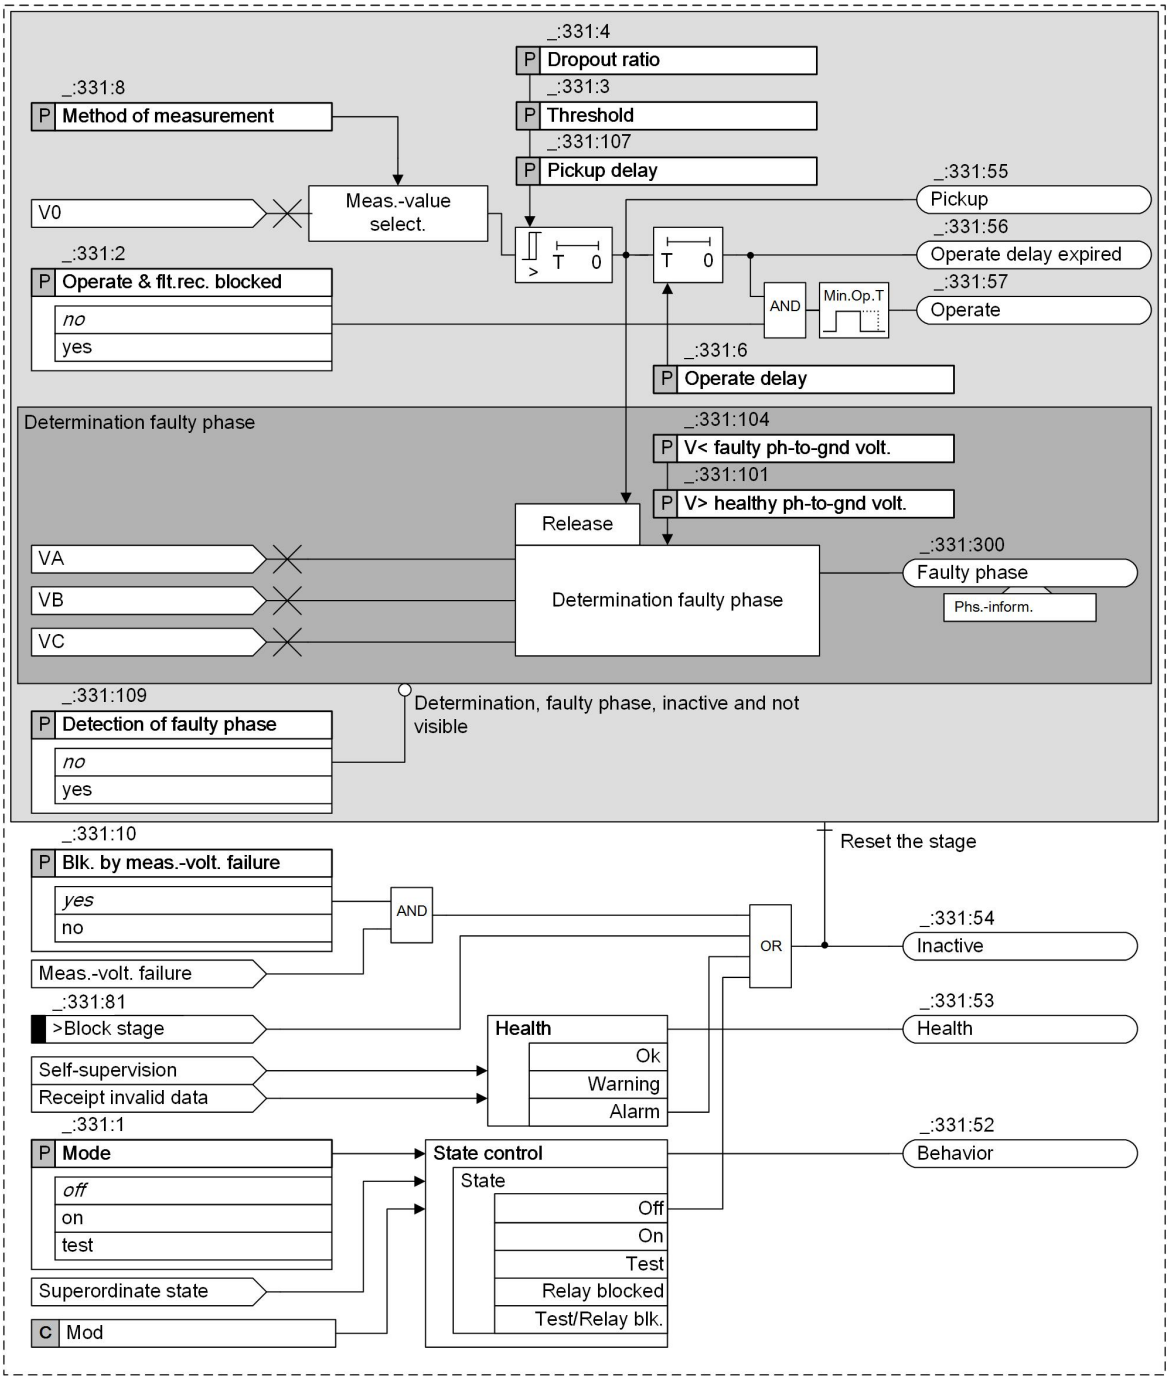
6.41.2 Structure of the Function

The function **Overvoltage protection with zero-sequence voltage/residual voltage** is used in protection function groups with voltage measurement.

The function **Overvoltage protection with zero-sequence voltage/residual voltage** comes factory-set with 1 stage **Definite-time overvoltage protection**. In this function, the following stages can operate simultaneously:

- 3 stages **Definite-time overvoltage protection**
- 2 stages **Inverse-time overvoltage protection**

Stages that are not preconfigured are shown in gray in the following figure.



[dw_u0_ovps, 3, en_US]

Figure 6-553 Structure/Embedding of the Function

6.41.3 Stage with Definite-Time Characteristic Curve

6.41.3.1 Stage Description

Logic of the Stage

[lo_ovp_u_03, 3, en_US]

Figure 6-554 Logic Diagram of the Definite-Time Overvoltage Protection with Zero-Sequence Voltage/ Residual Voltage

Measured Value, Method of Measurement

The device measures the residual voltage at the broken-delta winding. The measured voltage is converted to the zero-sequence voltage V_0. If the residual voltage is not available to the device as a measurand, the zero-sequence voltage V_0 is calculated from the measured phase-to-ground voltages V_A, V_B, and V_C using the defining equation.

With the parameter **Method of measurement**, you select the relevant method of measurement, depending on the application:

- ***fundamental comp.*** (standard filter):
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- ***RMS value*** (true RMS):
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value.
- ***fund. comp. long filter*** (fundamental component over 2 cycle filters with triangular window):
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically. The extended filter length compared to the standard filter and the use of the triangular window results in a particularly strong attenuation of harmonics and transient faults. The extended filter length causes the pickup time to increase slightly compared to the standard filter (refer to the technical data in *12.36 Overvoltage Protection with Zero-Sequence Voltage/Residual Voltage*).

Pickup, Dropout

The stage compares the **Threshold** with the zero-sequence voltage V_0. The parameter **Pickup delay** allows you to delay the pickup of the stage depending on the residual voltage.

With the parameter **Dropout ratio**, you can define the ratio of the dropout value to the **Threshold**.

Determination of the Faulty Phase

You can use the parameter **Detection of faulty phase** to enable or disable the determination of the phase affected by the ground fault. Determining is released when the stage picks up. If 2 phases exceed the threshold value **V> healthy ph-to-gnd volt.** and 1 phase falls below the threshold value **V< faulty ph-to-gnd volt.**, the last phase is considered to be affected by the ground fault and is signaled as such.

Blocking the Stage

In the event of blocking, the picked up stage is reset. The following blocking options are available for the stage:

- Via the binary input signal **>Block stage** from an external or internal source
- From inside on pickup of the function **Measuring-voltage failure detection** (refer to *8.3.2.1 Overview of Functions*). The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the stage or does not block it.
- From an external source via the binary input signal **>Open** of the function block **Voltage-transformer circuit breaker**, which links in the tripping of the voltage-transformer circuit breaker. The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the stage or does not block it.

6.41.3.2 Application and Setting Notes

Parameter: Method of measurement

- Default setting **(_:331:8) Method of measurement** = ***fundamental comp.***

With the parameter **Method of measurement**, you define whether the function works with the fundamental component or the calculated RMS value.

Parameter Value	Description
fundamental comp.	This method of measurement suppresses the harmonics or transient voltage peaks. Siemens recommends using this setting as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Do not set the **threshold value** of the tripping stage under 10 V for this method of measurement.
fund. comp. long filter	To implement a particularly strong attenuation of harmonics and transient faults, select this method of measurement. With this method, the length of the filter is longer than that of the standard filter. Note: In this case, the pickup time of the stage increases slightly (refer to the technical data in *12.36 Overvoltage Protection with Zero-Sequence Voltage/Residual Voltage*).

Parameter: Pickup delay

- Recommended setting value **(_:331:107) Pickup delay** = ***0.00 ms***

The **Pickup delay** parameter allows you to delay the analysis of the measurand (to generate the pickup) depending on the occurrence of the residual voltage. A pickup delay can be necessary if high transients are anticipated after fault inception due to high line and ground capacitances.

Siemens recommends using the default setting **Pickup delay** = ***0.00 ms***.

Parameter: Threshold

- Default setting **(_:331:3) Threshold** = ***30.000 V***[51]

The threshold value of the function is set as the zero-sequence voltage V0. The device calculates the zero-sequence voltage V0 either from the residual voltage measured via the broken-delta winding or from the 3 phase-to-ground voltages.

The setting value depends on the system grounding:

- Since virtually the full residual voltage occurs during ground faults in isolated or arc-suppression-coil-grounded systems, the setting value is uncritical there. It should range between 20 V and 40 V. A higher sensitivity (= lower threshold value) can be necessary for high fault resistances.
- You should select a more sensitive (smaller) value in a grounded system. This value must be higher than the maximum residual voltage anticipated during operation caused by system unbalances.

EXAMPLE

For an isolated system

The residual voltage is measured via the broken-delta winding:

- If the ground fault is fully unbalanced, a residual voltage of 100 V is present at the device terminals.
- The threshold value should be set so that the stage picks up on 50 % of the full residual voltage.
- At full residual voltage, the zero-sequence voltage is 100 V/$\sqrt{3}$ = 57.7 V
  Setting value: 0.5 · 57.7 V = 28.9 V ≈ 30 V

Parameter: Dropout ratio

- Recommended setting value **(_:331:4) Dropout ratio** = ***0.95***

The recommended set value of ***0.95*** is appropriate for most applications. The dropout ratio can be reduced for example, to 0.98 to achieve a high measurement precision.

51 The specific setting limits depend on the transformer data and transformer connections set.

Parameter: Operate delay

- Default setting **(_:331:6) Operate delay** = ***3.00 s***

The **Operate delay** allows you to prevent transient residual voltages from initiating a trip. The setting depends on the specific application.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:331:10) Blk. by meas.-volt. failure** = ***yes***

With the parameter **Blk. by meas.-volt. failure**, you control the behavior of the stage when a measuring-voltage failure is detected.
A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker (refer to *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

Parameter: Detection of faulty phase

- Default setting **(_:331:109) Detection of faulty phase** = ***no***

With the parameter **Detection of faulty phase**, you control how the stage responds to determine which phase is affected by the ground fault.

Parameter Value	Description
no	The phase affected by the ground fault is not determined. Select the default setting if you do not want to use the stage to detect ground faults, for example, for applications in grounded systems.
yes	After a pickup by the residual voltage, the device tries to determine which phase is affected by the ground fault. Select this setting for applications in isolated or arc-suppression-coil-grounded systems.

Parameter: V< faulty ph-to-gnd volt.

- Default setting **(_:331:104) V< faulty ph-to-gnd volt.** = ***40.000 V***[52]

With the parameter **V< faulty ph-to-gnd volt.**, you set the threshold value for determining which phase is affected by the ground fault. The setting value is a phase-to-ground quantity.
The setting value must be smaller than the minimum phase-to-ground voltage occurring during operation. Siemens recommends using the default setting of ***40.000 V***.

Parameter: V> healthy ph-to-gnd volt.

- Default setting **(_:331:101) V> healthy ph-to-gnd volt.** = ***75.000 V***[52]

With the parameter **V> healthy ph-to-gnd volt.**, you set the threshold value for the 2 healthy phases. The setting value is a phase-to-ground quantity.
The setting value must be greater than the maximum phase-to-ground voltage occurring during operation, but smaller than the minimum phase-to-phase voltage occurring during operation. At V_{rated} = 100 V, set the value, for example, to ***75.000 V***. Siemens recommends using the default setting of ***75.000 V***.

52 The specific setting limits depend on the transformer data and transformer connections set.

Operation as Supervision Function

If you want the stage to have a reporting effect only, you can set the parameter **Operate & flt.rec. blocked** to disable the generation of the operate indication and fault logging.

6.41.4 Stage with Inverse-Time Characteristic Curve

6.41.4.1 Description

Logic of the Stage

[lo_ovp_V0_3pole_inverse, 1, en_US]

Figure 6-555 Logic Diagram of the Inverse-Time Overvoltage Protection with Zero-Sequence Voltage/ Residual Voltage

Measured Value, Method of Measurement

The device measures the residual voltage at the broken-delta winding. The measured voltage is converted to the zero-sequence voltage V_0. If the residual voltage is not available to the device as a measurand, the

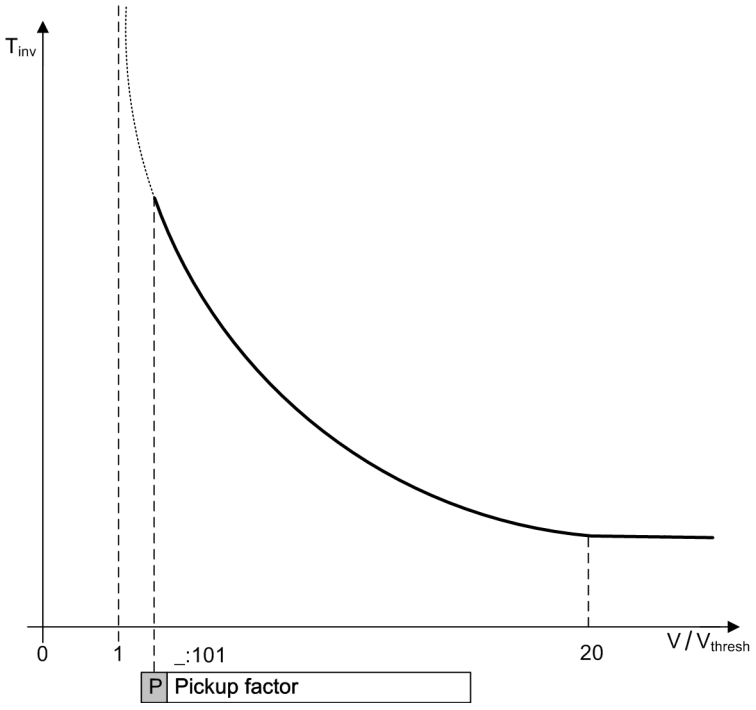
zero-sequence voltage V_0 is calculated from the measured phase-to-ground voltages V_A, V_B, and V_C using the defining equation.

With the parameter **Method of measurement**, you select the relevant method of measurement, depending on the application:

- ***fundamental comp.*** (standard filter):
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- ***RMS value*** (true RMS):
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value.
- ***fund. comp. long filter*** (fundamental component over 2 cycle filters with triangular window):
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically. The extended filter length compared to the standard filter and the use of the triangular window results in a particularly strong attenuation of harmonics and transient faults. The extended filter length causes the pickup time to increase slightly compared to the standard filter (refer to the technical data in *12.36 Overvoltage Protection with Zero-Sequence Voltage/Residual Voltage*).

Pickup and Operate Curve

When the input voltage exceeds the threshold value by a settable value **Pickup factor**, the stage picks up and the inverse-time characteristic curve is processed. The operate delay starts. The operate delay is the sum of the inverse-time delay and the additional time delay.



$$T_{op} = T_{inv} + T_{add}$$

Where

T_{op}	Operate delay
T_{inv}	Inverse-time delay
T_{add}	Additional time delay (parameter **Additional time delay**)

After pickup, the inverse-time delay T_{inv} is calculated for every input voltage that exceeds the threshold. An integrator accumulates the value $1/T_{inv}$. Once the accumulated integral reaches the fixed value 1, the inverse-time delay expires. The additional time delay T_{add} starts. The stage operates after the additional time delay expires.

The inverse-time characteristic curve is shown in the following figure.

[dw_ovp_inv, 2, en_US]

Figure 6-556 Operate Curve of Inverse-Time Characteristic Curve

The inverse-time delay is calculated with the following formula:

$$T_{inv} = T_p \left(\frac{k}{\left(\frac{V}{V_{thresh}} \right)^{\alpha} - 1} + c \right) [s]$$

Where

T_{inv}	Inverse-time delay
T_p	Time multiplier (parameter **Time dial**)
V	Zero-sequence voltage
V_{thresh}	Threshold value (parameter **Threshold**)
k	Curve constant k (parameter **Charact. constant k**)
α	Curve constant α (parameter **Charact. constant α**)
c	Curve constant c (parameter **Charact. constant c**)

When V/V_{thresh} is equal to or greater than 20, the inverse-time delay does not decrease any further.

Dropout Behavior

When the voltage falls below the dropout threshold (0.95 · pickup factor · threshold value), the dropout is initiated. You can define the dropout behavior via the parameter **Reset time**. An instantaneous reset takes place by setting **Reset time** to 0 s. A delayed reset takes place by setting the desired time delay.

During the **Reset time** (> 0 s), the elapsed operate delay is frozen. If the pickup value is exceeded again within this period, the stage operates when the rest of the operate delay expires.

Determination of the Faulty Phase

You can use the parameter **Detection of faulty phase** to enable or disable the determination of the phase affected by the ground fault. Determining is released when the stage picks up. If 2 phases exceed the

threshold value **V> healthy ph-to-gnd volt.** and 1 phase falls below the threshold value **V< faulty ph-to-gnd volt.**, the last phase is considered to be affected by the ground fault and is signaled as such.

Blocking the Stage

In the event of blocking, the picked up stage is reset. The following blocking options are available for the stage:

- Via the binary input signal **>Block stage** from an external or internal source
- From inside on pickup of the function **Measuring-voltage failure detection** (refer to *8.3.2.1 Overview of Functions*). The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the stage or does not block it.
- From an external source via the binary input signal **>Open** of the function block **Voltage-transformer circuit breaker**, which links in the tripping of the voltage-transformer circuit breaker. The parameter **Blk. by meas.-volt. failure** can be set so that the measuring-voltage failure detection blocks the stage or does not block it.

6.41.4.2 Application and Setting Notes

Parameter: Method of measurement

- Default setting **(_:8) Method of measurement** = ***fundamental comp.***

With the parameter **Method of measurement**, you define whether the function works with the fundamental component or the calculated RMS value.

Parameter Value	Description
fundamental comp.	This method of measurement suppresses the harmonics or transient voltage peaks. Siemens recommends using this setting as the standard method.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Do not set the **threshold value** of the tripping stage under 10 V for this method of measurement.
fund. comp. long filter	To implement a particularly strong attenuation of harmonics and transient faults, select this method of measurement. With this method, the length of the filter is longer than that of the standard filter. Note: In this case, the pickup time of the stage increases slightly (refer to the technical data in *12.36 Overvoltage Protection with Zero-Sequence Voltage/Residual Voltage*).

Parameter: Threshold, Pickup factor

- Default setting **(_:3) Threshold** = ***30.000 V***
- Default setting **(_:101) Pickup factor** = ***1.10***

The stage picks up when the measured voltage value exceeds the pickup value **Threshold** · **Pickup factor**.

With the parameter **Pickup factor**, you modify the pickup value. To avoid a long-time operate delay after pickup when the measured value is slightly over the threshold, Siemens recommends using the default setting.

Specify the **Threshold** (pickup threshold) and **Pickup factor** for the specific application.

Parameter: Charact. constant k, Charact. constant α, Charact. constant c

- Default setting **(_:102) Charact. constant k** = ***1.00***
- Default setting **(_:103) Charact. constant α** = ***1.000***
- Default setting **(_:104) Charact. constant c** = ***0.000***

With the parameters **Charact. constant k**, **Charact. constant α**, and **Charact. constant c**, you define the required inverse-time characteristic curve.

Parameter: Time dial

- Default setting **(_:105) Time dial** = ***1.00***

With the parameter **Time dial**, you displace the characteristic curve in the time direction.

As usually, there is no time grading for voltage protection and therefore no displacement of the characteristic curve, Siemens recommends leaving the parameter **Time dial** at ***1.00*** (default setting).

Parameter: Additional time delay

- Default setting **(_:106) Additional time delay** = ***0.00 s***

With the parameter **Additional time delay**, you define a definite-time delay in addition to the inverse-time delay.

If you keep the default setting of ***0.00 s***, only the inverse-time delay is operative.

Parameter: Reset time

- Default setting **(_:107) Reset time** = ***0.00 s***

With the parameter **Reset time**, you define the reset time delay which is started when the voltage falls below the dropout threshold. Set the parameter **Reset time** to ***0.00 s*** when an instantaneous reset is desired.

Under network conditions of intermittent faults or faults which occur in fast succession, Siemens recommends setting the **Reset time** to an appropriate value (> ***0.00 s***) to ensure the operation. Otherwise, Siemens recommends keeping the default value to ensure a fast reset of the function.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:10) Blk. by meas.-volt. failure** = ***yes***

With the parameter **Blk. by meas.-volt. failure**, you control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker (refer to *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

Parameter: Detection of faulty phase

- Default setting **(_:109) Detection of faulty phase** = ***no***

With the parameter **Detection of faulty phase**, you control how the stage responds to determine which phase is affected by the ground fault.

Parameter Value	Description
no	The phase affected by the ground fault is not determined. Select the default setting if you do not want to use the stage to detect ground faults, for example, for applications in grounded systems.
yes	After a pickup by the residual voltage, the device tries to determine which phase is affected by the ground fault. Select this setting for applications in isolated or arc-suppression-coil-grounded systems.

Parameter: V< faulty ph-to-gnd volt.

- Default setting **(_:6) V< faulty ph-to-gnd volt.** = ***40.000 V***[53]

With the parameter **V< faulty ph-to-gnd volt.**, you set the threshold value for determining which phase is affected by the ground fault. The setting value is a phase-to-ground quantity.
The setting value must be smaller than the minimum phase-to-ground voltage occurring during operation. Siemens recommends using the default setting of ***40.000 V***.

Parameter: V> healthy ph-to-gnd volt.

- Default setting **(_:5) V> healthy ph-to-gnd volt.** = ***75.000 V***[53]

With the parameter **V> healthy ph-to-gnd volt.**, you set the threshold value for the 2 healthy phases. The setting value is a phase-to-ground quantity.
The setting value must be greater than the maximum phase-to-ground voltage occurring during operation, but smaller than the minimum phase-to-phase voltage occurring during operation. At V_{rated} = 100 V, set the value, for example, to ***75.000 V***. Siemens recommends using the default setting of ***75.000 V***.

Operation as Supervision Function

If you want the stage to have a reporting effect only, you can set the parameter **Operate & flt.rec. blocked** to disable the generation of the operate indication and fault logging.

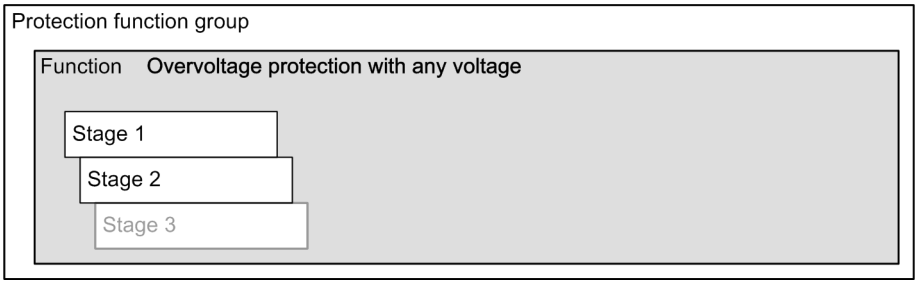
6.42 Overvoltage Protection with Any Voltage



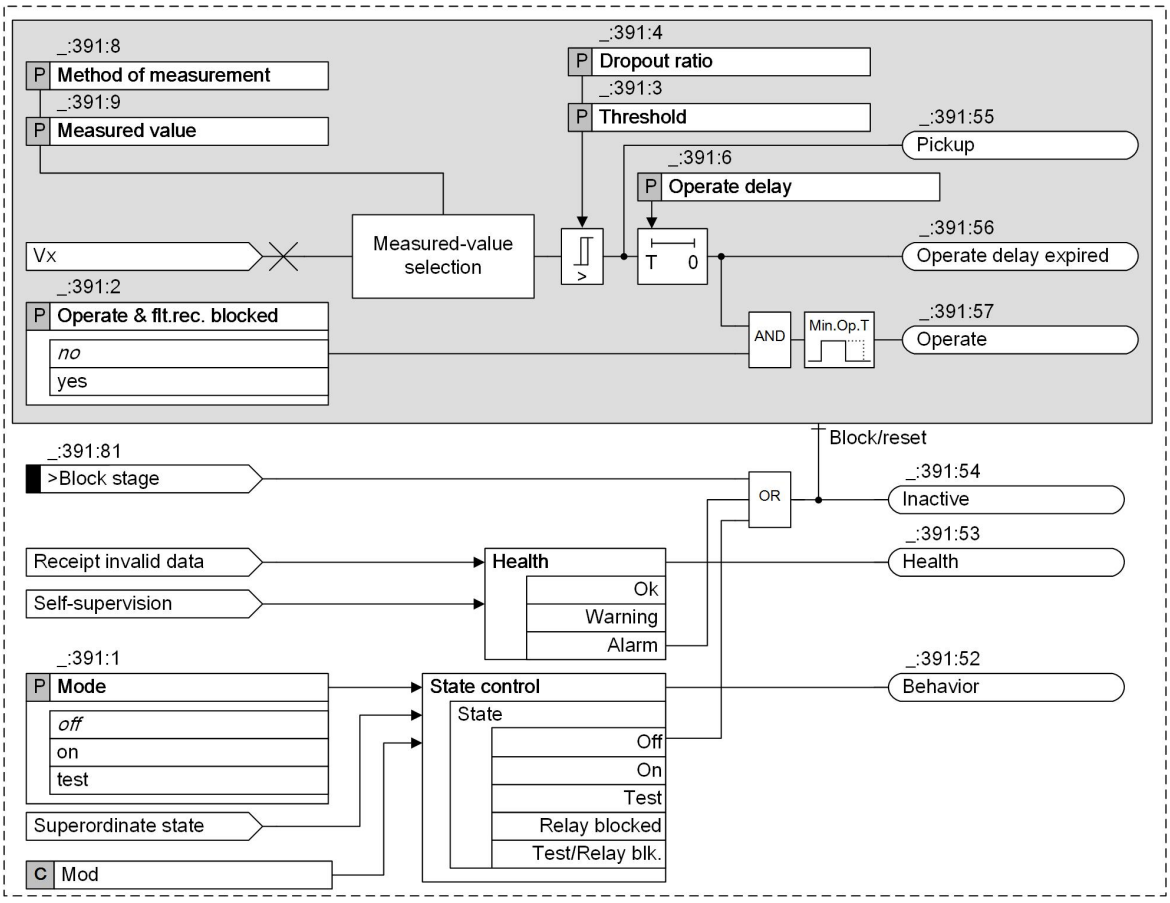
6.42.1 Overview of Functions

The function **Overvoltage protection with any voltage** (ANSI 59) detects any 1-phase overvoltages and is intended for special applications.

6.42.2 Structure of the Function

The **Overvoltage protection with any voltage** function is used in protection function groups, which are based on voltage measurement.

The function **Overvoltage protection with any voltage** comes factory-set with 2 stages. A maximum of 3 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.



[dw_ovp_uxs, 1, en_US]

Figure 6-557 Structure/Embedding of the Function

6.42.3 Stage Description

Logic of a Stage

[lo_ovp_Vx_any-volt, 2, en_US]

Figure 6-558 Logic Diagram of a Stage: Overvoltage Protection with Any Voltage

NOTE

If the function **Overvoltage protection with any voltage** is used in a 1-phase function group, the parameter **`Measured value`** is not visible.

Method of Measurement

The **`Method of measurement`** parameter allows you to define whether the function works with the fundamental component or the calculated RMS value.

- Measurement of the ***`fundamental comp.`***:
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- Measurement of the parameter value ***`RMS value`***:
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Measured Value

The parameter **`Measured value`** allows you to select whether the stage uses a measured (directly connected) voltage or a calculated phase-to-phase voltage.

If the function **Overvoltage protection with any voltage** is used in a 1-phase function group, the parameter **Measured value** is not visible.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking is possible externally or internally via the binary input signal *>Block stage*.

6.42.4 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:391:8) Method of measurement** = ***fundamental comp.***

Use the **Method of measurement** parameter to define whether the tripping stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends this method of measurement as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example at capacitor banks). Do not set the **threshold value** of the tripping stage under 10 V for this method of measurement.

Parameter: Measured value

- Default setting **(_:391:9) Measured value** = ***VA measured***

The **Measured value** parameter is used to specify which voltage is monitored by the stage.

The scope of setting options depends on the connection type for the voltage transformers and the routing of the measured values to the terminals of the voltage measuring point. You can find connection examples for voltage transformers in the *Appendix*.

The following setting options can be available:

- Measured phase-to-ground voltage V_A (***VA measured***)
- Measured phase-to-ground voltage V_B (***VB measured***)
- Measured phase-to-ground voltage V_C (***VC measured***)
- Measured phase-to-phase voltage V_{AB} (***VAB measured***)
- Measured phase-to-phase voltage V_{BC} (***VBC measured***)
- Measured phase-to-phase voltage V_{CA} (***VCA measured***)
- Calculated phase-to-phase voltage V_{AB} (***VAB calculated***)
- Calculated phase-to-phase voltage V_{BC} (***VBC calculated***)
- Calculated phase-to-phase voltage V_{CA} (***VCA calculated***)
- Calculated voltage V0 (***V0 calculated***)

The selection depends on the corresponding application.

NOTE

From V7.30 on, the value ***VN measured*** is no longer provided. If you have selected this value in earlier versions, you can use either the following methods instead after upgrading the configuration to V7.30 or a later version:

- Select the value ***V0 calculated*** for the **Measured value** parameter in the function **Overvoltage protection with any voltage**.
- Use the function **Overvoltage protection with zero-sequence voltage/residual voltage**.

If the function **Overvoltage protection with any voltage** is used in a 1-phase function group, the parameter **Measured value** is not visible.

Parameter: Threshold

- Default setting **(_:391:3) Threshold** = ***110 V***

Specify the **Threshold** (pickup threshold) for the specific application.

Depending on the measured value, the **Threshold** is set either as **Measured voltage** or as **Phase-to-phase** quantity.

NOTE

If the function is used in a **Voltage-current 1-phase** function group connected to the 1-phase voltage measuring point with the voltage type ***VN broken-delta***, you set the threshold value based on the equivalent zero-sequence voltage.

Calculate the equivalent zero-sequence voltage $V_{0\ equiv.\ sec}$ from the measured voltage $V_{N\ sec}$ with the following formula:

$$\frac{V_{0\ equi\ sec}}{V_{N\ sec}} = \frac{\text{Matching ratio Vph/VN}}{3}$$

For more information about the parameter **Matching ratio Vph / VN**, refer to *6.1.4 Application and Setting Notes for Measuring-Point Voltage 3-Phase (V-3ph)*.

Parameter: Operate delay

- Default setting **(_:391:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:391:4) Dropout ratio** = ***0.95***

The recommended set value of ***0.95*** is appropriate for most applications. To achieve high measurement precision, the **Dropout ratio** can be reduced, to 0.98, for example.

Operation as Supervision Function

If you want the tripping stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

6.42.5 Settings

Addr.	Parameter	C	Setting Options	Default Setting
Stage 1				
_:391:1	Stage 1:Mode		• off • on • test	off

6.43 Undervoltage Protection with 3-Phase Voltage

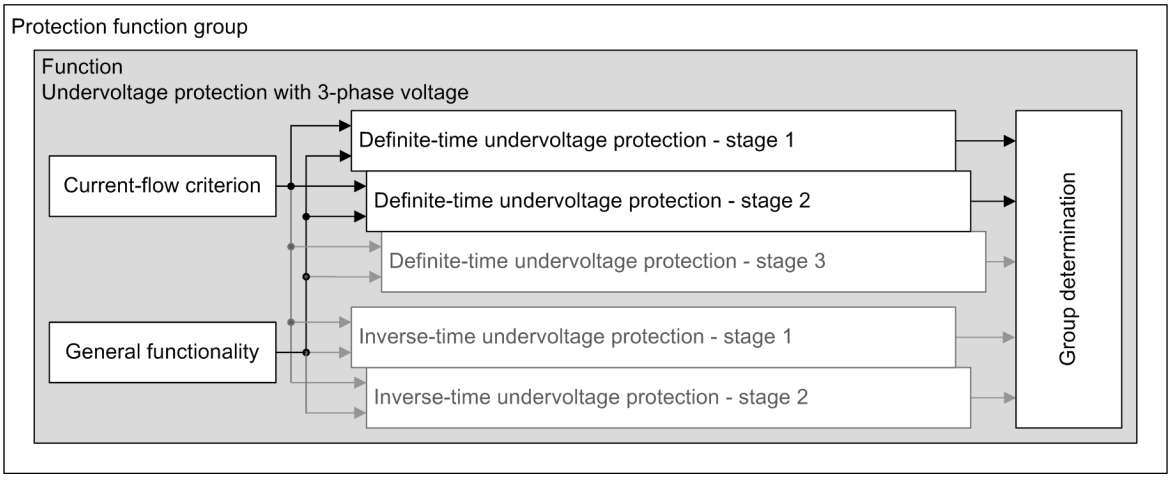
6.43.1 Overview of Functions

The function **Undervoltage protection with 3-phase voltage** (ANSI 27):

- Monitors the permissible voltage range
- Protects equipment (for example, plant components and machines) against damages caused by undervoltage
- Handles disconnection or load shedding tasks in a system

6.43.2 Structure of the Function

The function **Undervoltage protection with 3-phase voltage** is used in protection function groups with voltage measurement.



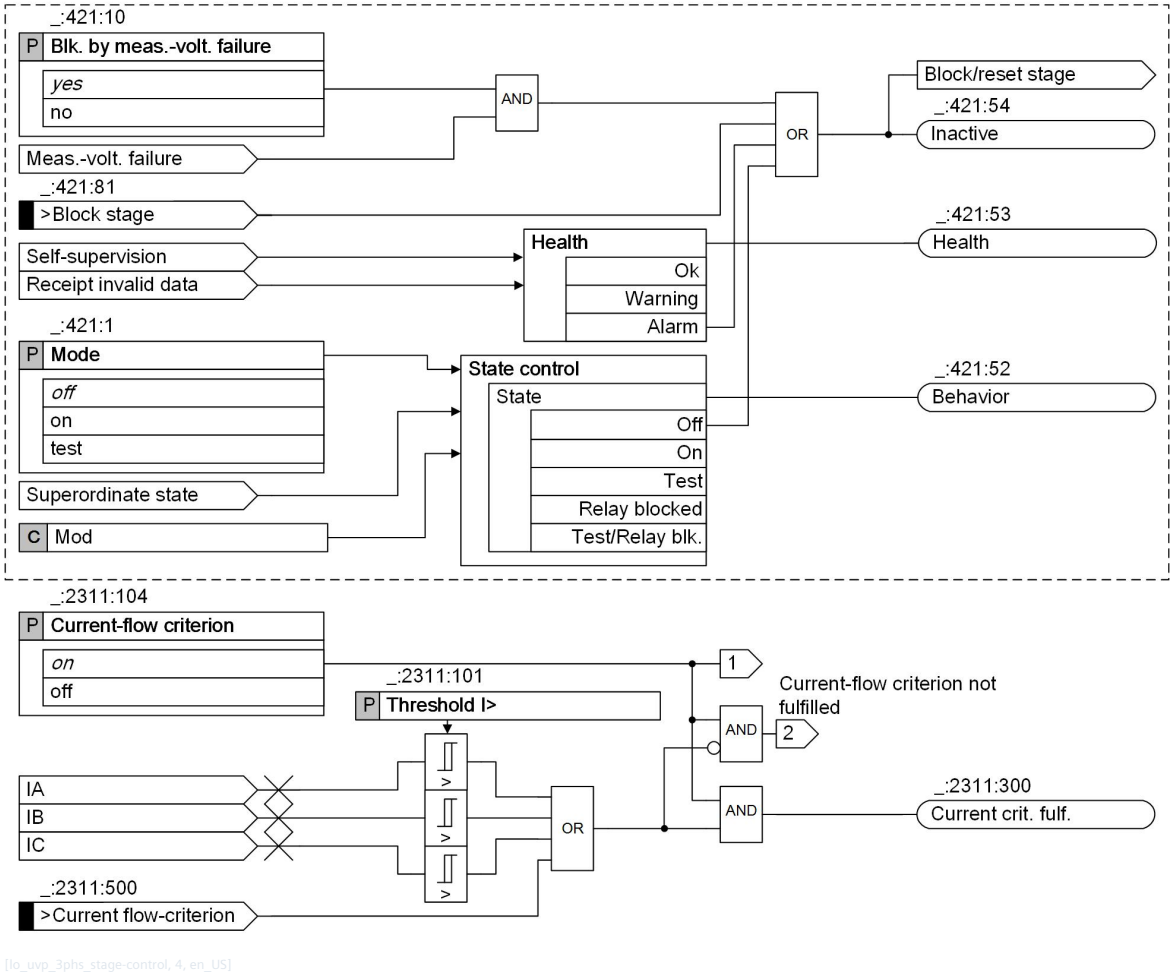
The function **Undervoltage protection with 3-phase voltage** comes factory-set with 2 **Definite-time undervoltage protection** stages.

In the function **Undervoltage protection with 3-phase voltage**, the following stages can be operated simultaneously:

- 3 stages **Definite-time undervoltage protection**
- 2 stages **Inverse-time undervoltage protection**

Stages that are not preconfigured are shown in gray in the following figure.

The protection function is structured such that one current-flow criterion can act on all undervoltage protection stages (see *Figure 6-559*). If the protection function group used has no current measurement, you can only set the current-flow criterion as **fulfilled** via the corresponding binary input signal.



[dw_stru_3p, 5, en_US]

Figure 6-560 Logic Diagram Stage Control

[lo_uvp_3ph, 3, en_US]

Figure 6-561 Logic Diagram of the Definite-Time Undervoltage Protection with 3-Phase Voltage

Method of Measurement

With the **Method of measurement** parameter, you select the relevant method of measurement, depending on the application.

- Measurement fundamental component:
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- Measurement RMS value:
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Measured Value

With the **Measured value** parameter, you define whether the stage analyzes the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C.

If the measured value is set to phase-to-phase, the function reports those measuring elements that have picked up.

Pickup Stabilization

To enable the pickup stabilization, you set the **Stabilization counter** parameter to a value other than 0. Then, if the input voltage keeps being below the **Threshold** for a specified number (1 + **Stabilization**

counter value) of successive measuring cycles, the stage picks up. For 50 Hz, the measuring cycle time is 10 ms.

If you set this parameter to ***0*** (default value), the stabilization is not applied. The pickup signal is issued after the input voltage falls below the threshold value.

Pickup Mode

With the **Pickup mode** parameter, you define whether the stage picks up when there is a lower threshold-value violation in one measuring element (***1 out of 3***) or when there is a lower threshold-value violation in all 3 measuring elements (***3 out of 3***).

Pickup Delay

The **Pickup delay** parameter is only available and of relevance if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***).

If the circuit breaker opens when the current-flow criterion is being used, the undervoltage detection and current-flow dropout functions conflict with one another. Depending on the threshold value settings for undervoltage detection and current-flow criterion, it is possible that the undervoltage is detected before the current-flow criterion has dropped out. In this case, the stage picks up briefly. Use the **Pickup delay** parameter to prevent the stage from briefly picking up in this way when the circuit breaker opens. This is achieved by delaying the pickup by approximately 40 ms.

Current-Flow Criterion

The undervoltage protection stages work optionally with a current-flow criterion. The **Current-flow criterion** works across all tripping stages.

When the **Current-flow criterion** parameter is activated, the undervoltage protection stages only pick up if a settable minimum current (**Threshold I>**) is exceeded. A current below the minimum current blocks the stages.

The current-flow criterion can also be set to **fulfilled** with the binary input signal **>Current flow-criterion**. The function reports when the current-flow criterion is fulfilled.

Figure 6-561 illustrates the influence of the current-flow criterion.

NOTE

If the **(_:2311:104) Current-flow criterion** parameter is deactivated, the device picks up immediately if a missing measuring voltage is detected while the undervoltage protection is active. The parameter setting can be changed even when the device has picked up.

Blocking the Stage

In the event of blocking, the picked-up stage will be reset. The following blocking options are available for the stage:

- Via the binary input signal *>Block stage* from an external or internal source
- From inside on pickup of the **Measuring-voltage failure detection** function (see *8.3.2.1 Overview of Functions*). The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker. The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

6.43.3.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:421:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends using this parameter value as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example at capacitor banks). Do not set the **threshold value** of the stage under 10 V for this method of measurement.

Parameter: Measured value

- Recommended setting value **(_:421:9) Measured value** = ***phase-to-phase***

With the **Measured value** parameter, you define whether the stage monitors the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C. Parameter Value

Parameter Value	Description
phase-to-phase	If you want to detect voltage dips caused by multiphase short circuits, or generally monitor the voltage range, keep phase-to-phase as the default setting. The function will not pick up on ground faults. Siemens recommends the measured value ***phase-to-phase*** as the default setting.
phase-to-ground	Select the ***phase-to-ground*** setting if you want to detect voltage unbalances or overvoltage conditions caused by ground faults.

Parameter: Threshold

- Default setting **(_:421:3) Threshold** = ***80 V***

The **Threshold** is set in accordance with the **Measured value** as either a ***phase-to-phase*** or ***phase-to-ground*** variable.

Specify the **Threshold** (pickup threshold) for the specific application.

For the default setting, the lower limit of the voltage range to be monitored is assumed to be 80 % of the rated voltage of the protected object.

EXAMPLE:

Rated voltage of the protected object: $V_{rated,\ obj.} = 10\ kV$

Voltage transformer:

$$Ratio_V = \frac{10\ kV/\sqrt{3}}{100\ V/\sqrt{3}}$$

Threshold value: 80 % of $V_{rated,\ obj.}$

The secondary setting value is calculated as follows:

$$V_{Threshold\ value,\ sec} = \frac{0.8 \cdot V_{rated,obj.}}{Ratio_V} = \frac{0.8 \cdot 10\ kV \cdot 100\ V}{10\ kV} = 80\ V$$

[fo_schw_lw, 2, en_US]

Parameter: Stabilization counter

- Default setting **(_:2311:103) Stabilization counter** = ***0***

You can configure the **Stabilization counter** parameter in the function block **General**.

For special applications, it could be desirable that a short falling of the input voltage below the pickup value does not lead to the pickup of the stage, which starts fault logging and recording. This is achieved by setting the **Stabilization counter** parameter to a value other than zero.

For example, if you set this parameter to ***1***, the pickup signal is issued when the voltage keeps being below the **Threshold** for 2 successive measuring cycles. For 50 Hz, the measuring cycle time is 10 ms.

Parameter: Pickup mode

- Recommended setting value **(_:421:101) Pickup mode** = ***1 out of 3***

With the **Pickup mode** parameter, you specify whether the stage picks up when there is a lower threshold-value violation in one measuring element (***1 out of 3***) or when there is a lower threshold-value violation in all 3 measuring elements (***3 out of 3***).

Parameter Value	Description
1 out of 3	Use this setting for protection applications or for monitoring the voltage range. Siemens recommends ***1 out of 3*** as the default setting. This reflects how the function behaved in previous generations (SIPROTEC 4, SIPROTEC 3).
3 out of 3	Select this setting when using the stage to disconnect from the power system (in the case of wind farms, for example).

Parameter: Pickup delay

- Default setting **(_:421:102) Pickup delay** = ***no***

The **Pickup delay** parameter is only available if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***). If the current-flow criterion is deactivated, no pickup delay is required.

With the **Pickup delay** parameter, you set whether pickup of the stage is to be delayed by approximately 40 ms or not. The delay avoids possible brief pickup of the stage when the circuit breaker opens.

When applied in parallel, the pickup delay and the delay through pickup stabilization add up.

Parameter Value	Description
no	Use this setting if you definitely do not want stage pickup to be subject to a time delay in the event of a fault. This setting results in pickup and, where applicable, tripping being performed as quickly as possible. Note that switching procedures (opening of the CB) can result in brief pickup of the stage, depending on the threshold-value settings for under-voltage pickup and the current-flow criterion. To prevent unwanted trip-ping, you must set a minimum tripping delay of 50 ms.
yes	Use this setting when switching procedures (opening of the CB) are not permitted to result in stage pickup. Note that pickup is delayed by approximately 40 ms. This delay is added to the operate time.

Parameter: Operate delay

- Default **(_:421:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:421:4) Dropout ratio** = ***1.05***

The recommended setting value of ***1.05*** is appropriate for most applications. To achieve high-precision measurements, the **Dropout ratio** can be reduced (to 1.02, for example).

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:421:10) Blk. by meas.-volt. failure** = ***yes***

With the **Blk. by meas.-volt. failure** parameter, you control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following two conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

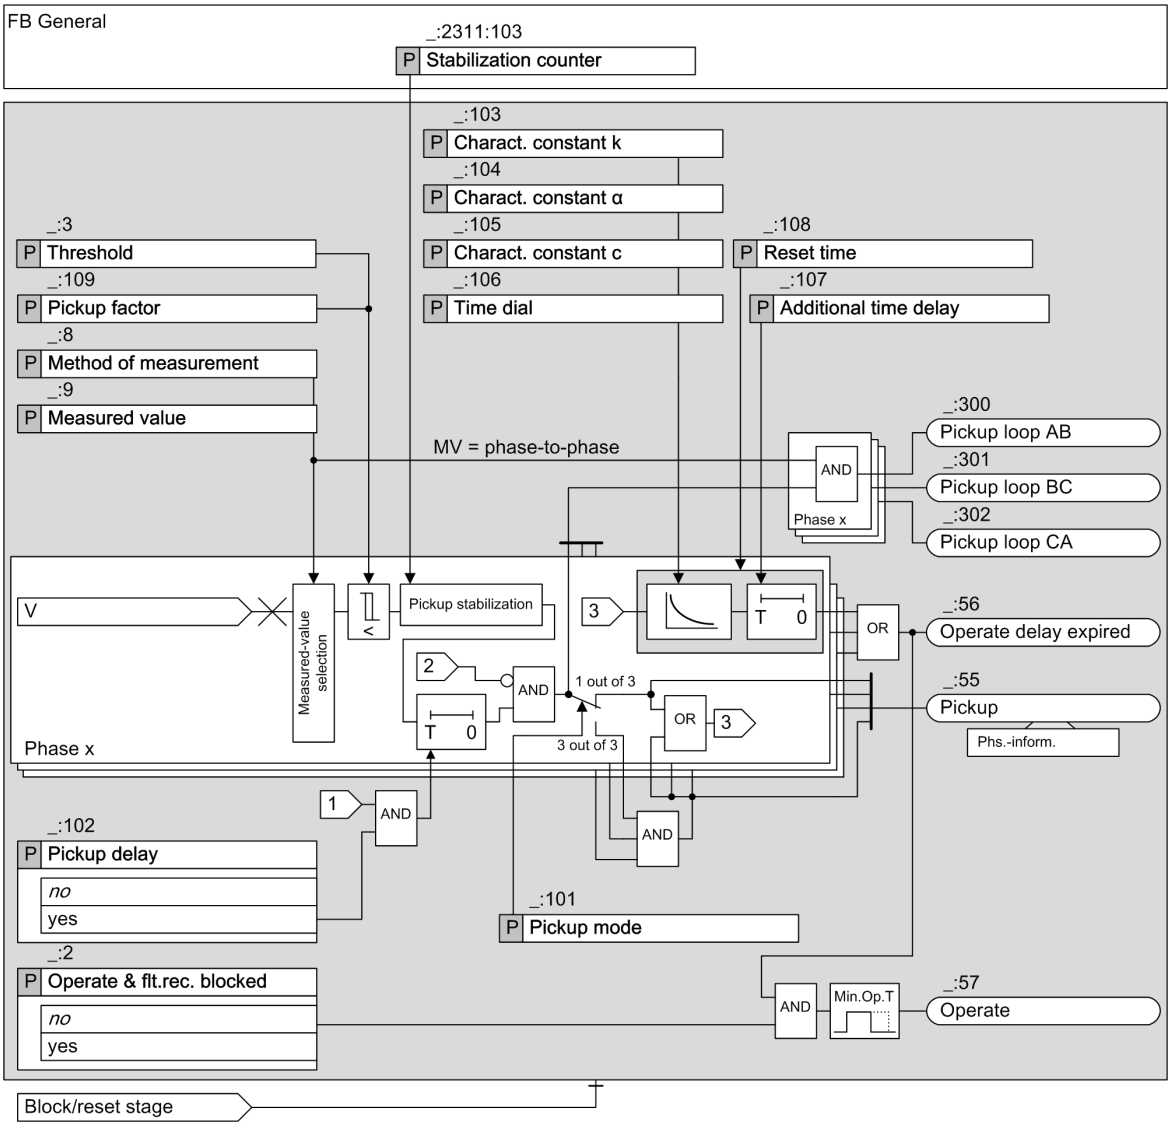
6.43.4 Stage with Inverse-Time Characteristic Curve



6.43.4.1 Description

Logic of the Stage

[lo_UVP3ph_in_stage control, 4, en_US]

Figure 6-562 Logic Diagram of the Stage Control

[lo_UVP3ph_In, 5, en_US]

Figure 6-563 Logic Diagram of the Inverse-Time Undervoltage Protection with 3-Phase Voltage

Method of Measurement

With the **Method of measurement** parameter, you define whether the stage uses the ***fundamental comp.*** or the ***RMS value***.

- Measurement ***fundamental comp.***:
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.
- Measurement ***RMS value***:
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Measured Value

With the **Measured value** parameter, you define whether the stage analyzes the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C.

If the measured value is set to phase-to-phase, the function reports those measuring elements that have picked up.

Pickup Stabilization

To enable the pickup stabilization, you set the **Stabilization counter** parameter to a value other than zero. Then, if the input voltage keeps being below the pickup value for a specified number (1 + **Stabilization counter** value) of successive measuring cycles, the stage picks up. For 50 Hz, the measuring cycle time is 10 ms.

If you set this parameter to ***0*** (default value), the stabilization is not applied. The pickup signal is issued after the input voltage falls below the pickup value.

Pickup Mode

With the **Pickup mode** parameter, you define whether the stage picks up when there is a lower threshold-value violation in one measuring element (***1 out of 3***) or when there is a lower threshold-value violation in all 3 measuring elements (***3 out of 3***).

Pickup and Operate Curve

When the input voltage falls below the threshold value by a settable value **Pickup factor**, the stage picks up and the inverse-time characteristic curve is processed. The operate delay starts. The operate delay is the sum of inverse-time delay and additional time delay.

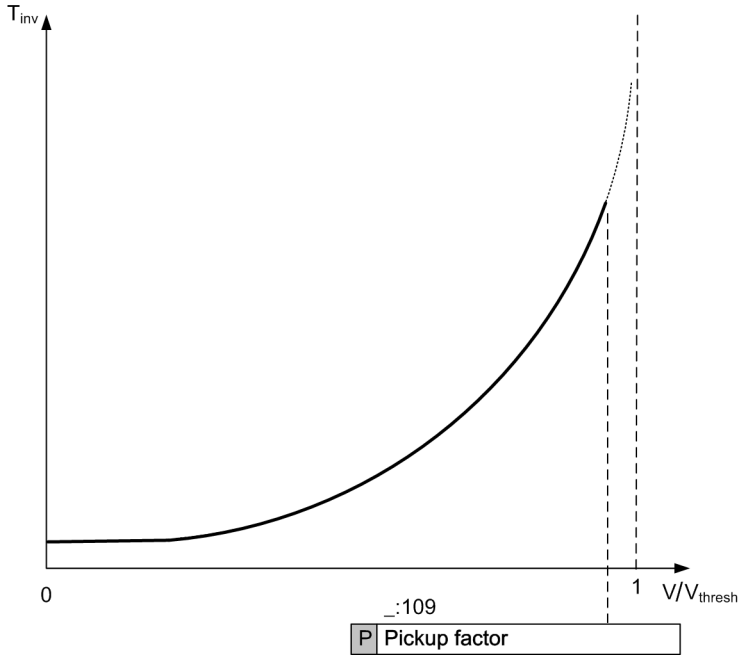
$T_{op}=T_{Inv}+T_{add}$

Where:

T_{op}	Operate delay
T_{Inv}	Inverse-time delay
T_{add}	Additional time delay (Parameter **Additional time delay**)

After pickup the time value T_{Inv} is calculated for every input voltage less than the dropout value. An integrator accumulates the value $1/T_{Inv}$. Once the accumulated integral reaches the fixed value 1, the inverse-time delay expires. The stage operates after the additional time delay.

The inverse-time delay is calculated with the following formula:



$$T_{Inv} = T_p \left(\frac{k}{1 - \left(\frac{V}{V_{Thresh}} \right)^{\alpha}} + c \right) [s]$$

[fo_uvp_3ph_inverse, 2, en_US]

Where

T_{Inv}	Inverse-time delay
T_p	Time multiplier (Parameter **Time dial**)
V	Measured undervoltage
V_{Thresh}	Threshold value (Parameter **Threshold**)
k	Curve constant k (Parameter **Charact. constant k**)
α	Curve constant α (Parameter **Charact. constant α**)
c	Curve constant c (Parameter **Charact. constant c**)

The inverse-time characteristic is shown in the following figure:

[dw_uvp_3ph_inverse, 1, en_US]

Figure 6-564 Inverse-Time Characteristics for Undervoltage Protection

Pickup Delay

The **Pickup delay** parameter is only available and of relevance if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***).

If the circuit breaker opens when the current-flow criterion is being used, the undervoltage detection and current-flow dropout functions conflict with one another. Depending on the threshold value settings for undervoltage detection and current-flow criterion, it is possible that the undervoltage is detected before the current-flow criterion has dropped out. In this case, the stage picks up briefly. Use the **Pickup delay** parameter to prevent the stage from briefly picking up in this way when the circuit breaker opens. This is achieved by delaying the pickup by approximately 40 ms.

Dropout Behavior

When the voltage exceeds the dropout value (1.05 x pickup factor x threshold value), the pickup signal is going and the dropout is started. You can define the dropout behavior via parameter **Reset time**. Instantaneous reset takes place by setting **Reset time** to 0 s. A delayed reset takes place by setting the desired delay time.

During the Reset time (> 0 s), the elapsed operate delay is frozen. If the stage picks up again within this period, the stage operates when the rest of operate delay expires.

Current-Flow Criterion

The undervoltage protection stages work optionally with a current-flow criterion. The **Current-flow criterion** works across all tripping stages.

When the **Current-flow criterion** parameter is activated, the undervoltage-protection stages only pick up if a settable minimum current (**Threshold I>**) is exceeded. A current below the minimum current blocks the stages.

The current-flow criterion can also be set to **fulfilled** with the binary input signal **>Current flow-criterion**. The function reports when the current-flow criterion is fulfilled.

Figure 6-563 illustrates the influence of the current-flow criterion.

NOTE

If the **(_:2311:104) Current-flow criterion** parameter is deactivated, the device picks up immediately if a missing measuring voltage is detected while the undervoltage protection is active. The parameter setting can be changed even when the device has picked up.

Blocking the Stage

In the event of blocking, the picked-up stage is reset. The following blocking options are available for the stage:

- Via the binary input signal *>Block stage* from an external or internal source
- From inside on pickup of the **Measuring-voltage failure detection** function (see *8.3.2.1 Overview of Functions*) . The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker. The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

6.43.4.2 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:8) Method of measurement** = ***fundamental comp.***

With the **Method of measurement** parameter, you define whether the stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends using this parameter value as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example, at capacitor banks). Do not set the **threshold value** of the stage under 10 V for this method of measurement.

Parameter: Measured value

- Recommended setting value **(_:9) Measured value** = ***phase-to-phase***

With the **Measured value** parameter, you define whether the stage monitors the phase-to-phase voltages V_{AB}, V_{BC}, and V_{CA}, or the phase-to-ground voltages V_A, V_B, and V_C.

Parameter Value	Description
phase-to-phase	If you want to detect voltage dips caused by multiphase short circuits, or generally monitor the voltage range, keep phase-to-phase as the default setting. The function will not pick up on ground faults. Siemens recommends the measured value ***phase-to-phase*** as the default setting.
phase-to-ground	Select the ***phase-to-ground*** setting if you want to detect voltage unbalances or overvoltage conditions caused by ground faults.

Parameter: Threshold, Pickup factor

- Default setting **(_:3) Threshold** = ***80.000 V***
- Default setting **(_:109) Pickup factor** = ***0.90***

The stage picks up when the measured voltage value falls below the pickup value **Threshold** × **Pickup factor**.

Depending on the **Measured value**, the **Threshold** is set either as ***phase-to-phase*** quantity or as ***phase-to-ground*** quantity.

With the **Pickup factor** parameter, you modify the pickup value. To avoid a long operate delay time after pickup, Siemens recommends using the default value of **Pickup factor**.

Specify the **Threshold** (pickup threshold) and **Pickup factor** for the specific application.

Parameter: Stabilization counter

- Default setting **(_:2311:103) Stabilization counter** = ***0***

You can configure the **Stabilization counter** parameter in the function block **General**.

For special applications, it could be desirable that a short falling of the input voltage below the pickup value does not lead to the pickup of the stage, which starts fault logging and recording. This is achieved by setting the **Stabilization counter** parameter to a value other than zero.

For example, if you set this parameter to ***1***, the pickup signal is issued when the voltage keeps being below the pickup value for 2 successive measuring cycles. For 50 Hz, the measuring cycle time is 10 ms.

Parameter: Pickup mode

- Recommended setting value **(_:101) Pickup mode** = ***1 out of 3***

With the **Pickup mode** parameter, you specify whether the stage picks up when there is a lower threshold-value violation in one measuring element (***1 out of 3***) or when there is a lower threshold-value violation in all 3 measuring elements (***3 out of 3***).

Parameter Value	Description
1 out of 3	Use this setting for protection applications or for monitoring the voltage range. Siemens recommends ***1 out of 3*** as the default setting. This reflects how the function behaved in previous generations (SIPROTEC 4, SIPROTEC 3).
3 out of 3	Select this setting when using the stage to disconnect from the power system (in the case of wind farms, for example).

Parameter: Pickup delay

- Default setting **(_:102) Pickup delay** = ***no***

The **Pickup delay** parameter is only available if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***). If the current-flow criterion is deactivated, no pickup delay is required.

With the **Pickup delay** parameter, you set whether pickup of the stage is to be delayed by approximately 40 ms or not. The delay avoids possible brief pickup of the stage when the circuit breaker opens.

When applied in parallel, the pickup delay and the delay through pickup stabilization add up.

Parameter Value	Description
no	Use this setting if you definitely do not want stage pickup to be subject to a time delay in the event of a fault. This setting results in pickup and, where applicable, tripping being performed as quickly as possible. Note that switching procedures (opening of the CB) can result in brief pickup of the stage, depending on the threshold-value settings for under-voltage pickup and the current-flow criterion. To prevent unwanted tripping, you must set a minimum tripping delay of 50 ms.
yes	Use this setting when switching procedures (opening of the CB) are not permitted to result in stage pickup. Note that pickup is delayed by approximately 40 ms. This delay is added to the operate time.

Parameter: Charact. constant k, Charact. constant α, Charact. constant c

- Default setting **(_:103) Charact. constant k** = ***1.00***
- Default setting **(_:104) Charact. constant α** = ***1.000***
- Default setting **(_:105) Charact. constant c** = ***0.000***

With the **Charact. constant k**, **Charact. constant α**, and **Charact. constant c** parameters, you define the required inverse-time characteristic.

Parameter: Time dial

- Default setting **(_:106) Time dial** = ***1.00***

With the **Time dial** parameter, you displace the characteristic curve in the time direction.

As usually, there is no time grading for voltage protection and therefore no displacement of the characteristic curve, Siemens recommends leaving the **Time dial** parameter at ***1.00*** (default setting).

Parameter: Reset time

- Default setting **(_:108) Reset time** = ***0.00 s***

With the **Reset time** parameter, you define the reset time delay which is started when the voltage exceeds the dropout value. Set the parameter **Reset time** to 0 s when instantaneous reset is desired.

Under network conditions of intermittent faults or faults which occur in rapid succession, Siemens recommends setting the **Reset time** to an appropriate value > 0 s to ensure the operation. Otherwise, Siemens recommends keeping the default value to ensure a fast reset of the function.

Parameter: Additional time delay

- Default setting **(_:107) Additional time delay** = ***0.00 s***

With the **Additional time delay** parameter, you define a definite-time delay in addition to the inverse-time delay.

If the setting is left on its default value of 0 s, only the inverse-time delay is operative.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:10) Blk. by meas.-volt. failure** = ***yes***

With the **Blk. by meas.-volt. failure** parameter, you control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

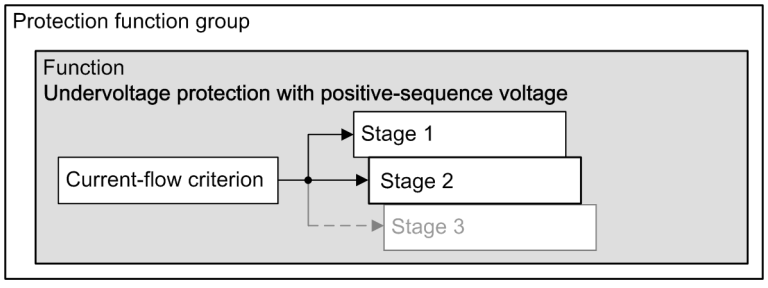
6.44 Undervoltage Protection with Positive-Sequence Voltage

6.44.1 Overview of Functions

The **Undervoltage protection with positive-sequence voltage** function (ANSI 27):

- Monitors the permissible voltage range
- Protects equipment (for example, plant components and machines) from damages caused by undervoltage
- Protects motors and generators from inadmissible operating states and a possible loss of stability in the event of voltage dips



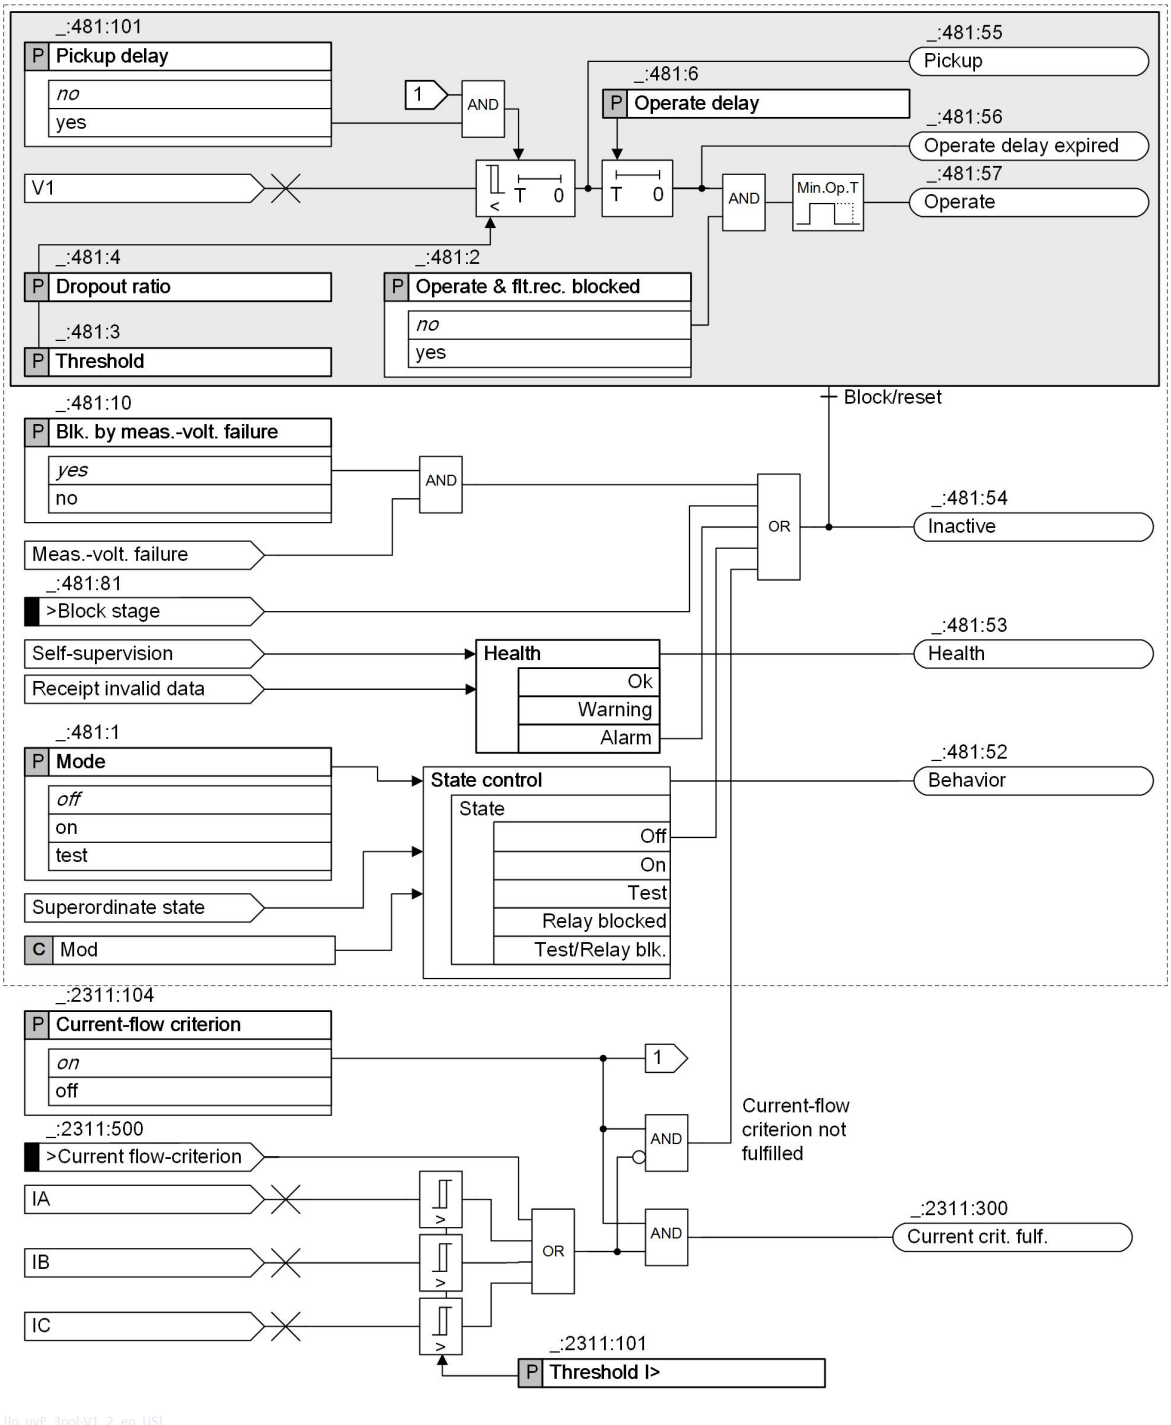
2-phase short circuits or ground faults lead to an unbalanced voltage collapse. In comparison to three 1-phase measuring systems, such events have no noticeable impact on the positive-sequence voltage. This makes this function particularly suitable for the assessment of stability problems.

6.44.2 Structure of the Function

The **Undervoltage protection with positive-sequence voltage** function is used in protection function groups, which are based on voltage measurement.

The **Undervoltage protection with positive-sequence voltage** function comes factory-set with 2 tripping stages. A maximum of 3 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.

The protection function is structured such that one current-flow criterion can act on all undervoltage protection stages (see *Figure 6-565*). If the protection function group used has no current measurement, you can only set the current-flow criterion as **fulfilled** via the corresponding binary input signal.



[dw_stuvu1, 3, en_US]

Figure 6-565 Structure/Embedding of the Function

6.44.3 Stage Description

Logic of the Stage

[lo_uvP_3pol-V1, 2, en_US]

Figure 6-566 Logic Diagram of the Stage Undervoltage Protection with Positive-Sequence Voltage

Method of Measurement

The stage uses the positive-sequence voltage. The positive-sequence voltage is calculated from the measured phase-to-ground voltages according to the defining equation.

Pickup Delay

The **Pickup delay** parameter is only available and of relevance if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***).

If the circuit breaker opens when the current-flow criterion is being used, the undervoltage detection and current-flow dropout functions conflict with one another. Depending on the threshold value settings for undervoltage detection and current-flow criterion, it is possible that the undervoltage is detected before the current-flow criterion has dropped out. In this case, the tripping stage picks up briefly. Use the **Pickup delay** parameter to prevent the tripping stage from briefly picking up in this way when the circuit breaker opens. This is achieved by delaying pickup by approximately 40 ms.

Current-Flow Criterion

The undervoltage-protection stages work optionally with a current-flow criterion. The current-flow criterion works across all stages.

When the **Current-flow criterion** parameter is switched on, the undervoltage protection stages only pick up if a settable minimum current (**Threshold I>**) is exceeded in at least one phase. A current below the minimum current blocks the tripping stages.

The current-flow criterion can also be set to **fulfilled** via the binary input signal **>Current flow-criterion**. The function reports when the current-flow criterion is fulfilled.

Figure 6-566 illustrates the influence of the current-flow criterion.

NOTE

If the **Current-flow criterion** parameter is switched off, the device picks up immediately if a missing measuring voltage is detected while the undervoltage protection is active. The parameter setting can be changed even when the device has picked up.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- Via the binary input signal *>Block stage* from an external or internal source
- From inside on pickup of the **Measuring-voltage failure detection** function (see chapter *8.3.2.1 Overview of Functions*). The **Blk. by meas.-volt. failure** parameter can be set to either block or not block the tripping stage when the measuring-voltage failure detection picks up.
- From an external source via the binary input signal *>Open* of the function block **Volt.-transf. c. b.**, which links in the tripping of the voltage-transformer circuit breaker. The **Blk. by meas.-volt. failure** parameter can be set so that measuring-voltage failure detection blocks the stage or does not block it.

6.44.4 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:481:3) Threshold** = ***46 V***

Specify the **Threshold** (pickup threshold) for the specific application. For the default setting, the lower limit of the voltage range to be monitored is assumed to be 80 % of the rated voltage of the protected object.

Parameter: Pickup delay

- Default setting **(_:481:101) Pickup delay** = ***no***

The **Pickup delay** parameter is only available if you are using the current-flow criterion of the function (parameter **Current-flow criterion** = ***on***). If the current-flow criterion is deactivated, no pickup delay is required.

With the parameter **Pickup delay** you set whether pickup of the stage is to be delayed by approximately 40 ms or not. The delay avoids possible brief pickup of the stage when the circuit breaker opens.

Parameter Value	Description
no	Use this setting if you definitely do not want tripping-stage pickup to be subject to a time delay in the event of a fault. This setting results in pickup and, where applicable, tripping being performed as quickly as possible. Note that switching procedures (opening of the CB) can result in brief pickup of the tripping stage, depending on the threshold-value settings for undervoltage pickup and the current-flow criterion. To prevent unwanted tripping, you must set a minimum tripping delay of 50 ms.
yes	Use this setting when switching procedures (opening of the CB) are not permitted to result in tripping-stage pickup. Note that pickup is delayed by approximately 40 ms. This delay is added to the operate time.

Parameter: Operate delay

- Default setting **(_:481:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:481:4) Dropout ratio** = ***1.05***

The recommended setting value of 1.05 is sufficient for many applications. To obtain extremely accurate indications, the **Dropout ratio** can be reduced.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:481:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the stage when a measuring-voltage failure is detected.
A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and switched on.
- The binary input signal **>Open** of the function block **VTCB** is connected to the voltage-transformer circuit breaker (see chapter *8.3.4.1 Overview of Functions*).

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

Parameter: Current-flow criterion

- Recommended setting value **(_:2311:104) Current-flow criterion** = ***on***

Depending on the system, the voltage transformers can be located on the supply or the output side. These 2 possible voltage transformer locations induce a different behavior of the function after tripping and opening of the circuit breaker:

- If they are located on the supply side, the voltage still exists.
- If they are located on the output side, the voltage does not exist.

Parameter Value	Description
on	If the voltage transformers are located on the output side, you can use the current-flow criterion to make the pickup drops out when the current falls below a minimum value (parameter Threshold value I>).
off	In the case of undervoltage, the pickup of the undervoltage-protection stage persists when the current-flow criterion is not used.

Parameter: Threshold I>

- Recommended setting value **(_:2311:101) Threshold I>** = ***0.05 A***

The **Threshold I>** parameter makes it possible to detect when the circuit breaker is closed. Siemens recommends setting the **Threshold I>** parameter to 5% of the rated current. With a secondary rated transformer current of 1 A, the secondary setting value for **Threshold I>** would be 0.05 A.

If the sensitivity of the **Threshold I>** parameter is set too high, compensation processes in the secondary circuit of the current transformer extend the dropout time when breaking extremely high currents. To speed up dropout, increase the default setting.

Operation as Supervision Function

If you want the tripping stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

6.44.5 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General				
_:2311:104	General:Current-flow criterion		• off • on	on

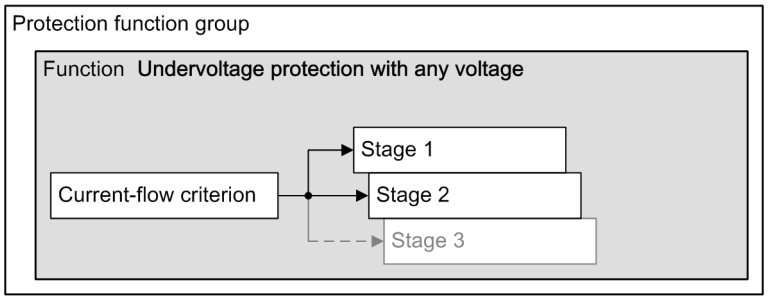
6.45 Undervoltage Protection with Any Voltage

6.45.1 Overview of Functions



The function **Undervoltage protection with any voltage** (ANSI 27) detects any 1-phase undervoltage and is intended for special applications.

6.45.2 Structure of the Function

The **Undervoltage protection with any voltage** function is used in protection function groups, which are based on voltage measurement.

The function **Undervoltage protection with any voltage** comes factory-set with 2 stages. A maximum of 3 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.

The protection function is structured such that one current-flow criterion can act on all undervoltage protection stages (see *Figure 6-567*).

[dw_stuvux, 1, en_US]

Figure 6-567 Structure/Embedding of the Function

6.45.3 Stage Description

Logic of a Stage

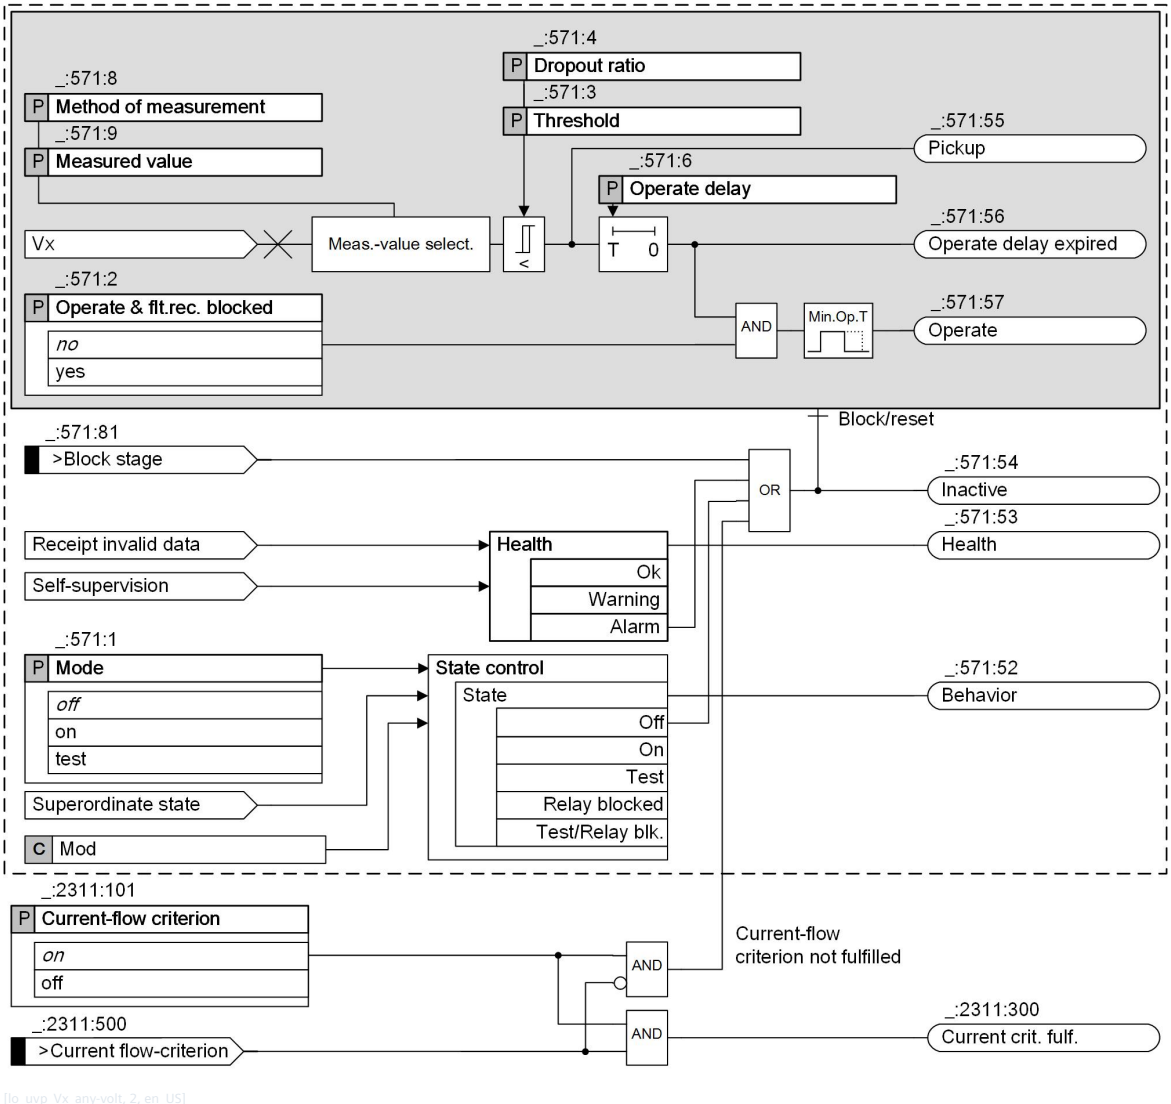


Figure 6-568 Logic Diagram of a Stage: Undervoltage Protection with Any Voltage

NOTE

If the function **Undervoltage protection with any voltage** is used in a 1-phase function group, the parameter **`Measured value`** is not visible.

Method of Measurement

The **`Method of measurement`** parameter allows you to define whether the function works with the fundamental component or the calculated RMS value.

- Measurement of the fundamental component:
  This method of measurement processes the sampled voltage values and filters out the fundamental component numerically.

- Measurement of the RMS value:
  This method of measurement determines the voltage amplitude from the sampled values according to the defining equation of the RMS value. Harmonics are included in the analysis.

Measured Value

The parameter **Measured value** allows you to select whether the stage uses a measured (directly connected) voltage or a calculated phase-to-phase voltage.

If the function **Undervoltage protection with any voltage** is used in a 1-phase function group, the parameter **Measured value** is not visible.

Current-Flow Criterion

The undervoltage-protection stages work optionally with a current-flow criterion. The current-flow criterion works across all stages.

When the **Current-flow criterion** parameter is switched on, the undervoltage protection stages only pick up when the current-flow criterion has been set to **fulfilled** via the binary input signal **>Current flow-criterion**. The function reports when the current-flow criterion is fulfilled.

Figure 6-568 illustrates the influence of the current-flow criterion.

NOTE

If the **(_:2311:101) Current-flow criterion** parameter is deactivated, the device picks up immediately if a missing measuring voltage is detected while the undervoltage protection is active. The parameter setting can be changed even when the device has picked up.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking the stage is possible externally or internally via the binary input signal *>Block stage*.

6.45.4 Application and Setting Notes

Parameter: Method of measurement

- Recommended setting value **(_:571:8) Method of measurement** = ***fundamental comp.***

Use the **Method of measurement** parameter to define whether the tripping stage uses the fundamental component (standard method = default setting) or the calculated RMS value.

Parameter Value	Description
fundamental comp.	Select this method of measurement to suppress harmonics or transient voltage peaks. Siemens recommends using this parameter value as the default setting.
RMS value	Select this method of measurement if you want the stage to take harmonics into account (for example at capacitor banks). Do not set the **threshold value** of the tripping stage under 10 V for this method of measurement.

Parameter: Measured value

- Default setting **(_:571:9) Measured value** = ***VA measured***

The **Measured value** parameter is used to specify which voltage is monitored by the stage.

The scope of setting options depends on the connection type for the voltage transformers and the routing of the measured values to the terminals of the voltage measuring point. You can find connection examples for voltage transformers in the *Appendix*.

The following setting options can be available:

- Measured phase-to-ground voltage V_A (***VA measured***)
- Measured phase-to-ground voltage V_B (***VB measured***)
- Measured phase-to-ground voltage V_C ***VC measured***)
- Measured phase-to-phase voltage V_{AB} (***VAB measured***)
- Measured phase-to-phase voltage V_{BC} (***VBC measured***)
- Measured phase-to-phase voltage V_{CA} (***VCA measured***)
- Calculated phase-to-phase voltage V_{AB} (***VAB calculated***)
- Calculated phase-to-phase voltage V_{BC} (***VBC calculated***)
- Calculated phase-to-phase voltage V_{CA} (***VCA calculated***)
- Calculated voltage V0 (***V0 calculated***)

The selection depends on the corresponding application.

NOTE

From V7.30 on, the value ***VN measured*** is no longer provided. If you have selected this value in earlier versions, you can select the value ***V0 calculated*** instead after upgrading the configuration to V7.30 or a later version.
If the function **Undervoltage protection with any voltage** is used in a 1-phase function group, the parameter **Measured value** is not visible.

Parameter: Threshold

- Default setting **(_:571:3) Threshold** = ***80 V***

Specify the **Threshold** (pickup threshold) for the specific application.
Depending on the **Measured value**, the **Threshold** is set either as **measured voltage** or as a **phase-to-phase** variable.

NOTE

If the function is used in a **Voltage-current 1-phase** function group connected to the 1-phase voltage measuring point with the voltage type ***VN broken-delta***, you set the threshold value based on the equivalent zero-sequence voltage.
Calculate the equivalent zero-sequence voltage $V_{0\ equiv.\ sec}$ from the measured voltage $V_{N\ sec}$ with the following formula:

$$\frac{V_{0\ equi\ \ sec}}{V_{N\ sec}} = \frac{\text{Matching ratio Vph/VN}}{3}$$

For more information about the parameter **Matching ratio Vph / VN**, refer to *6.1.4 Application and Setting Notes for Measuring-Point Voltage 3-Phase (V-3ph)*.

Parameter: Operate delay

- Default setting **(_:571:6) Operate delay** = ***3 s***

The **Operate delay** must be set for the specific application.

Parameter: Dropout ratio

- Recommended setting value **(_:571:4) Dropout ratio** = ***1.05***

The recommended set value of ***1.05*** is appropriate for most applications. To achieve high measurement precision, the **Dropout ratio** can be reduced to 1.02, for example.

Parameter: Current-flow criterion

- Recommended setting value **(_:2311:101) Current-flow criterion** = ***on***

Parameter Value	Description
on	Because of the application, it makes sense that the stage is only active (that is, not blocked) when a certain current flow is present (see note).
off	Current flow monitoring does not make sense for the application.

NOTE

Because of the flexible setting options of the voltage measurand, the function itself does not determine the current associated with the voltage. A suitable current-flow monitoring function must be created by the user with the Continuous Function Chart (CFC), and connected to the binary input signal **>Current flow-criterion**.

Operation as Supervision Function

If you want the tripping stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

6.46 Rate-of-Voltage-Change Protection

6.46.1 Overview of Functions

In a power system, in addition to short circuits, there are other situations which also cause voltage changes. For example, too high loads can reduce the voltage level at the end of the line, or too high power production can cause a voltage-level increase.

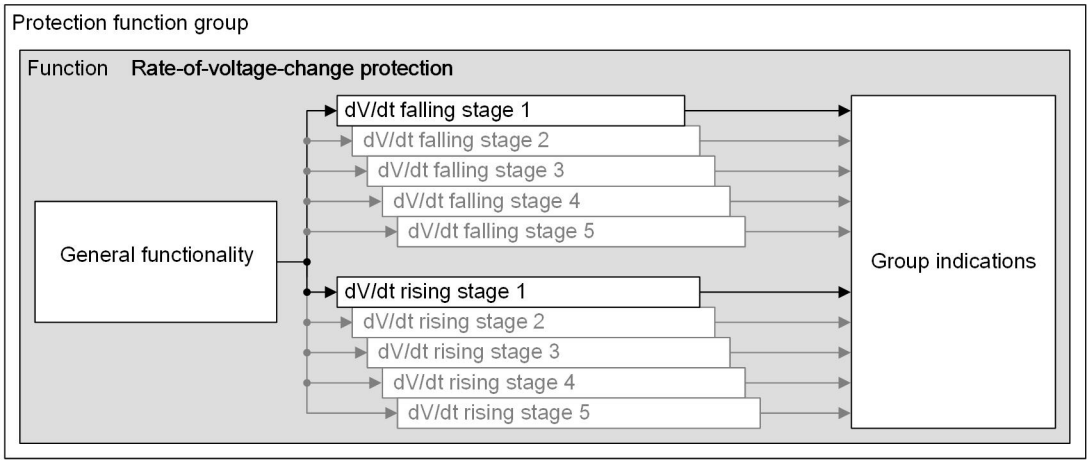
The function **Rate-of-voltage-change protection** can be used to:

- Prevent the system from not secure states caused by unbalance between the generated and consumed active power
- Detect a network island state
- Advanced load-shedding applications
- Detect a rather fast voltage change related to a fault in the power system

6.46.2 Structure of the Function

The function **Rate-of-voltage-change protection** can be used in protection function groups with 3-phase voltage measurement.

2 stage types are available:



- **dV/dt rising**
- **dV/dt falling**

The function **Rate-of-voltage-change protection** comes factory-set with 1 **dV/dt rising** stage and 1 **dV/dt falling** stage. A maximum of 5 **dV/dt rising** stages and 5 **dV/dt falling** stages can be operated simultaneously within the function. Both stage types are similar in structure.

The general functionality works across stages on the function level.

The group-indication output logic generates the following group indications of the protection function by the logical OR of the stage-selective indications:

- Pickup
- Operate

[dw_dVdt structure, 1, en_US]

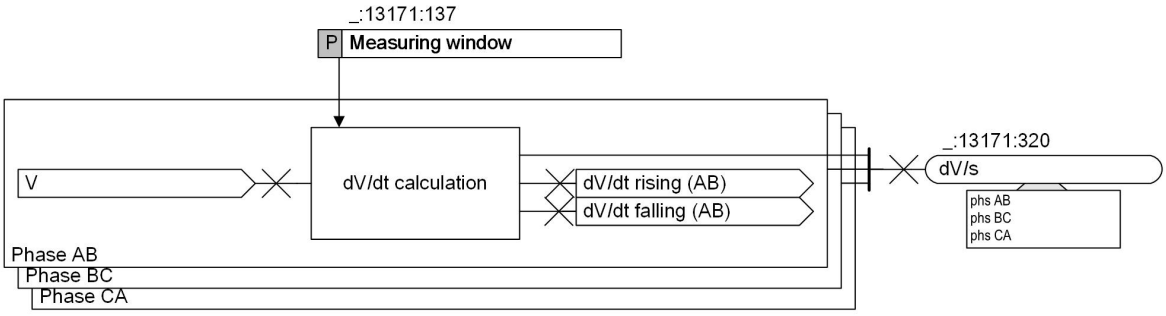


Figure 6-569 Structure/Embedding of the Function

6.46.3 General Functionality

6.46.3.1 Description

Logic

The following figure shows the dV/dt calculation logic. It applies to all configured stages.

[lo_dvdt_general, 1, en_US]

Figure 6-570 Logic Diagram of the General Functionality

dV/dt Calculation

The measured phase-to-phase voltages are used for calculating the rate of voltage change.

The measuring-window interval is used for calculating the dV/dt mean value for further processing. A larger measuring window increases the accuracy of the dV/dt mean value while simultaneously increasing the pickup time.

The ratio between the voltage difference and the time difference reflects the voltage change which can be positive or negative.

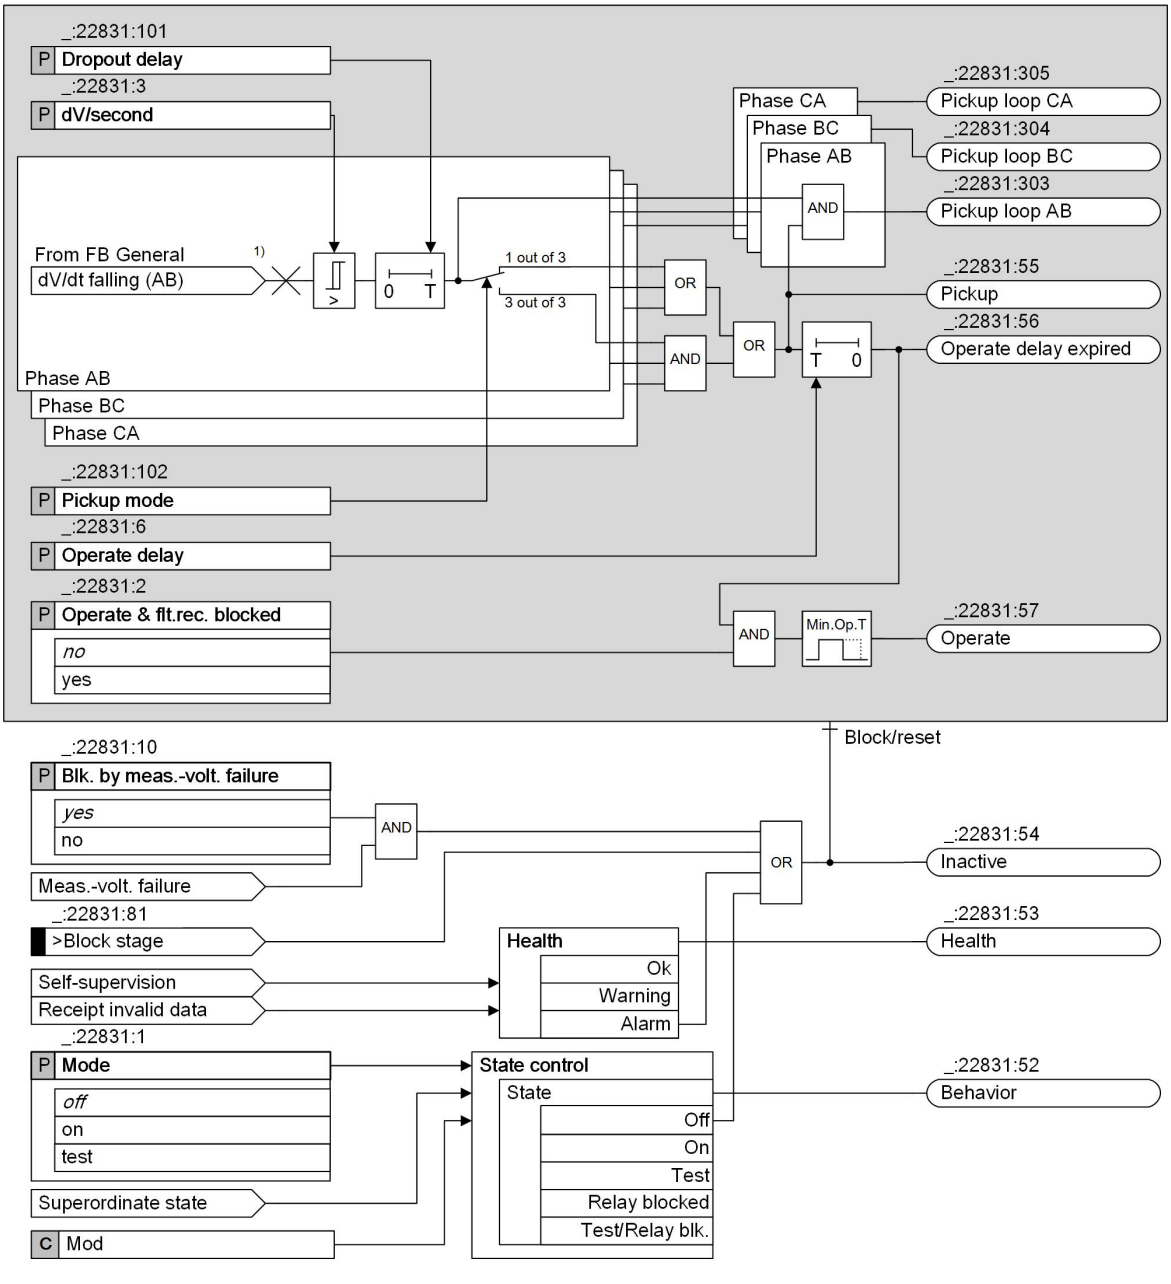
Functional Measured Value

Value	Description
dV/s	Calculated mean voltage change per second

6.46.3.2 Application and Setting Notes

Parameter: `Measuring window`

- Default setting **`(_:13171:137) Measuring window`** = ***`5 periods`***



With the **`Measuring window`** parameter, you optimize the measuring accuracy or the pickup time of the function. If the measuring window increases, the measuring accuracy increases while the pickup time increases as well. You can find more information about the pickup time and measuring accuracy in the technical data in chapter *12.41 Rate-of-Voltage-Change Protection*.

If you do not have specific requirements for an especially short pickup time, Siemens recommends using the default setting. The default setting is a reasonable compromise between the measuring accuracy and the pickup time. If the measuring window is smaller than 5 periods, the accuracy of the calculated dV/dt value is affected.

6.46.4 Stage Description

6.46.4.1 Description

Logic of the Stage

[lo_dvdt_stage, 1, en_US]

Figure 6-571 Logic Diagram of the dV/dt Falling Stage

(1) For the stage type **dV/dt rising**, the value **dV/dt rising (AB)** is used.

Voltage Change

The stage **dV/dt falling** is used to detect a system-voltage decrease and the stage **dV/dt rising** is used to detect a system-voltage increase.

You set the threshold value **dV/second** as the absolute voltage change per second. You define the voltage-change direction via the stage type.

Pickup Mode

The **Pickup mode** parameter defines whether the stage picks up if all 3 measuring elements detect the voltage-change condition (***3 out of 3***) or if only 1 measuring element detects the voltage-change condition (***1 out of 3***).

Dropout Delay

If the dV/dt value falls below the dropout threshold, the dropout of the stage can be delayed. The pickup is maintained for the specified time. The operate delay continues to run. If the operate delay expires while the pickup is still maintained, the stage operates.

Blocking the Stage via Binary Input Signal

You can block the stage externally or internally via the binary input signal *>Block stage*. In the event of blocking, the picked up stage will be reset.

Blocking the Stage in Case of Measuring-Voltage Failure

The stage can be blocked if a measuring-voltage failure occurs. In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- From inside on pickup of the **Measuring-voltage failure detection** function
- From an external source via the binary input signal *>Open* of the function block **Voltage-transformer circuit breaker**, which links in the tripping of the voltage-transformer circuit breaker.

The **Blk. by meas.-volt. failure** parameter can be set so that **Measuring-voltage failure detection** blocks the stage or not.

6.46.4.2 Application and Setting Notes

Parameter: dV/second

- Default setting **(_:22831:3) dV/second** = ***20.000 V***

With the **dV/second** parameter, you determine the pickup value of the stage. The pickup value depends on the application.

For the load-shedding application, it is necessary to detect faster rates of voltage change in the range from 20 V to 30 V per second.

For an island-state detection of the network, the pickup value can be set much lower in the range of 1 V per second or less.

Parameter: Dropout delay

- Default setting **(_:22831:101) Dropout delay** = ***0.00 s***

The **Dropout delay** parameter maintains the pickup even if the measured value drops temporarily below the threshold value. A delay is required for very low pickup values to prevent a chattering of the function.

Parameter: Operate delay

- Default setting **(_:22831:6) Operate delay** = ***3.00 s***

You can use the **Operate delay** parameter to avoid overfunction due to disturbing influences (for example, switching operations). If the protection function is supposed to respond immediately, set the **Operate delay** to 0.00 s.

Parameter: Pickup mode

- Default setting **(_:22831:102) Pickup mode** = ***1 out of 3***

With the **Pickup mode** parameter, you define whether the protection stage picks up if all 3 measuring elements detect the voltage falling/rising condition (***3 out of 3***) or if only 1 measuring element detects the voltage falling/rising condition (***1 out of 3***).

Parameter Value	Description
1 out of 3	Select the setting for protection applications or for monitoring the voltage range. This setting reflects how the function operated in previous generations (SIPROTEC 4).
3 out of 3	Select this setting when using the stage to disconnect from the power system (for example in the case of wind farms).

Operation as Supervision Function

If you want the stage to have a reporting effect only, generation of the operate indication and fault logging can be disabled via the **Operate & flt.rec. blocked** parameter.

Parameter: Blk. by meas.-volt. failure

- Default setting **(_:22831:10) Blk. by meas.-volt. failure** = ***yes***

You use the **Blk. by meas.-volt. failure** parameter to control the behavior of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal supervision function **Measuring-voltage failure detection** is configured and enabled.
- The binary input signal *>Open* of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker.

Parameter Value	Description
yes	The protection stage is blocked (= default setting). Siemens recommends using the default setting.
no	The protection stage is not blocked.

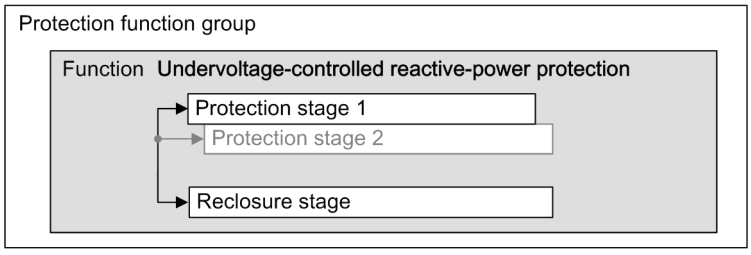
6.47 Undervoltage-Controlled Reactive-Power Protection



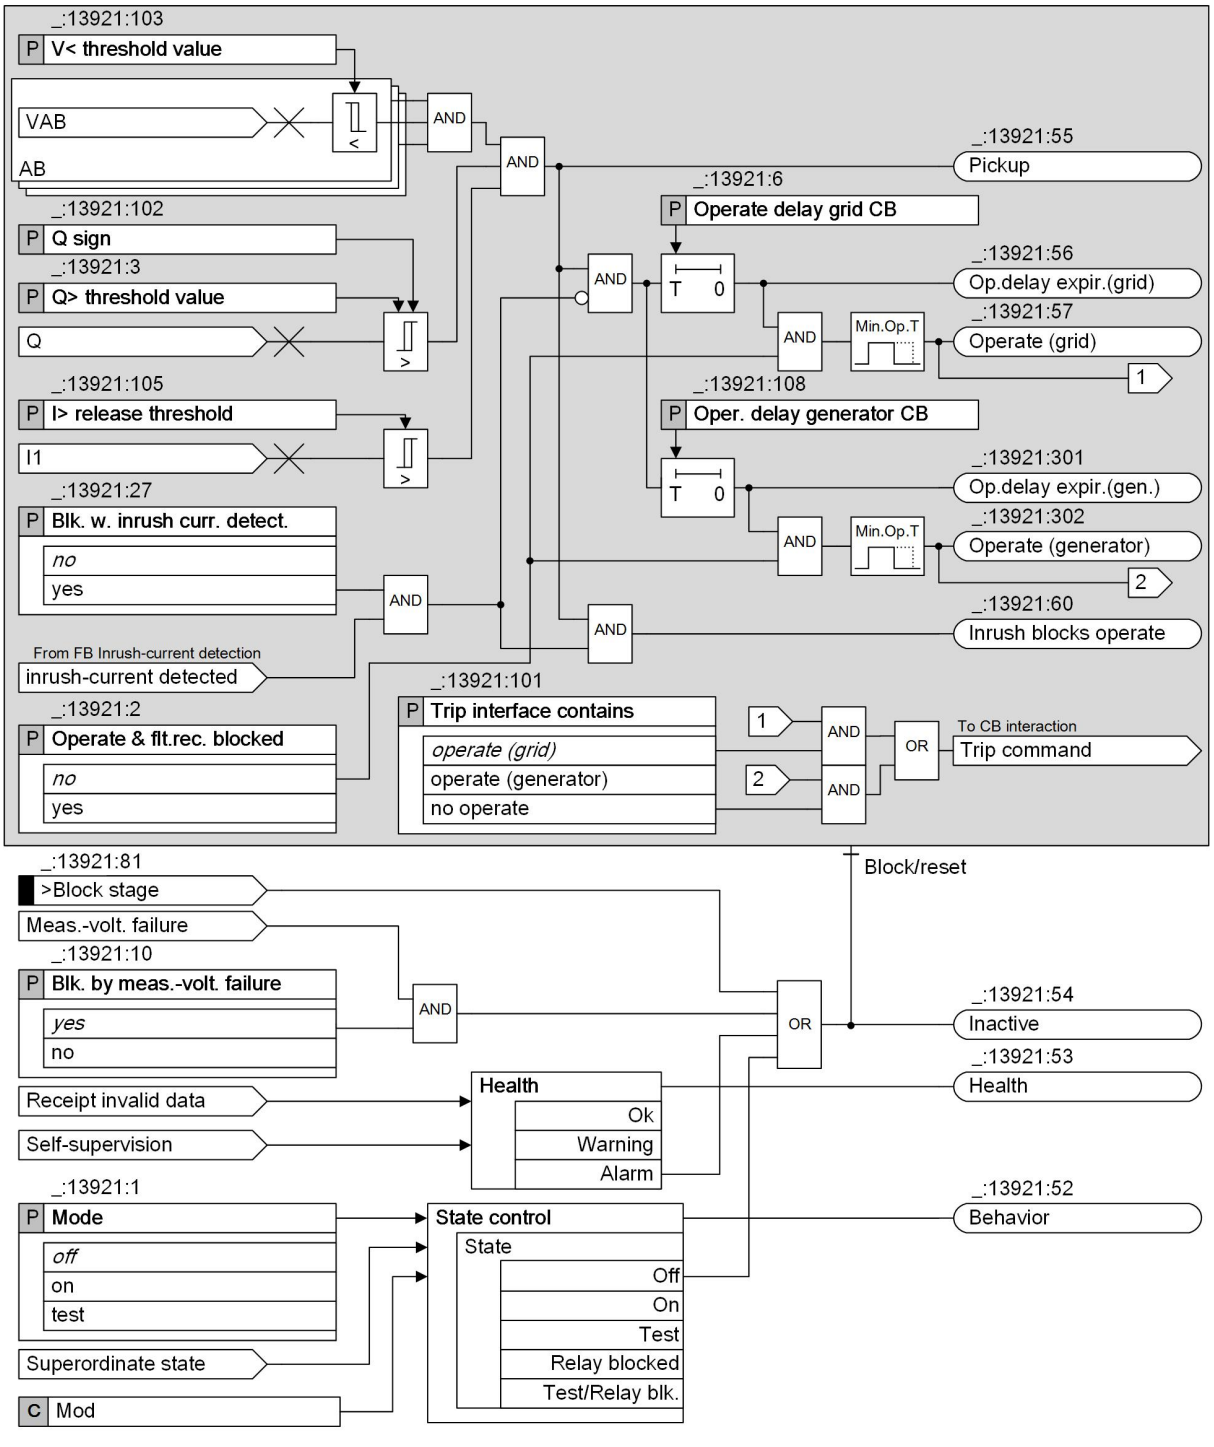
6.47.1 Overview of Functions

The **Undervoltage-controlled reactive-power protection** function (ANSI 27/Q):

- Detects critical power-system situations, mainly in case of regenerative generation
- Prevents a voltage collapse in power system by disconnecting the power-generation facility from the main power systems
- Ensures reconnection under stable power-system conditions

6.47.2 Structure of the Function

The **Undervoltage-controlled reactive-power protection** function can be used in protection function groups containing 3-phase voltage and current measurement. Depending on the device, it is preconfigured by the manufacturer with 1 **Protection stage** and 1 **Reclosure stage**. A maximum of 2 **Protection stages** and 1 **Reclosure stage** can operate simultaneously within the function.



[dw_qvprot, 1, en_US]

Figure 6-572 Structure/Embedding of the Function

6.47.3 Protection Stage

6.47.3.1 Description

Logic of the Stage

[lo_qvprst, 2, en_US]

Figure 6-573 Logic Diagram of the Protection Stage of the Undervoltage-Controlled Reactive-Power Protection

Measurand

To detect critical power-system situations, the **Undervoltage-controlled reactive-power protection** function uses the fundamental values of the phase-to-phase voltages, the positive-sequence current, and the reactive power.

Q-Measurement Direction

The default directions of the positive reactive-power flow Q and the forward direction of the short-circuit protection are identical, in the direction of the protected object. Via parameter **`Q sign`**, the direction of the positive reactive-power flow Q can be changed by inverting the sign of the reactive power Q.

Pickup

The protection stage picks up under the following conditions:

- All 3 phase-to-phase voltages are below the parameterized threshold value.
- The positive-sequence current I_1 is above the parameterized threshold value.
- The power-generation facility requires more than the parameterized reactive power (Q is above the parameterized threshold value).

Trip Interface

The stage provides 2 operate signals, the *`Operate (generator)`* and the *`Operate (grid)`*. Depending on the parameter **`Trip interface contains`**, one or none of them will be forwarded to the trip interface of the circuit-breaker interaction.

Blocking of the Stage

The following blockings reset the picked up stage completely:

- Externally or internally via the binary input signal *`>Block stage`*
- Measuring-voltage failure

Blocking of the Operate Delay and Operate Signal via the Device-Internal Inrush-Current Detection Function

The **`Blk. w. inrush curr. detect.`** parameter permits you to define whether the operate delay should be blocked by a threshold-value violation due to an inrush current.

For further information about device-internal **Inrush-current detection** function, refer to chapter *6.23.7.1 Description* .

6.47.3.2 Application and Setting Notes

Parameter: **`Blk. by meas.-volt. failure`**

- Recommended setting value **`(_:13921:10) Blk. by meas.-volt. failure`** = ***`yes`***

You use the **`Blk. by meas.-volt. failure`** parameter to control the response of the stage when a measuring-voltage failure is detected.

A measuring-voltage failure can only be detected if one of the following 2 conditions is met:

- The device-internal **Measuring-voltage failure detection** function is configured and switched on.
- The binary input signal *>Open* of the function block **Voltage-transformer circuit breaker** is connected to the voltage-transformer circuit breaker.

Parameter Value	Description
yes	The **Protection stage** is blocked when a measuring-voltage failure is detected. Siemens recommends using the default setting, as there is no assurance that the **Protection stage** will function correctly if the measuring voltage fails.
no	The **Protection stage** is not blocked when a measuring-voltage failure is detected.

Parameter: `Blk. w. inrush curr. detect.`

- Default setting **`(_:13921:27) Blk. w. inrush curr. detect.`** = ***no***

You use the **`Blk. w. inrush curr. detect.`** parameter to determine whether the operate delay and operate signal are blocked during the detection of an inrush current.

Parameter: `I> release threshold`

- Recommended setting value **`(_:13921:105) I> release threshold`** = ***0.100 A***

You use the **`I> release threshold`** parameter to define a precondition that the stage can pick up. The default setting is at 10 % of the rated current. Siemens recommends using the default setting.

Parameter: `V< threshold value`

- Recommended setting value **`(_:13921:103) V< threshold value`** = ***85.000 V***

You use the **`V< threshold value`** parameter to define one of the 2 pickup criteria. If all 3 phase-to-phase voltages drop below the parameterized undervoltage threshold value, the pickup criterion is fulfilled.

The setting should be set below the lower value of the permissible voltage range, according to the national transmission code. In Germany, the recommended undervoltage threshold is 85 % of the rated voltage. Therefore Siemens recommends using the default setting.

Parameter: `Q> threshold value`

- Default setting **`(_:13921:3) Q> threshold value`** = ***5 %***

You use the **`Q> threshold value`** parameter to define the second of the 2 pickup criteria. If the positive reactive power exceeds the parameterized **`Q> threshold value`**, the pickup criterion is fulfilled.

In the following example, the pickup takes place if Q exceeds 5 % of the power-supply system rated power.

EXAMPLE

The following example is given for settings in secondary values.

Rated voltage: $V_{rated,\ sec}$ = 100 V

Rated current: $I_{rated,\ sec}$ = 1 A

Threshold value: 5 % of the power-supply system rated power

You can calculate the setting value as follows:

$$Q >_{threshold} = 100\ V \cdot 1\ A \cdot \sqrt{3} \cdot 0.05 = 8.7\ VAr$$

[fo_qvprot, 1, en_US]

Parameter: Operate delay

- Default setting **`(_:13921:6) Operate delay grid CB`** = ***1.50 s***
- Default setting **`(_:13921:108) Oper. delay generator CB`** = ***0.50 s***

You can set the **`Operate delay grid CB`** for the circuit breaker at the power-supply system connection point, or set the **`Oper. delay generator CB`** for the circuit breaker of the facility, for example, the generator.

The time of the **Operate delay grid CB** should always be set longer than the time of the **Oper. delay generator CB**.

Parameter: Trip interface contains

- Default setting **(_:13921:101) Trip interface contains** = ***operate (grid)***

The stage provides 2 operate signals, the *Operate (generator)* and the *Operate (grid)*.
You use the **Trip interface contains** parameter to define whether one or none of them will be forwarded to the trip interface of the circuit-breaker interaction. The selected operate signal will trip the circuit breaker that has been connected to the protection function group.
The setting depends on the specific application.

Parameter: Q sign

- Default setting **(_:13921:102) Q sign** = ***not reversed***

The default directions of the positive reactive-power flow Q and the forward direction of the short-circuit protection are identical, in the direction of the main protected object (for example, a feeder). You use the **Q sign** parameter to reverse the sign and therefore the direction of the reactive-power flow Q. This reversal may be required for specific application, where the main protected object (for example, a line towards the main power systems) is in different direction to the power-generation facility.

Parameter Value	Description
not reversed	The protected object is in the same direction as the power-generation facility.
reversed	The protected object is not in the same direction as the power-generation facility.

6.47.4 Reclosure Stage

6.47.4.1 Description

Logic of the Stage

[lo_qvclst_4, en_US]

Figure 6-574 Logic Diagram of Reclosure Stage in Undervoltage-Controlled Reactive-Power Protection

Measurand

The stage works with fundamental values of voltage and current.

Release for Reconnecting

The release for reconnecting the power-generation facility is given under the following conditions:

- All 3 phase-to-phase voltages are above the threshold value.
- The power frequency is within a specified range.
- The reclosure time delay, started by the operate of specific protection functions, has elapsed. The time delay is started by the first operate signal of the protection stages configured via the **Configuration** parameter. All protection stages of the voltage protection, the frequency protection, and the QV protection are available for configuration.

External Start of Reclosure Time Delay

Reclosure time delay can be started via the binary input signal *>V, f trip*, which can be connected to external voltage and frequency protection trip signals.

Blocking of the Stage

The stage can be blocked via the binary input signal *>Block stage*.

6.47.4.2 Application and Setting Notes

Parameter: Configuration

- Default setting **(_:13951:102) Configuration** = ***no stage***

You use the **Configuration** parameter to define which operate signal of specific protection functions starts the release time delay of the **Reclosure stage**:

- Overfrequency protection
- Underfrequency protection
- Overvoltage protection
- Undervoltage protection
- Protection stage of undervoltage-controlled reactive-power protection

When the protection stage of undervoltage-controlled reactive-power protection is selected, only the signal *Operate (generator)* can start the release time delay of this stage. The signal *Operate (grid)* cannot start the release time delay.

The configuration depends on the specific application.

Parameter: I> release threshold

- Recommended setting value **(_:13951:106) I> release threshold** = ***0.100 A***

You use the **I> release threshold** parameter to define a precondition that the stage can work.

The default setting is at 10 % of the rated current. Siemens recommends using the default setting.

Parameter: V> threshold value

- Recommended setting value **(_:13951:101) V> threshold value** = ***95.000 V***

You use the **V> threshold value** parameter to set one of the 2 release criteria. The setting should be set above the lower value of the allowed voltage range, according to the national transmission code. In Germany, the recommended overvoltage threshold is 95 % of the rated voltage. Therefore Siemens recommends using the default setting.

Parameter: Frequency range

- Recommended setting value **(_:13951:104) f difference positive** = ***0.05 Hz***
- Recommended setting value **(_:13951:105) f difference negative** = ***-2.50 Hz***

You use these 2 parameters to define the admitted frequency deviation from the rated frequency. **f difference positive** defines the upper frequency range limit. **f difference negative** defines the lower frequency range limit.

Siemens recommends using the default settings, which reflect common practice in Germany. Other national transmission codes may require a slightly different range.

Parameter: Time delay

- Default setting **(_:13951:108) Time delay** = ***0.00 s***

You use the **Time delay** parameter to specify the minimum time delay for releasing the reconnection of the power-generation facility after tripping by protection.

The setting depends on the specific application.

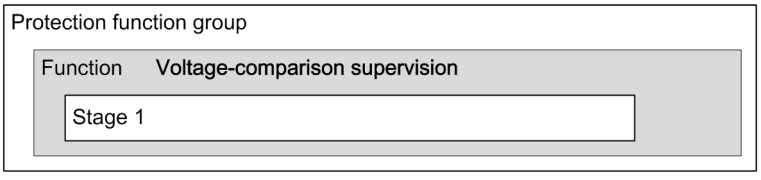
6.48 Voltage-Comparison Supervision

6.48.1 Overview of Functions

The **Voltage-comparison supervision** function (ANSI 60):

- Monitors the voltage-transformer circuits by comparing the voltages from 2 voltage transformers
  If failures in the voltage circuits are detected, voltage-related protection functions can be blocked.
- Requires the connection of 2 voltage measuring points to the voltage interface of the function group
  You can take one of the voltages as the reference voltage and then the other becomes the main voltage. The reference voltage is used for comparison.

NOTE



The voltage selection for the protection function in the FGs works independent of the status of the **Voltage-comparison supervision** function.

6.48.2 Structure of the Function

The **Voltage-comparison supervision** function can be used in the following function groups:

- Generator stator
- Generator side
- Voltage-current 3-phase (VI 3ph)
- Transformer side
- Auto transformer autoside (Auto trf. autoside)

The **Voltage-comparison supervision** function supports only 1 stage. The stage is preconfigured at the factory.

{dw_structure_VBP, 1, en_US}

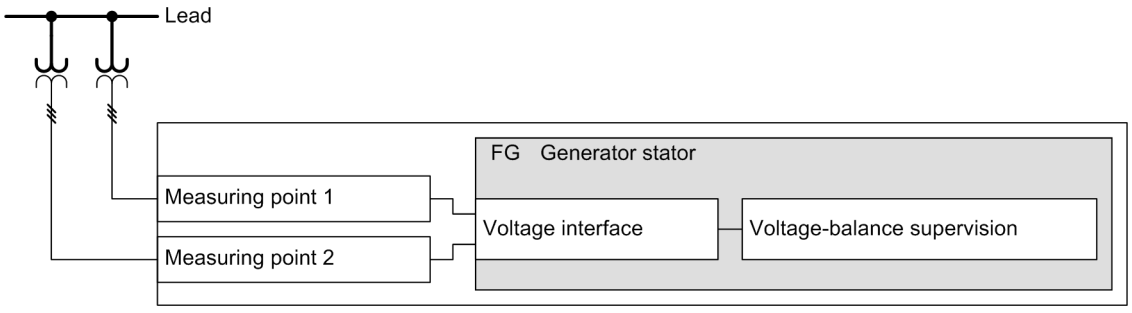


Figure 6-575 Structure/Embedding of the Function

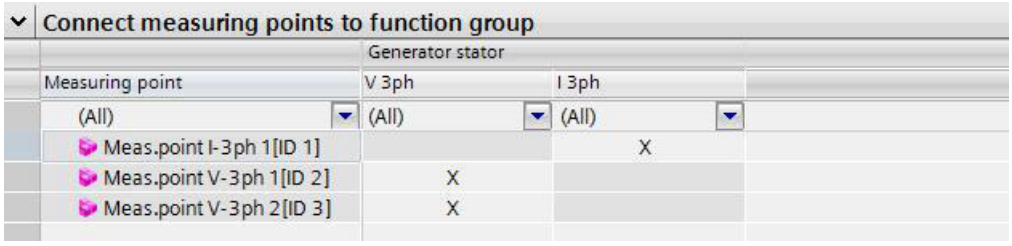
6.48.3 Stage Description

6.48.3.1 Description

Function Application

The following figure shows an application example.



[dw_VBP application, 1, en_US]

Figure 6-576 Application Example

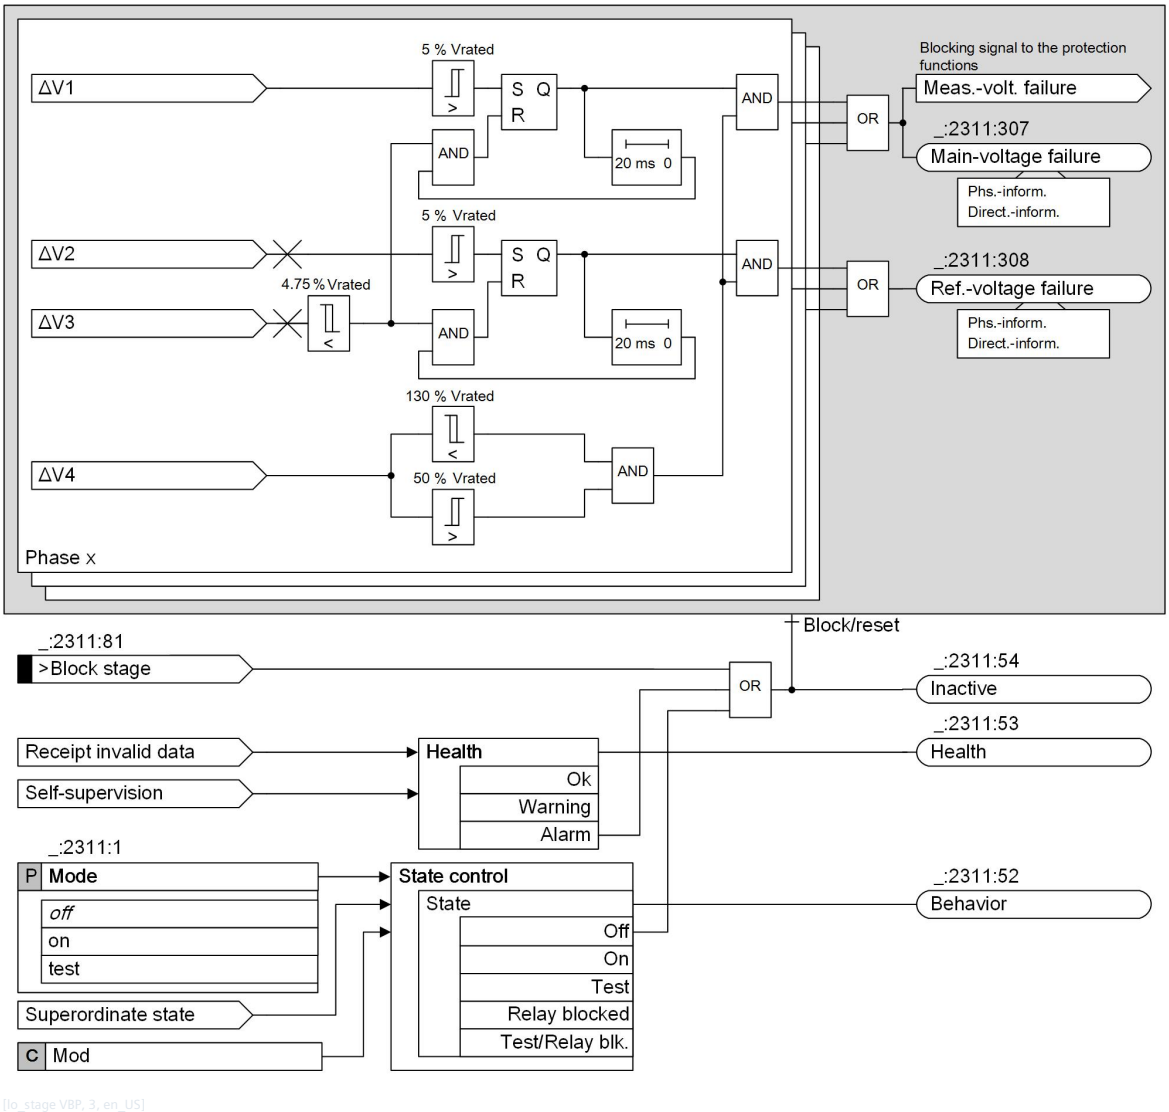
Connecting Measuring Points to a Function Group

The following figure shows the connection of the function group **Generator stator** with several measuring points in DIGSI. The ID of each measuring point appears in the brackets after the name.

[sc_VBStoFG, 1, en_US]

Figure 6-577 Connecting the Measuring Points to the Generator Stator Function Group

There are consistency checks that validate the connections of voltage measuring points to the function group:



- The connection type must be identical for all measuring points connected to the same interface of the function group.
- The rated voltage (primary and secondary) must be identical for all measuring points connected to the same interface.
- 2 voltage measuring points must be connected to one voltage interface.
- Either the **Voltage-comparison supervision** function or the **Voltage measuring-point selection** function must be instantiated. They must not be instantiated at the same time.
  About the **Voltage measuring-point selection** function, you can find more information in chapter *6.71 Voltage Measuring-Point Selection*.

Voltage Selection

2 voltage measuring points are connected to a voltage interface of a function group. In the **Voltage-comparison supervision** function, you can set one of the voltages as the reference voltage via the parameter **`Reference voltage`**, and the other voltage becomes the main voltage.

- The reference voltage is used for voltage comparison.
- The main voltage is used for all voltage-related functions in the FGs that contain the **Voltage-comparison supervision** function.
  If the main voltage transformer is disconnected, the **Voltage-comparison supervision** function issues the blocking signal *`Meas.-volt failure`*. The signal is transmitted to all voltage-related protection functions which are used in the same FGs as the **Voltage-comparison supervision**.

Logic of the Stage

[lo_stage VBP, 3, en_US]

Figure 6-578 Logic Diagram of the Supervision Stage

The voltage inputs in the preceding figure are calculated with the following equations:

$\Delta V1 = |v(n)_{ref.}| - |v(n)_{main}|$

$\Delta V2 = |v(n)_{main}| - |v(n)_{ref.}|$

$\Delta V3 = |V_{ref.} - V_{main}|$

$\Delta V4 = \text{Max.}\ (V1_{ref.}, V1_{main})$

The following table shows the description of the voltages.

Table 6-20 Voltage Description

Voltages	Description
$v(n)_{ref.}$	Sampled value of the reference voltage
$v(n)_{main}$	Sampled value of the main voltage
$V_{ref.}$	Fundamental value of the reference voltage
V_{main}	Fundamental value of the main voltage
$V1_{ref.}$	Positive-sequence value of the reference voltage
$V1_{main}$	Positive-sequence value of the main voltage

Pickup

If the voltage difference between each 2 of 3 continuous sampling points is over 8 % Vrated of the plant, the supervision stage picks up.

Voltage Supervision

For the **Voltage-comparison supervision** function, the following 2 connection types are allowed:

- Phase-to-ground
  The phase-to-ground voltages are used for the voltage-difference comparison.
- Phase-to-phase
  The phase-to-phase voltages are used for the voltage-difference comparison.

NOTE

The **2 ph-to-ph volt. + VN** and **2 ph-to-ph voltages** connection types are not allowed.

Voltage-Failure Indication

For different connection types, the indications are different.

- Phase-to-ground
  You can get the voltage-failure information from the output signals *Main-voltage failure* and *Ref.-voltage failure*.
- Phase-to-phase
  - If one phase is influenced, the phase information is indicated.
  - If more than one phase is influenced, the phase-to-phase information is indicated.
    Take the main voltage transformer for example. You can determine the faulty phase with the following table.

Determination Criteria	Calculated Result		
(|vAB(n)ref.| - |vAB(n)main|) - 8 % Vrated	> 0	> 0	< 0
(|vBC(n)ref.| - |vBC(n)main|) - 8 % Vrated	< 0	> 0	> 0
(|vAC(n)ref.| - |vAC(n)main|) - 8 % Vrated	> 0	< 0	> 0
Failure Information	**Phase A is failed.**	**Phase B is failed.**	**Phase C is failed.**

Release Voltage

If the main positive-sequence voltage or the reference positive-sequence voltage is between 50 % Vrated and 130 % Vrated, the function is released.

Selection Invalid

An invalid measuring-point selection results in the following:

- The voltage measured values are displayed as ***Failure***.
- The validity of the voltage measured values is set to ***Invalid***.
- The indication *Health* is set to ***Alarm***.
- The indication *Selection invalid* becomes true.

Blocking of the Stage

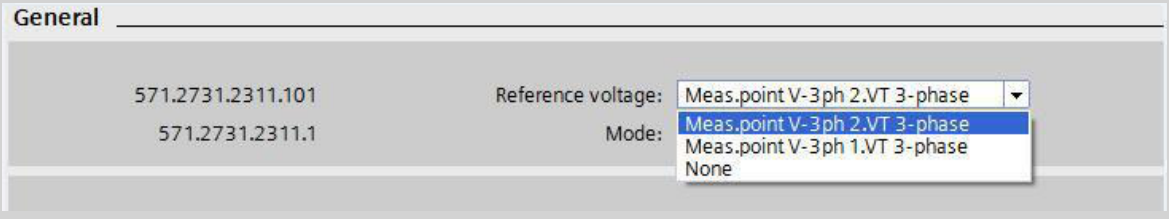
In the event of blocking, the picked up function is reset. Blocking is possible externally or internally via the binary input signal *>Block stage*.

6.48.3.2 Application and Setting Notes

Parameter: Reference voltage

- Default setting **Reference voltage** = ***None***

With the parameter **Reference voltage**, you can set a measured voltage as the reference voltage.



NOTE

You must assign a voltage measuring point to the parameter **Reference voltage**. The assignment influences the voltage-related protection functions which are used in the same FGs as the **Voltage-comparison supervision** function. These voltage-related protection functions use the unassigned voltage measuring point, which is defined as the main voltage in the **Voltage-comparison supervision** function. You can find more information in section *Voltage Selection, Page 1557*.

EXAMPLE

Meas.point V-3ph 1 and **Meas.point V-3ph 2** are connected to the **Voltage-comparison supervision** function. Then you have 2 more setting options, as shown in the following figure. You must select one of these setting options for the parameter **Reference voltage**.

[sc_VBS_ref_voltage, 1, en_US]

Parameter: Mode

- Default setting **(_:2311:1) Mode** = ***off***

With the parameter **Mode**, you can activate and deactivate the **Voltage-comparison supervision** function. If you switch to ***test*** mode, the **Voltage-comparison supervision** function is marked as invalid.

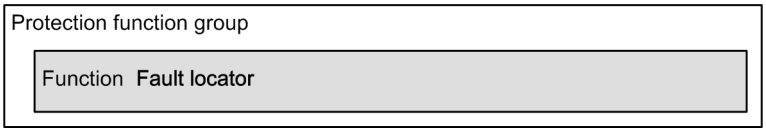
6.49 Fault Locator



6.49.1 Overview of Functions

The **Fault locator** function is used to determine the distance to the fault location.

Quick determination of fault location and the associated rapid troubleshooting increase the availability of the line for the power transmission in the electrical power system. Fault-location determination is based on the determination of the reactance of the short-circuited measuring loops.

6.49.2 Structure of the Function

The function **Fault locator** can be used in protection function groups with 3-phase current and voltage measurement.

[dw_stbafo, 1, en_US]

Figure 6-579 Structure/Embedding of the Function

The fault location is calculated based on the line parameter. The fault-location determination is always carried out ***with going pickup*** of the short-circuit protection. There is an option to limit the fault-location determination to cases with tripping (setting value for parameter **Start** = ***with operate***).

The fault locator can be started as follows:

- Via the phase-segregated binary inputs *>Fault detected phs A*, *>Fault detected phs B*, *>Fault detected phs C*, and *>Fault detected gnd.*
- Via the differential protection
- Via the distance protection
- Via the directional overcurrent protection, phases or ground
- Via the overcurrent protection, phases or ground
- Via the non-phase segregated binary input *>Flt. det. w/o phs.&gnd.*

If multiple protection functions are operating in parallel, the fault locator is only started by the protection-function pickup with the highest priority. The functions are listed in decreasing priority.

The **Fault locator** function only works with the following current and voltage-transformer connection types (see parameter value).

Parameter	Parameter Value
CT connection	• ***3-phase + IN-separate*** • ***3-phase + IN*** • ***3-phase*** • ***2ph, 2p. CT + 2 IN-sep***
VT connection	• ***3 ph-to-gnd volt. + VN*** • ***3 ph-to-gnd voltages***

NOTE

The **Fault locator** function does not work with all possible current and voltage transformer connection types. An error message is displayed in DIGSI 5 if the **Fault locator** function cannot work with the set connection types. In this case check the current and voltage transformer connection type. You will find the **`CT connection`** or **`VT connection`** parameters in DIGSI 5 under **Power system** → **Meas.point I-3ph** or **Power system** → **Meas.point V-3ph**.

6.49.3 Function Description

Starting Conditions

Each protection function that can start the fault locator also provides the **fault locator** with information on the pickup and tripping times. If multiple protection functions pick up at the same time, the **fault locator** is started only by the function with the highest priority. The pickup pattern for the other protection functions is discarded.

The fault locator uses the pickup and tripping information for the protection function being started to form its own measurand memory for the following calculations. Depending on the pickup duration of the protection function, the measurand memory is positioned such that it contains prefault processes, short-circuit processes, and switch-off processes. If the pickup lasts for a longer time, only the short-circuit processes and switch-off processes are recorded by the measurand memory. The fault-location determination always starts only after the dropout of the pickup.

Fault-location determination is also possible via the starting condition ***`with going pickup`***, if the protection device only picks up and does not trigger. Fault-location determination is then performed via the starting condition ***`with operate`*** only if the protection device has reported the tripping and the pickup has dropped out.

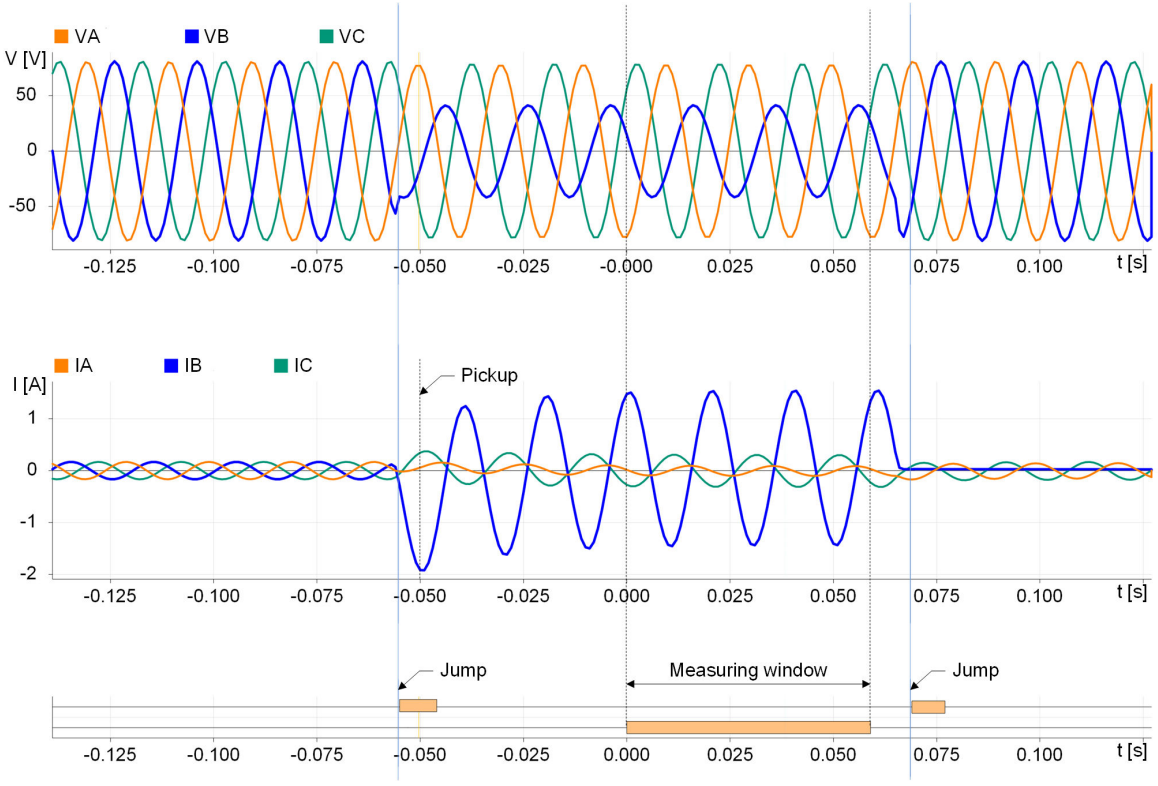
Alternatively, the **fault locator** can be started via one or more binary inputs. If the phase-segregated indications *`>Fault detected phs A`*, *`>Fault detected phs B`*, *`>Fault detected phs C`*, and *`>Fault detected gnd.`* are routed in the DIGSI 5 information routing, the **fault locator** interprets the binary inputs as a phase-segregated external protection function and treats them with the highest priority.

NOTE

The phase-segregated start of the fault locator is only possible if you have routed all 4 indications in the DIGSI 5 information routing.

When routing the binary input *`>Flt. det. w/o phs.&gnd.`*, the binary input is interpreted as a non-segregated external protection function and is treated with the lowest priority. The fault locator starts when the binary input drops out.

When the parameter ***`with operate`*** is set and the **fault locator** is started via the binary input, the fault-location determination is started only when a device-internal protection function generates an operate indication, or when the binary input *`>Fault locator start`* is activated in addition to the above mentioned binary inputs.



Fault locator	21.8671		*	*	*	*
>Fault detected phs A	21.8671.501	SPS	H			
>Fault detected phs B	21.8671.502	SPS		H		
>Fault detected phs C	21.8671.503	SPS			H	
>Fault detected gnd.	21.8671.504	SPS				H
>Flt. det. w/o phs.&gnd.	21.8671.505	SPS				
>Fault locator start	21.8671.506	SPS				

[sc_rout_BE, 1, en_US]

Figure 6-580 Routing Matrix for the Triggering of the Fault Locator via Binary Input

Determining Fault Location

The recorded sampled values of the short-circuit currents and voltages are transferred to an internal measurand memory. The pickup indications are used to determine the short-circuited loops. The measurand memory is searched for an optimal measurement window. The largest possible measurement window is selected. If possible, the measurement window is positioned at the end of the short-circuit process. This means that the transient response and the ring down have the least possible impact on the measuring result.

[dw_sigra_flo, 1, en_US]

Figure 6-581 Determining the Measurement Window

The impedances of the short-circuit loops are calculated of the measurement-window data. If there are multiple short-circuited loops, a selection process is used to select a loop and the results are then issued.

If it is not possible to determine a sufficient data window with usable measured values or a plausible short-circuited loop, the indication *FLO invalid* signals the invalid measuring result.

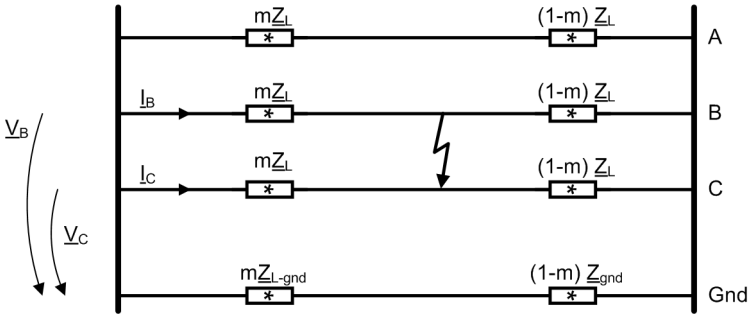
Output of the Fault Location

The following results for the fault location are output:

- The fault reactance X in Ω primary
- The fault resistance R in Ω primary
- The fault distance ***d*** of the line proportional to the reactance in kilometers or miles, converted on the basis of the parameterized reactance per unit length of the line
- The fault distance ***d*** as a percentage of the line length, calculated on the basis of the parameterized reactance per unit length and the parameterized line length
- The selected fault loop for calculation of the fault location

NOTE

The indication of distance in kilometers, miles, or percent is applicable only for homogeneous line sections. If the line comprises parts which exhibit different reactances per unit of length (for example, overhead-line-cable sections), you can then analyze the reactance determined from the fault location for separate calculation of the fault distance. Alternatively, you can use the **Fault locator plus** function, with which the non-homogeneous lines can be parameterized in line sections.



Impedance-Based Fault Location

The determination of the fault distance is based on the evaluation of the imaginary part of the calculated short-circuit impedance. The fault distance is determined by dividing the calculated reactance X with the parameterizable reactance per unit length (parameter **`X per length unit`**). Both the impedance up to the fault location and the fault distance are issued by the fault locator.

An impedance measuring element is available for each of the 6 possible short-circuit loops A-gnd, B-gnd, C-gnd, A-B, B-C, C-A. The loop to be measured is selected depending on the fault type.

For 2-phase short circuits with grounding, the phase-to-phase loop is preferred for fault location. For 3-phase short circuits, the average reactance, determined from the reactance of the 3 phase-to-phase loops is used.

A 2-phase short circuit B-C, for example, is used for the calculation of the phase-to-phase loop.

[dw_llschleife_flo, 1, en_US]

Figure 6-582 Short Circuit of a Phase-to-Phase Loop

The loop equation for the calculation of the short-circuit impedance of the phase-to-phase loop B-C is:

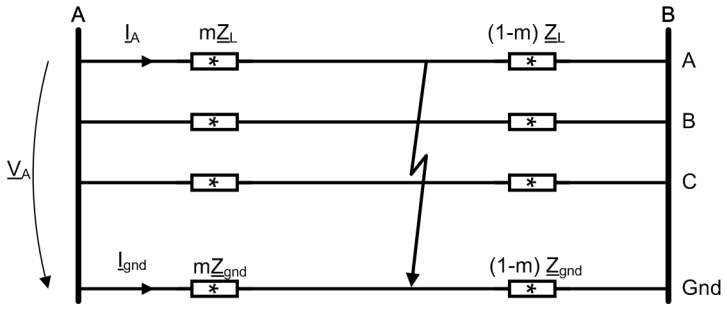
$$\underline{I}_A \cdot m \cdot \underline{Z}_L - \underline{I}_B \cdot m \cdot \underline{Z}_L = \underline{V}_A - \underline{V}_B$$

[fo_L2-L3_schl, 1, en_US]

With:

$\underline{V}_B$, $\underline{V}_C$	Short-circuit voltage phasor for phases B and C
$\underline{I}_B$, $\underline{I}_C$	Short-circuit current phasor phases B and C
m	Proportionate distance to the fault
$m\underline{Z}_L = m \cdot (R_L + jX_L)$	Line impedance up to fault location

The line impedance is calculated as follows:



$$R = \frac{\mathrm{Rgnd}(\underline{V}_A - \underline{V}_B) \cdot \mathrm{Rgnd}(\underline{I}_A - \underline{I}_B) + \mathrm{Im}(\underline{V}_A - \underline{V}_B) \cdot \mathrm{Im}(\underline{I}_A - \underline{I}_B)}{\left[\mathrm{Rgnd}(\underline{I}_A - \underline{I}_B)\right]^2 + \left[\mathrm{Im}(\underline{I}_A - \underline{I}_B)\right]^2}$$

[fo_R_L2-L3_schl, 1, en_US]

$$X = \frac{\mathrm{Im}(\underline{V}_A - \underline{V}_B) \cdot \mathrm{Rgnd}(\underline{I}_A - \underline{I}_B) - \mathrm{Rgnd}(\underline{V}_A - \underline{V}_B) \cdot \mathrm{Im}(\underline{I}_A - \underline{I}_B)}{\left[\mathrm{Rgnd}(\underline{I}_A - \underline{I}_B)\right]^2 + \left[\mathrm{Im}(\underline{I}_A - \underline{I}_B)\right]^2}$$

[fo_X_L2-L3_schl, 1, en_US]

In case of a phase-to-ground short circuit, for example, A-gnd, for the calculation of a phase-to-ground loop, it must be considered that the impedance of the ground-return path does not match the impedance of the phases.

[dw_leschleife_flo, 1, en_US]

Figure 6-583 Short Circuit of a Phase-to-Ground Loop

In case of A-gnd short circuit, the phase-to-ground voltage $\underline{V}_A$, the phase current $\underline{I}_A$ and the ground current $\underline{I}_{gnd}$ are measured.

$$\underline{V}_A = \underline{I}_A \cdot m \cdot (R_L + jX_L) - \underline{I}_{gnd} \cdot m \cdot (k_r \cdot R_L + jk_xX_L)$$

[fo_L1-E_schl, 1, en_US]

The impedance at the fault location is calculated as:

$$R = \frac{\mathrm{Rgnd}(\underline{V}_A) \cdot \mathrm{Rgnd}(\underline{I}_x) + \mathrm{Im}(\underline{V}_A) \cdot \mathrm{Im}(\underline{I}_x)}{\mathrm{Rgnd}(\underline{I}_R) \cdot \mathrm{Rgnd}(\underline{I}_x) + \mathrm{Im}(\underline{I}_R) \cdot \mathrm{Im}(\underline{I}_x)}$$

[fo_R_L1-E_schl, 1, en_US]

and

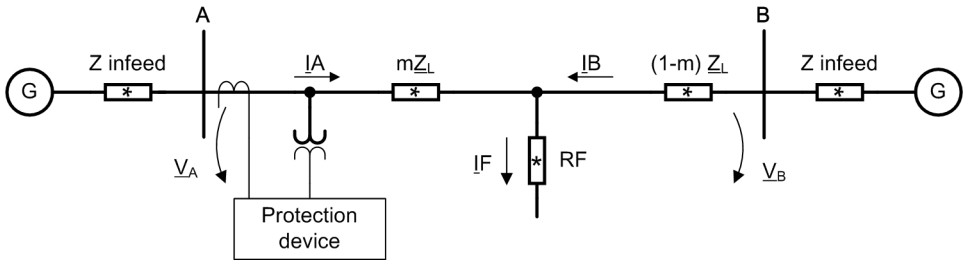
$$X = \frac{\mathrm{Im}(\underline{V}_A) \cdot \mathrm{Rgnd}(\underline{I}_R) - \mathrm{Rgnd}(\underline{V}_A) \cdot \mathrm{Im}(\underline{I}_R)}{\mathrm{Rgnd}(\underline{I}_R) \cdot \mathrm{Rgnd}(\underline{I}_x) + \mathrm{Im}(\underline{I}_R) \cdot \mathrm{Im}(\underline{I}_x)}$$

[fo_X_L1-E_schl, 1, en_US]

With:

$\underline{V}_A$	Short-circuit voltage phasor
$\underline{I}_A$	Short-circuit current phasor phase A
$\underline{I}_{gnd}$	Ground-fault current phasor
$\underline{I}_R = \underline{I}_A - k_r \cdot \underline{I}_{gnd}$	Auxiliary quantity
$\underline{I}_x = \underline{I}_A - k_x \cdot \underline{I}_{gnd}$	Auxiliary quantity

The factors $k_r = R_{gnd}/R_{ph}$ and $k_x = X_{gnd}/X_{ph}$ depend only on the line constants and not on the distance to the fault.



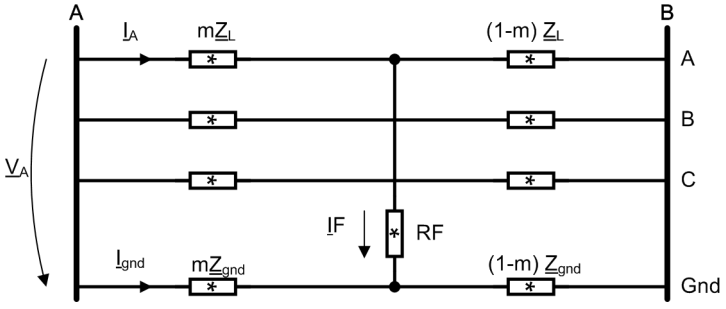
Measured-Value Correction at Load Current on Lines Fed on Both Sides

In the case of faults on lines fed on both sides and with load transport and contact resistance (see *Figure 6-584*), the fault voltage $\underline{V}_A$ is influenced not only by the voltage source on side A, but also by the voltage source on side B if both voltage sources feed to the fault location. Without special measures, this leads to measuring errors in the impedance, since the current portion $\underline{I}_B$ cannot be recorded at measuring point A. For long and highly loaded lines, this measuring error in the X portion of the fault impedance can be considerable. This X component is critical for the distance calculation.

The X component can be corrected when using load compensation. When using load compensation, the calculated R component comprises the combination of the fault resistance to be determined and the resistance of the line up to the fault location. This form of impedance calculation corresponds to the distance-protection

measurement protocol using the reactance method. The load compensation impacts both the 1-pole short circuit and the 2-pole short circuit. You can activate and deactivate the load compensation via the parameter **`Load compensation`**. If the distance protection operates with the reactance method, Siemens recommends switching on the load compensation for the fault locator too.

The following figure serves as an example of the description of the impedance calculation:



[dw_ueb_impedanzber, 2, en_US]

Figure 6-584 Fault Currents and Voltages of a Line Fed on Both Sides (1-Pole Display)

A	Measuring point
$\underline{V}_A$, $\underline{V}_B$	Voltage source
$\underline{I}_A$, $\underline{I}_B$	Partial fault currents
$\underline{I}_F$	Total fault current
$\underline{V}_A$	Fault voltage at measuring point A
RF	Common fault resistance
$\underline{Z}_L$, (1-m) $\underline{Z}_L$	Fault impedances
$\underline{Z}_A$, $\underline{Z}_B$	Source impedances
m	Proportionate distance to the fault

Impedance Calculation for Phase-to-Ground Loops

For calculation of a phase-to-ground loop, it must be considered that the impedance of the ground-return path generally does not match the impedance of the phases. This is the case, for example, for an A-gnd short circuit.

[dw_leschleife_rmd, 2, en_US]

Figure 6-585 Short Circuit of a Phase-to-Ground Loop

The loop equation for calculating the impedance is:

$$\underline{V}_A = m \cdot \underline{Z}_L \cdot (\underline{I}_A - \underline{k}_0 \cdot \underline{I}_{Gnd}) + RF \cdot \underline{I}F$$

[fo schl le ohne icomp, 3, en_US]

The loop equation is extended with the equivalent current $\underline{I}_{Subst.}$ on both sides and converted according to the impedance.

$$m \cdot |\underline{Z}_L| = \frac{\mathrm{Im}\{\underline{V}_A \cdot [\underline{I}_{Subst.} \cdot e^{j\delta_{comp}}]^*\}}{\mathrm{Im}\{\underline{Z}_L/|\underline{Z}_L| \cdot (\underline{I}_A - \underline{k}_0 \cdot \underline{I}_{gnd}) \cdot [\underline{I}_{Subst.} \cdot e^{j\delta_{comp}}]^*\}}$$

[fo schl le mit icomp, 4, en_US]

The following applies:

$$X = m \cdot |Z_L| \cdot \sin\varphi$$

[fo_x_impber, 1, en_US]

The reactance **X** of the phase-to-ground loop is calculated as follows:

$$X = \frac{\mathrm{Im}\{\underline{V}_A \cdot [\underline{I}_{Subst.} \cdot e^{j\delta_{comp}}]^*\}}{\mathrm{Im}\{\underline{Z}_L/|Z_L| \cdot (\underline{I}_A - \underline{k}_0 \cdot \underline{I}_{Gnd}) \cdot [\underline{I}_{Subst.} \cdot e^{j\delta_{comp}}]^*\}} \cdot \sin\varphi$$

[fo xf impber, 2, en_US]

With:

A	Measuring point
$\underline{V}_A$,	Fault voltage at measuring point A (phase-to-ground voltage)
$\underline{I}_A$, $\underline{I}_{Gnd}$	Partial fault currents
$\underline{I}_F$	Total fault current
RF	Common fault resistance
$\underline{Z}_L$, $\underline{Z}_B$	Line impedance
m	Proportionate distance to the fault
$\underline{I}_{Subst.}$	Equivalent current
$\underline{k}_0$	Ground-fault factor
δ_{Comp}	Compensation angle

You can select the equivalent current $\underline{I}_{Subst.}$ such that the impact of the fault current $\underline{I}_B$ is compensated at the fault resistance R_F. This prevents the measuring error in the reactance.

The resulting measuring error in RF can be compensated only partially.
RF is calculated as follows:

$$R = \frac{\mathrm{Im}\{\underline{V}_A \cdot [\underline{Z}_L \cdot (\underline{I}_A - \underline{k}_0 \cdot \underline{I}_{gnd})]^*\}}{\mathrm{Im}\{\underline{I}_F \cdot [\underline{Z}_L \cdot (\underline{I}_A - \underline{k}_0 \cdot \underline{I}_{gnd})]^*\}} + X \cdot \mathrm{ctg}(\varphi)$$

[fo_rf_impber, 4, en_US]

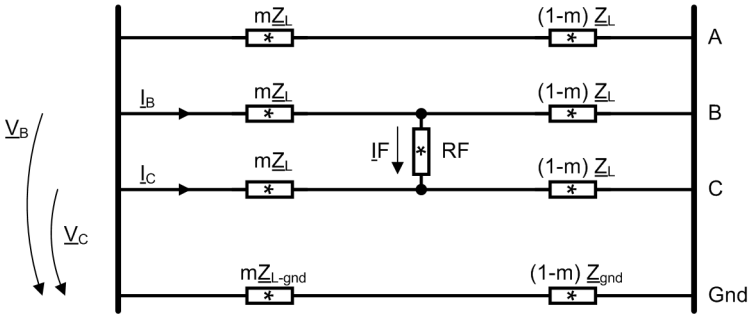
The protection device cannot measure the fault current $\underline{I}_F$ directly. Therefore, either $3\underline{I}_0$ or $3\underline{I}_2$ is used as an equivalent for $\underline{I}_F$. In order to achieve the best result, the procedure uses the larger one of the 2 equivalent currents. If the angles of the source impedances and the line impedance are not equal, you can compensate the inhomogeneity using the compensation angles.

The compensation angles δ_{comp} depend on the network conditions and can be calculated for the zero and negative-sequence system using the following formulas:

$$\delta_{comp,0} = \arg\left(\frac{\underline{Z}_{A,0} + \underline{Z}_{B,0} + \underline{Z}_{L,0}}{(1-m)\underline{Z}_{L,0} + \underline{Z}_{B,0}}\right)$$

[fo_kompwi_nullsys_impber, 1, en_US]

$$\delta_{comp,2} = \arg\left(\frac{\underline{Z}_{A,2} + \underline{Z}_{B,2} + \underline{Z}_{L,2}}{(1-m)\underline{Z}_{L,2} + \underline{Z}_{B,2}}\right)$$



[fo_kompwi_gegensys_impber, 1, en_US]

With:

$\underline{Z}_{A,0}$, $\underline{Z}_{B,0}$	Source impedances in zero-sequence system
$\underline{Z}_{L,0}$	Line impedance in zero-sequence system
m	Proportionate distance to the fault
$\delta_{comp,0}$	Compensation angle in zero-sequence system
$\underline{Z}_{A,2}$, $\underline{Z}_{B,2}$	Source impedances in negative-sequence system
$\underline{Z}_{L,2}$	Line impedance in negative-sequence system
$\delta_{comp,2}$	Compensation angle in negative-sequence system

Impedance Calculation for Phase-to-Phase Loops

A 2-phase short circuit B-C is assumed as an example for the calculation:

[dw_llschleife_rmd, 3, en_US]

Figure 6-586 Short Circuit of a Phase-to-Phase Loop

The loop equation for the calculation of the phase-to-phase loop is:

$$\underline{V}_{BC} = m \cdot \underline{Z}_L \cdot (\underline{I}_B - \underline{I}_C) + RF \cdot \underline{I}F$$

[fo schl II ohne icomp, 2, en_US]

Thus, **X** is calculated as follows:

$$X = \frac{\mathrm{Im}\left\{\underline{V}_{BC} \cdot \left[\underline{I}_{subst} \cdot e^{j\delta_{comp}}\right]^*\right\}}{\mathrm{Im}\left\{\underline{Z}_L / |\underline{Z}_L| \cdot (\underline{I}_B - \underline{I}_C) \cdot \left[\underline{I}_{subst} \cdot e^{j\delta_{comp}}\right]^*\right\}} \cdot \sin\varphi$$

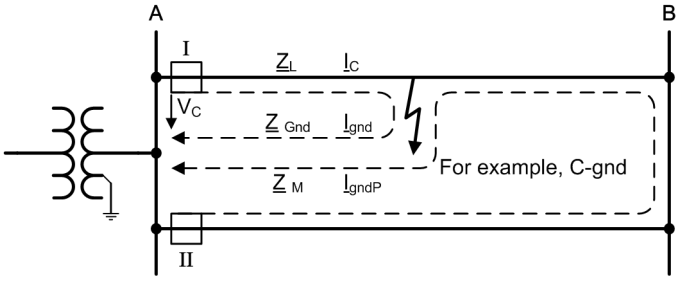
[fo xf impber LLschl, 2, en_US]

Whereby the following applies for the B-C loop: $\underline{I}_{subst} = (\underline{a} - \underline{a}^2) \cdot \underline{I}_2$ and $\underline{a} = e^{j120°}$.

The rotation of the negative-sequence system, which is dependent on the fault loop, performs the fault-locator algorithm internally.

RF is calculated as follows:

$$R = \frac{\mathrm{Im}\left\{\underline{V}_{BC} \cdot \left[\underline{Z}_L \cdot (\underline{I}_B - \underline{I}_C)\right]^*\right\}}{\mathrm{Im}\left\{2 \cdot \underline{I}_{subst} \cdot \left[\underline{Z}_L \cdot (\underline{I}_B - \underline{I}_C)\right]^*\right\}} + X \cdot \mathrm{ctg}(\varphi)$$



[fo rf impber LLschl, 4, en_US]

Measured-Value Correction for Parallel Lines

For ground faults on double lines, the values determined for the impedance calculation are influenced by the coupling of the ground impedances of both line systems. Without special measures, this leads to measuring errors in the impedance-calculation result. The device is therefore equipped with parallel-line compensation. This parallel-line compensation considers the ground current of the parallel line in the line equation and thereby compensates the coupling influence, similar to the determination of the distance in distance protection. To this end, you must connect the ground current of the parallel line to the device and configure it. The parallel-line compensation only provides correct values for 1-phase short circuits on the line to be protected.

Compensation is not possible for faults located externally, including those on the parallel line, and does not improve the measured values.

You can activate and deactivate the parallel-line compensation with the parameter **`Parallel-line compensat.`**. Furthermore, the parallel-line compensation is only released, if the ratio between the calculated ground current $\underline{I}_{gnd}$ of the particular line and the ground current of the parallel line $\underline{I}_{gndP}$ is above the parameterized threshold **`Gnd.curr.ratio(MutComp)`**.

[dw_parkomp_L3-E, 1, en_US]

Figure 6-587 Ground Fault on a Double Line

The impact of the parallel-line compensation is calculated as follows:

Calculation without load-current compensation:

$$\underline{V}_C = \underline{I}_C \cdot m \cdot \underline{Z}_L - \underline{I}_{gnd} \cdot m \cdot \underline{Z}_{gnd} - \underline{I}_{gndP} \cdot m \cdot \underline{Z}_{0M}/3$$

[fo_parkomp1, 1, en_US]

$$\underline{V}_C = \underline{I}_C \cdot m \cdot (R_L + jX_L) - \underline{I}_{gnd} \cdot m \cdot (k_r \cdot R_L + jk_x \cdot X_L) - I_{gndP} \cdot m \cdot (k_{mR} \cdot R_L + jk_{mX} \cdot X_L)$$

[fo_parkomp2, 1, en_US]

I_{gndP} is the ground current of the parallel line. The ratios $k_{mR} = R_{0M}/3R_{ph}$ and $k_{mx} = X_{0M}/3X_{ph}$ are line constants that result from the geometry of the double line and the suitability of the grounding.

Calculation with load-current compensation:

$$\underline{V}_C = \underline{I}_C \cdot m \cdot \underline{Z}_L - \underline{I}_{gnd} \cdot m \cdot \underline{Z}_{gnd} - \underline{I}_{gndP} \cdot m \cdot \underline{Z}_{0M}/3 + R_F \cdot \underline{I}_F$$

[fo_parkomp1_rmd, 1, en_US]

$$\underline{V}_C = m \cdot \underline{Z}_L\left(\underline{I}_C - \underline{I}_{gnd} \cdot \underline{k}_0 - \underline{I}_{gndP} \cdot \underline{k}_{0M}\right) + R_F \cdot \underline{I}_F$$

[fo_parkomp2_rmd, 1, en_US]

The factor $\underline{k}_{0M} = \underline{Z}_{0M}/(3\underline{Z}_{ph})$ is a line constant that results from the geometry of the double line and the suitability of the grounding.

With:

$\underline{Z}_{0M}$	Coupling impedance in zero-sequence system
R_{0M}	Coupling resistance in zero-sequence system
X_{0M}	Coupling reactance in zero-sequence system
$\underline{k}_{0M}$	Coupling factor in zero-sequence system

6.49.4 Application and Setting Notes

The function requires the following key line data to calculate fault distance:

- Reactance per unit length of the line per kilometer or per mile
- Line length for the correct output of the fault distance as a percentage of the line length
- Residual-compensation factors in the setting format **Kr** and **Kx** or **K0** and **Angle (K0)**.

Parameter: Start

- Recommended setting value **(_:101) Start** = ***with going pickup***

The **Start** parameter is used to define the criterion for starting the fault location.

Parameter Value	Description
with going pickup	If a pickup signal of the protection functions designated for the start has dropped out, the fault-location determination starts.
with operate	If one of the protection functions designated for start has reported the tripping and the pickup has dropped out, the fault-location determination starts.

As an alternative, the fault locator can be started using external binary input.

Parameter: Parallel-Line Compensation

- Default setting **(_:102) Parallel-line compensat.** = ***no***

The parameter **Parallel-line compensat.** is only visible if the ground current of the parallel line is connected to the **Line** function group.

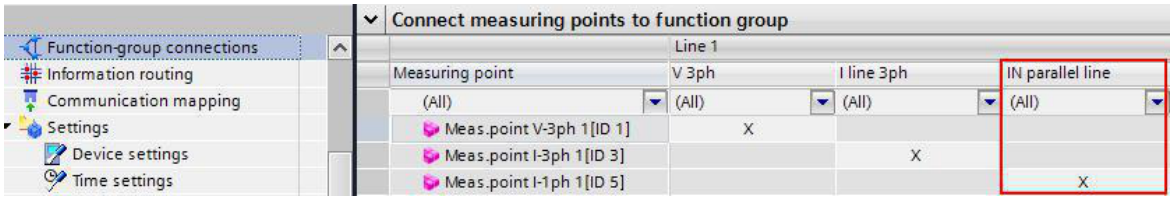


Figure 6-588 Routing in DIGSI

If you wish to apply the parallel-line compensation for double lines, set the **Parallel-line compensat.** parameter to ***yes***.

Parameter Value	Description
no	The parallel-line compensation does not become effective with this setting.
yes	The parallel-line compensation becomes effective with this setting.

The following conditions have to be fulfilled so that the parallel-line compensation functions:

- Connect the ground current of the parallel line in the correct polarity to an additional current input.
- Set the input used for the parallel current in the correct ratio to the phase currents for the power-system data.

  The parallel-line compensation is carried out only if the ground current of the line to be protected (I_{gnd}) is greater than the ground current of the parallel line (I_{gndP}) evaluated with the parameter **Gnd.curr.ratio(MutComp)**.

  Siemens recommends keeping the default setting **Gnd.curr.ratio(MutComp)** = ***85*** **%** . In highly unbalanced system conditions and if the coupling factor is very small (XM/XL less than 0.4), a smaller value may be advisable.
- Set the coupling impedances to the parallel system for the line data.

Parameter: Load Compensation

- Default setting **(_:103) Load compensation** = ***no***

With the **Load compensation** parameter, you can correct measuring errors for 1-phase and 2-phase short circuits on lines fed on both sides.

Parameter Value	Description
no	The load compensation does not become effective with this setting.
yes	The load compensation becomes effective with this setting. If you use the load compensation, the following parameters are relevant and are shown automatically: • **(_:104) Substitute for IF** • **(_:106) Comp. angle zero seq.** • **(_:107) Comp. angle neg. seq.** If the distance protection operates with the reactance method, Siemens recommends switching on the load compensation.

Parameter: Substitute for IF

- Default setting **(_:104) Substitute for IF** = ***3I0***

The parameter **Substitute for IF** is only visible and relevant if you use the load compensation.

With the **Substitute for IF** parameter, for ground-impedance loops, you define which substitute value to use at the fault location for the fault current IF that cannot be measured due to the fault resistance.

First, calculate the compensation angles for the zero-sequence system and the negative-sequence system. Set the parameter **Substitute for IF** according to the smaller compensation angle. The smaller compensation angle indicates that the associated system (zero-sequence or negative-sequence system) is more homogeneous and that the fault current can be approximated in a better way through the fault resistance at the fault location.

Parameter: Compensation Angle for Zero-Sequence System/Negative-Sequence System

- Default setting **(_:106) Comp. angle zero seq.** = ***0.00°***
- Default setting **(_:107) Comp. angle neg. seq.** = ***0.00°***

The parameters **Comp. angle zero seq.** and **Comp. angle neg. seq.** are only visible and relevant if you use the load compensation.

If you have determined an angle difference between the measured $3I_0$ or $3I_2$ and I_F based on network model tests or calculations, you can compensate this with the parameters **Comp. angle zero seq.** or parameter **Comp. angle neg. seq.**.

A setting of the compensation angle deviating from 0 is only relevant for non-homogeneous systems.

With the **Comp. angle zero seq.** parameter, you compensate the angle difference between the $3I_0$ calculated by the device and the fault current I_F.

With the **Comp. angle neg. seq.** parameter, you compensate the angle difference between the $3I_2$ calculated by the device and the fault current I_F.

NOTE

If you use the **Fault locator** function in the **Line** function group, the function operates with the line parameters of the function group.

If you use the **Fault locator** function in the **Voltage/current 3-phase** function group, you must enter the following line parameters in the **Voltage/current 3-phase** function group.

Parameter: X per length unit

- Default setting **(_:113) X per length unit** = *0.0525 Ω/km*

With the **X per length unit** parameter, you set the reactance per unit length for the line to be protected. You set the **X per length unit** parameter as a relative value in Ω/km or Ω/miles.

Parameter: Line length

- Default setting **(_:114) Line length** = *60 km*

With the **Line length** parameter, you can set the length of the line to be protected as a unit of length in km or miles.

Parameter: Line angle

- Default setting **(_:108) Line angle** = *85.00°*

Calculate the setting value for the parameter **Line angle** from the line constants for the line to be protected as follows:

$$\tan\varphi = \frac{X_L}{R_L} \qquad \text{or} \qquad \varphi = \arctan\left(\frac{X_L}{R_L}\right)$$

[fo_lwinkl, 1, en_US]

where:

R_L	Resistance of the line to be protected
X_L	Reactance of the line to be protected

EXAMPLE

110-kV overhead line, 150 mm² with the data

$R'_1 = 0.19\ \Omega/\text{km}$

$X'_1 = 0.42\ \Omega/\text{km}$

You calculate the setting value for the line angle as follows:

$$\tan\varphi = \frac{X_L}{R_L} = \frac{X'_1}{R'_1} = \frac{0.42\ \Omega/\text{km}}{0.19\ \Omega/\text{km}} = 2.21$$

[fo_tan_phi, 1, en_US]

$$\arctan(2.21) = 65.7°$$

[fo_arctan_phi, 1, en_US]

Parameter: Kr and Kx

- Default setting **(_:104) Kr** = *1.00*
- Default setting **(_:105) Kx** = *1.00*

The **Kr** and **Kx** parameters are used to set the residual compensation factors as scalar values. The **Kr** and **Kx** parameters are relevant for the **Fault locator** function.

Calculate the setting values for the parameters **Kr** and **Kx** from the line data as follows:

Resistance ratio	Reactance ratio
$Kr = \frac{R_{gnd}}{R_L} = \frac{1}{3} \cdot \left(\frac{R_0}{R_1} - 1\right)$	$Kx = \frac{X_{gnd}}{X_L} = \frac{1}{3} \cdot \left(\frac{X_0}{X_1} - 1\right)$

where:

R_0	Zero-sequence system resistance of the line
X_0	Zero-sequence system reactance of the line
R_1	Positive-sequence system resistance of the line
X_1	Positive-sequence system reactance of the line

This data can either be used for the entire line or as length-related values, since the quotients are length-independent. You can calculate the data both from the primary values and from the secondary values.

EXAMPLE

110-kV overhead line, 150 mm² with the data:

R_1/s	0.19 Ω/km positive-sequence system resistance
X_1/s	0.42 Ω/km positive-sequence system reactance
R_0/s	0.53 Ω/km zero-sequence system resistance
X_0/s	1.19 Ω/km zero-sequence system reactance
s	Line length

You receive the following setting values for the parameters **Kr** and **Kx**:

$$k_r = \frac{R_{Gnd}}{R_L} = \frac{1}{3} \cdot \left(\frac{R_0}{R_1} - 1\right) = \frac{1}{3} \cdot \left(\frac{0.53\ \Omega/km}{0.19\ \Omega/km} - 1\right) = 0.60$$

[fo_kr, 1, en_US]

$$k_x = \frac{X_{Gnd}}{X_L} = \frac{1}{3} \cdot \left(\frac{X_0}{X_1} - 1\right) = \frac{1}{3} \cdot \left(\frac{1.19\ \Omega/km}{0.42\ \Omega/km} - 1\right) = 0.61$$

[fo_kx, 1, en_US]

Parameter: K0 and Angle (K0)

- Default setting **K0** = ***1.000***
- Default setting **Angle (K0)** = ***0.00°***

NOTE

The visibility of the **K0** and **Angle (K0)** parameters depends on the selected setting format of the residual compensation factors. The parameters **K0** and **Angle (K0)** are only visible if you have set the parameter **Set. format residu. comp.** = ***K0*** for the device. The **Set. format residu. comp.** parameter can be found in the DIGSI 5 project tree under **Name of the device** → **Parameter** → **Device settings**.

The **K0** and **Angle (K0)** parameters are used to set the complex grounding-resistance factor.

Make sure that the line angle is set correctly because the device needs the line angle for calculation of the compensation components from the K0 factor. The complex grounding-resistance factor is defined by the value and the angle. You can calculate the complex grounding-resistance factor from the line data as follows:

$$K_0 = \left|\frac{\underline{Z}_{Gnd}}{\underline{Z}_L}\right| = \left|\frac{1}{3} \cdot \left(\frac{\underline{Z}_0}{\underline{Z}_1} - 1\right)\right|$$

[fo_K01, 1, en_US]

where:

$\underline{Z}_0$	(Complex) zero-sequence impedance
$\underline{Z}_1$	(Complex) positive-sequence impedance

This data can either be used for the entire line or as length-related values, since the quotients are length-independent. You can calculate the data both from the primary values and from the secondary values.

For overhead lines, you can use the values for the calculation because the angles of the zero-sequence system and the positive-sequence system differ only slightly. For cables, however, significant angular differences can occur, as the following example illustrates.

EXAMPLE

110-kV single-conductor liquid-filled cable 3 · 185 mm² Cu with the data:

$\underline{Z}_1/s$	$0.408 \cdot e^{j73^\circ}$ Ω/km positive-sequence impedance
$\underline{Z}_0/s$	$0.632 \cdot e^{j18.4^\circ}$ Ω/km zero-sequence impedance
s	Line length

The values for calculation of the grounding-resistance factor **K0** are:

$$\frac{\underline{Z}_0}{\underline{Z}_1} = \frac{0.632}{0.408} \cdot e^{j(18.4^\circ - 73^\circ)} = 1.55 \cdot e^{-j\,54.6^\circ} = 1.55 \cdot (0.579 - j\,0.815) = 0.898 - j\,1.263$$

[fo_1_k0, 1, en_US]

$$k_0 = \left|\frac{1}{3} \cdot \left(\frac{\underline{Z}_0}{\underline{Z}_1} - 1\right)\right| = \left|\frac{1}{3} \cdot (0.898 - j\,1.263 - 1)\right| = \left|\frac{1}{3} \cdot (-0.102 - j\,1.263)\right|$$

[fo_2_k0, 1, en_US]

The setting value of the parameter **K0** is calculated from:

$$k_0 = \left|\frac{1}{3} \cdot \sqrt{(-0.102^2) + (-1.263^2)}\right| = 0.42$$

[fo_3_k0, 1, en_US]

When determining the angle, take note of the quadrant of the result. The following table lists the quadrants and the angle range obtained from the operational signs of the real and imaginary parts of **K0**.

Real Part	Imaginary Part	tan Phi (K0)	Quadrant/Range		Calculation Method
+	+	+	I	0° to 90°	arc tan (|Im| / |Re|)
+	-	-	IV	-90° to 0°	–arc tan (|Im| / |Re|)
-	-	+	III	-90° to -180°	arc tan (|Im| / |Re|) –180°
-	+	-	II	+90° to +180°	–arc tan (|Im| / |Re|) +180°

In this example, the following setting value for the **Angle (K0)** parameter is obtained:

$$\varphi(K_0) = \arctan\left(\frac{1.263}{0.102}\right) - 180^\circ = -94.6^\circ$$

[fo_phi_K0, 1, en_US]

6.49.5 Settings

Settings for the Instantiation of the Fault Locator in the Line Function Group

Addr.	Parameter	C	Setting Options	Default Setting

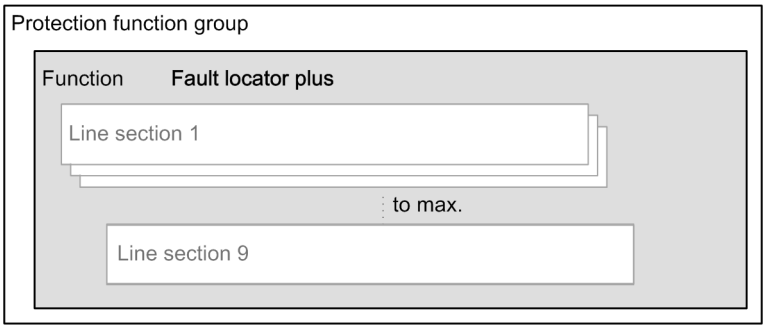
6.50 Fault Locator Plus

6.50.1 Overview of Functions

The **Fault locator plus** function

- Is used for 2-sided measurement of the distance to the fault location
- Also reliably detects the fault location with 2-sided infeed, faults with ground involvement and with fault resistances
- Can be used for fault-location determination with non-homogeneous lines



The **Fault locator plus** function calculates the fault location with the measured values of both line ends. For the transmission of the measured values between the line ends, a communication connection must be present via the protection interface.

If 2-sided fault-location determination is not possible, alternatively, the 1-sided method is used with a calculation of the reactance of the short-circuited measurement loops.

Fast fault-location determination and the associated fast fault clearance increase the availability of the line for power transmission in the electrical power system.

6.50.2 Structure of the Function

The **Fault locator plus** function can be used in protection function groups with 3-phase current and voltage measurement.

[dwst fo_double, 1, en_US]

Figure 6-589 Structure/Embedding of the Function

The fault location is calculated based on the line parameters. Fault-location determination is always carried out ***with going pickup*** of the short-circuit protection. There is an option to limit fault-location determination to cases with tripping (setting the value for the parameter **Start** = ***with operate***).

For inhomogeneous lines, such as overhead line/cable sections, you can set parameters for separate line sections with dedicated line data. You can instantiate a maximum of 9 line sections.

For 2-sided fault-location determination, the measured values of both line ends must to be available at each line end. For this purpose, a SIPROTEC 5 device must be installed with a protection interface at each end of the area to be protected. The devices exchange their measurands via protection interface. The measurands are encrypted in digital telegrams and transmitted via protection communication. The current and voltage transformers selectively delimit the protection range.

2-sided fault-location determination is not possible with the function **Fault locator plus** under the following conditions, for example:

- The fault is not located on the line.
- The devices at the line ends do not have a protection interface.

- Protection communication is disrupted.
- With a 1-sided infeed, a metallic fault occurs.

NOTE

If 2-sided fault-location determination is not possible, the function **Fault locator plus** alternatively works with the 1-sided method for fault-location determination.

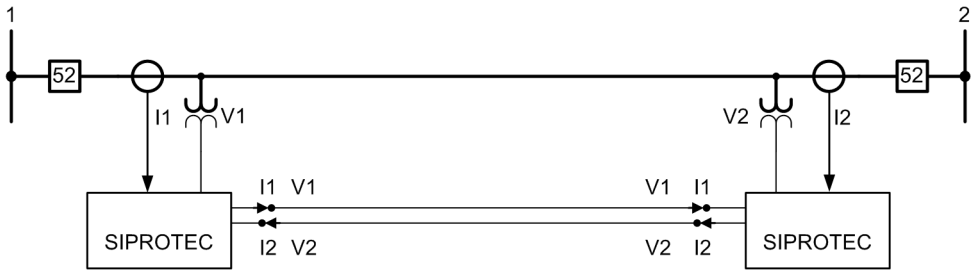


Figure 6-590 Data Exchange for 2 Devices, Each With Protection Communication

Fault locator plus can be started as follows:

- Via the phase-segregated binary inputs *>Fault detected phs A*, *>Fault detected phs B*, *>Fault detected phs C*, and *>Fault detected gnd.*
- Via differential protection
- Via distance protection
- Via directional overcurrent protection, phases or ground
- Via overcurrent protection, phases or ground
- Via the non-phase-segregated binary input *>Flt. det. w/o phs.&gnd.*

If multiple protection functions are operating in parallel, the fault locator is only started by the function pickup with the highest priority. The functions are listed in decreasing priority.

Connection Types of the Current and Voltage Transformers

NOTE

The function **Fault locator plus** does not work with all possible current and voltage transformer connection types.

An error message is displayed in DIGSI 5 if the function cannot work with the set connection type. In this case, check the current and voltage transformer connection type.

You can find the **CT connection** or **VT connection** settings in DIGSI 5 under **Power system** → **Meas.point I-3ph** or **System data** → **Meas.point V-3ph**.

The **Fault locator plus** function only works with the following current and voltage transformer connection types (see parameter value).

Parameter	Parameter Value
CT connection	• ***3-phase + IN-separate*** • ***3-phase + IN*** • ***3-phase***
VT connection	• ***3 ph-to-gnd volt. + VN*** • ***3 ph-to-gnd voltages***

6.50.3 Function Description

Starting Conditions

Each protection function that can start the fault locator also provides **Fault locator plus** with information on the pickup and tripping times. If multiple protection functions pick up at the same time, **Fault locator plus** is started only by the function with the highest priority.

The fault locator uses the pickup and tripping information for the protection function being started to form its own measurand memory for the following calculations. Depending on the pickup duration of the protection function, the measurand memory is positioned such that it contains prefault processes, short-circuit processes, and switch-off processes. If the pickup lasts for a longer time, only the short-circuit processes and switch-off processes are recorded by the measurand memory. The fault-location determination always starts only after the dropout of the pickup.

Fault-location determination is also possible via the starting condition ***with going pickup***, if the protection device only picks up and does not trigger. Fault-location determination is then performed via the starting condition ***with operate*** only if the protection device has reported the tripping and the pickup has dropped out.

Alternatively, the **Fault locator** can be started via one or more binary inputs. If the phase-segregated indications *>Fault detected phs A*, *>Fault detected phs B*, *>Fault detected phs C*, and *>Fault detected gnd.* are routed in the DIGSI 5 information routing, the **Fault locator** interprets the binary inputs as a phase-segregated external protection function and treats them with the highest priority.

NOTE

The phase-segregated start of the fault locator will only be possible if you have routed all 4 indications in the DIGSI 5 information routing.

When routing the binary input *>Flt. det. w/o phs.&gnd.*, the binary input is interpreted as a non-segregated external protection function and is treated with the lowest priority. The fault locator starts when the binary input drops out.

When the parameter ***with operate*** is set and the **Fault locator** is started via the binary input, the fault-location determination is started only when a device-internal protection function generates an operate indication, or when the binary *>Fault locator start* input is activated in addition to the above mentioned binary inputs.

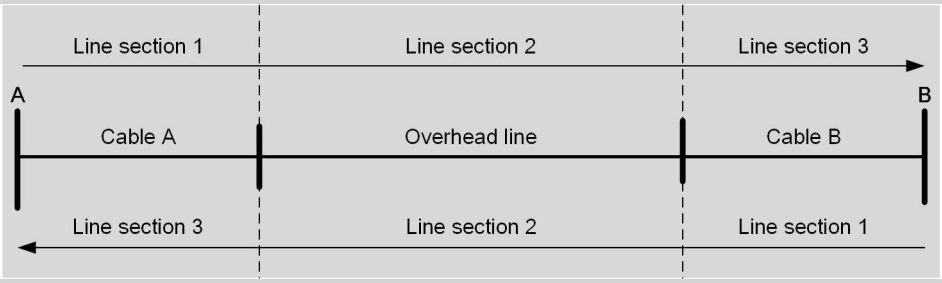
[scRang_FOplus, 1, en_US]

Figure 6-591 Routing Matrix for the Triggering of the Fault Locator via Binary Input

Definition of the Line Sections

For inhomogeneous lines, for example, cable/overhead line setions, you can define several line sections and set the line parameters separately for each line section.



NOTE

If you have an inhomogeneous line with several line sections, you must enter the line sections in the device at the opposite end back-to-front. The function checks the correct parameter configuration and issues the inconsistency indication *(_:2311:310) Line sect. setting err.* in the case of a fault.

EXAMPLE:

The line between line ends **A** and **B** consists of the line sections Cable **A** – overhead line – Cable **B**. Consider the following with the parameter configuration of the function:

- Instantiate each of 3 line ends in the device at line end **A** and at line end **B** and enter the line data for each section.
- Ensure that you enter the data for the line sections in device **B** back-to-front to device **A**.

[dw def line sections, 1, en_US]

Figure 6-592 Line with 3 Line Sections

Installation Site	Definition of Line Sections
Device **A**	Define the line sections on device **A** as follows: • Line section **1**: Line data from cable **A** • Line section **2**: Line data from the overhead line • Line section **3**: Line data from cable **B**
Device **B**	Define the line sections on device **B** as follows: • Line section **1**: Line data from cable **B** • Line section **2**: Line data from the overhead line • Line section **3**: Line data from cable **A**

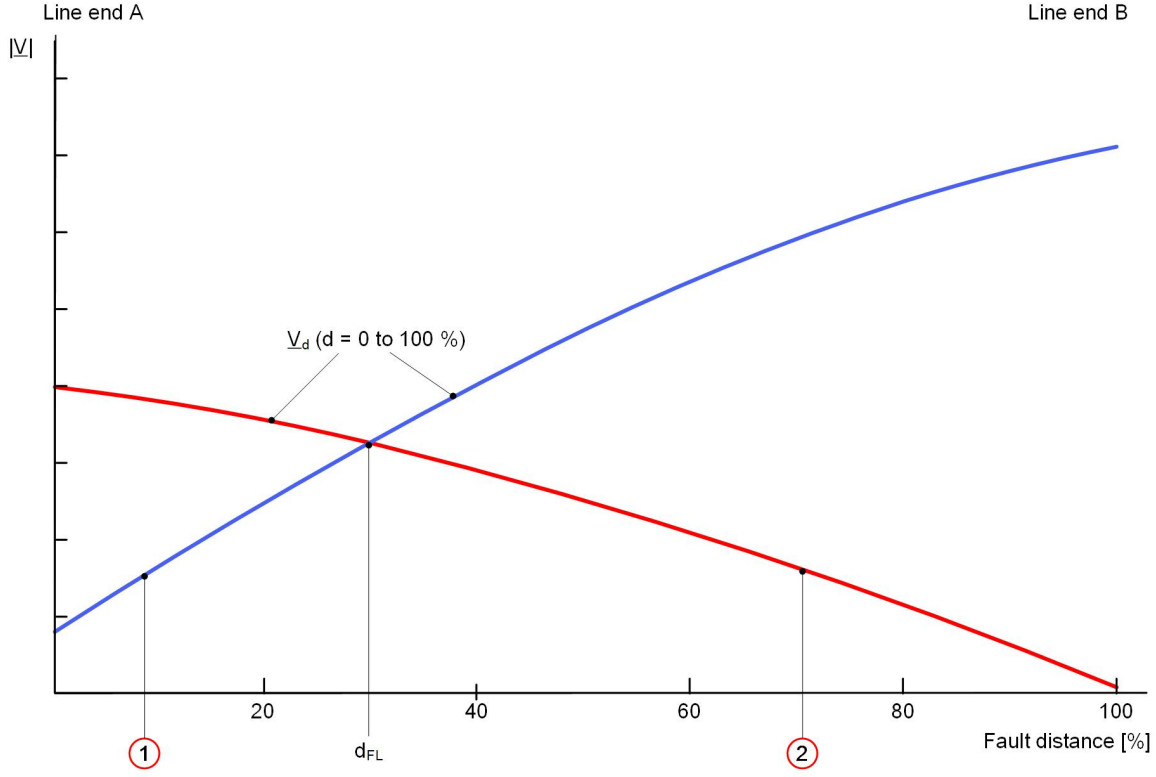
You can rename the instantiated line sections.

Algorithm for 2-Sided Fault-Location Determination

For an unbranched line with known current and known voltage on the line ends, the voltage can be calculated at any position x of the line. The algorithm calculates the voltage of both sides of the line. At the fault location itself, the voltage calculated from both line ends must correspond. If both voltage curves are displayed graphically, their intersection is the position of the fault location $\mathbf{d_{FL}}$. *Figure 6-593* illustrates the basic principle of 2-sided fault-location determination. The algorithm calculates the voltage curves with the measured data of the protection devices of both line ends **A** and **B**. The voltage curve is not linear and is calculated as follows with the telegraph equation:

$$\underline{V}_d(d) = \cosh\left(\underline{\gamma} \cdot d\right) \cdot \underline{V} - \underline{Z} \cdot \sinh(\underline{\gamma} \cdot d) \cdot I$$

[fo telegraph equation line, 1, en_US]



with

$\underline{\gamma} = j\omega \cdot \sqrt{L' \cdot C'}$ Wave propagation constant

$\underline{Z} = j\omega \sqrt{\frac{L'}{C'}}$ Wave impedance

d Distance

$\underline{V}$, $\underline{I}$ Measured values on the line ends

[dw fault locator voltage char, 1, en_US]

Figure 6-593 Voltage Curve, Calculated from Both Sides of the Line

with:

1 Voltage curve calculated with the measured values at line end **A**

2 Voltage curve calculated with the measured values at line end **B**

d_{FL} Fault location

The algorithm of the 2-sided fault-location determination offers the following advantages compared to the 1-sided method:

- Correct fault-location determination is also possible with power flow, 2-sided infeed and high fault resistances.
- The algorithm is independent from the zero-sequence system and therefore also from its influencing variables, such as inductive couplings of parallel lines.
- An imprecise setting of the residual impedance compensation factors has no influence on the precision of the fault location.

Output of the Fault Location

The following results for the fault location are issued:

- The fault resistance in Ω primary and secondary
- The fault transfer resistance in Ω primary and secondary
  This value is only issued, if 2-sided fault-location determination is possible.
- The fault reactance up to the fault location in Ω primary and secondary
- The fault distance ***d*** in km or miles
- The fault distance ***d*** in percentage of the line length
- The number of the line section, in which the fault was localized
- The selected fault loop for calculation of the fault location

The indication of distance in kilometers, miles, or percent is also applicable only for inhomogeneous line sections (for example, overhead line cable routes). If you have defined several line sections for an inhomogeneous line, the **Fault locator plus** function issues the number of the faulty line section.

NOTE

If 2-sided fault-location determination is not possible by the **Fault locator plus** function, the function works automatically with the algorithm for the 1-sided fault-location determination.
You can find the description for the 1-sided fault locator in *6.49.1 Overview of Functions*.

6.50.4 Application and Setting Notes

The following line data are relevant for the 2-sided fault-location determination:

- Reactance per unit length of the line per kilometer or per mile
- Line length for the correct output of the fault distance as a percentage of the line length

The following parameters are only relevant for the 1-sided fault-location determination:

- **`Parallel-line compensat.`**
- **`Gnd.curr.ratio(MutComp)`**
- **`Load compensation`**
- The residual compensation factors in the setting format **`Kr`** and **`Kx`** or **`K0`** and **`Angle (K0)`**.

NOTE

Parallel-line compensation and load compensation are only possible with homogeneous lines.
If you define more than one line section and set the parameter **`Parallel-line compensat.`** or **`Load compensation`** = ***`yes`***, DIGSI reports an inconsistency.

Parameter: Start

- Recommended setting value **`(_:2311:101) Start`** = ***`with going pickup`***

With the parameter **`Start`**, you define the criterion for starting the fault location.

Parameter Value	Description
`with going pickup`	If a pickup signal of the protection functions designated for the startup has dropped out, fault-location determination starts.
`with operate`	If one of the protection functions designated for startup has reported the tripping and the pickup has dropped out, fault-location determination starts.

As an alternative, the fault locator can be started using an external binary input.

Parameter: Parallel-line compensat.

- Default setting **(_:2311:102) Parallel-line compensat.** = ***no***

The parameter **Parallel-line compensat.** is only visible when the ground current of the parallel line is connected to the **Line** function group.

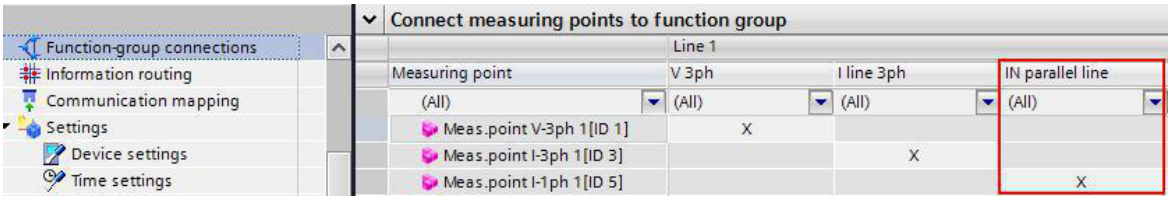


Figure 6-594 Routing in DIGSI

This parameter is only relevant for 1-sided fault-location determination.
If you wish to apply the parallel-line compensation for double lines, set the **Parallel-line compensat.** parameter to ***yes***.

Parameter Value	Description
no	The parallel-line compensation is not effective with this setting.
yes	The parallel-line compensation is effective with this setting.

The following conditions have to be fulfilled so that the parallel-line compensation functions:

- Connect the ground current of the parallel line in the correct polarity to an additional current input.
- Set the input used for the parallel current in the correct ratio to the phase currents for the power-system data.

  Parallel-line compensation is only carried out if the ground current of the line to be protected (I_{gnd}) is greater than the ground current of the parallel line (I_{gndP}) evaluated with the parameter **Gnd.curr.ratio(MutComp)**.

  Siemens recommends keeping the default setting **Gnd.curr.ratio(MutComp)** = ***85*** **%**. In highly unbalanced system conditions and if the coupling factor is very small (XM/XL less than 0.4), a smaller value may be advisable.
- Set the coupling impedances to the parallel system correctly for the line data.

Parameter: Gnd.curr.ratio(MutComp)

- Recommended setting value **(_:2311:109) Gnd.curr.ratio(MutComp)** = ***85*** **%**

This parameter is only relevant for the 1-sided fault-location determination.
With the **Gnd.curr.ratio(MutComp)** parameter, you define the ground-current balance for parallel-line compensation. This parameter is important for parallel-line compensation in the event of ground faults outside of the line to be protected.
For the ground-current balance of the distance protection, the setting value indicates the current ratio I_{gnd}/I_{gndP} for the protection device at installation site II (see *Figure 5-48*).

[dwparkomrw-161013, 1, en_US]

Figure 6-595 Radius of Parallel-Line Compensation at II

Parallel-line compensation is only carried out if the ground current of the line to be protected (I_{gnd}) is greater than the ground current of the parallel line (I_{gndP}) evaluated with the parameter **Gnd.curr.ratio(MutComp)**.

Siemens recommends keeping the default setting **Gnd.curr.ratio(MutComp)** = ***85 %*** . In highly unbalanced system conditions and if the coupling factor is very small (XM/XL less than 0.4), a smaller value may be advisable.

Parameter: Load compensation

- Default setting **(_:2311:103) Load compensation** = ***no***

This parameter is only relevant for 1-sided fault-location determination.

With the parameter **Load compensation**, you correct measuring errors for 1-phase short circuits on lines fed on both sides. This is the case for overhead lines without grounding cable or with unfavorable grounding conditions of the towers, if high contact resistances can occur in the event of 1-phase short circuits.

Parameter Value	Description
no	The load compensation is not effective with this setting.
yes	The load compensation is effective with this setting. If you operate using load compensation, the following parameters are relevant and are shown automatically: • **Substitute for IF** • **Comp. angle zero seq.** • **Comp. angle neg. seq.** If distance protection operates with the reactance method, Siemens recommends switching on load compensation.

Parameter: Substitute for IF

- Default setting **(_:2311:104) Substitute for IF** = ***3I0***

The parameter **Substitute for IF** is only visible and relevant if you operate using load compensation.

With the parameter **Substitute for IF**, you define which substitute value can be used in ground-impedance loops for the unmeasurable fault current IF and replace it with the fault resistance at the fault location.

First, calculate the compensation angle for the zero-sequence system and the negative-sequence system. Set the parameter **Substitute for IF** for the relatively smaller compensation angle. The relatively smaller compensation angle indicates that the associated system (zero-sequence and negative-sequence system) is more homogeneous and the fault current can be approximated better through the fault resistance at the fault location.

Parameter: Compensation Angle for Zero-Sequence System/Negative-Sequence System

- Default setting **(_:2311:106) Comp. angle zero seq.** = ***0.00°***
- Default setting **(_:2311:107) Comp. angle neg. seq.** = ***0.00°***

The parameters **Comp. angle zero seq.** and **Comp. angle neg. seq.** are only visible and relevant if you operate using load compensation.
If, based on network model tests or calculations, an angle difference between the measured $3I_0$ or $3I_2$ and I_F was determined, this can be compensated for with the parameter **Comp. angle zero seq.** or the parameter **Comp. angle neg. seq.**.
A setting of the compensation angle deviating from 0 is only relevant for non-homogeneous systems.
When using the **Comp. angle zero seq.** parameter, the angle difference between the $3I_0$ calculated by the device and the fault current I_F is being compensated.
When using the **Comp. angle neg. seq.** parameter, the angle difference between the $3I_2$ calculated by the device and the fault current I_F is being compensated.

NOTE

For non-homogeneous lines, for example, cable/overhead line routes, you can define several line sections and set the line parameters separately for each line section.
You can find further information on the line parameters in *6.49.4 Application and Setting Notes*.

Parameter: C1 per length unit

- Default setting **(_:16921:112) C1 per length unit** = ***0.010 µF/km***

With the **C1 per length unit** parameter, you specify the capacitance per unit length in the positive-sequence system for the line to be protected. You set the **C1 per length unit** parameter as a relative value in µF/km or µF/miles. The capacitance per unit length in the positive-sequence system is identical to the operating capacitance c_b'.

Parameter: C0 per length unit

- Default setting **(_:16921:148) C0 per length unit** = ***0.010 µF/km***

With the **C0 per length unit** parameter, you specify the capacitance per unit length in the zero-sequence system for the line to be protected. You set the **C0 per length unit** parameter as a relative value in µF/km or µF/miles. The capacitance per unit length in the zero-sequence system is identical to the ground capacitance c_{gnd}'.

Parameter: X per length unit

- Default setting **(_:16921:113) X per length unit** = ***0.0525 Ω/km***

With the **X per length unit** parameter, you set the reactance per unit length for the line to be protected. You set the **X per length unit** parameter as a relative value in Ω/km or Ω/miles.

Parameter: Line length

- Default setting **(_:16921:114) Line length** = ***60 km***

With the **Line length** parameter, you can set the length of the line to be protected as a unit of length in km or miles.

Parameter: Line angle

- Default setting **(_:16921:108) Line angle** = ***85.00°***

Calculate the setting value for the parameter **Line angle** from the line constants for the line to be protected as follows:

$$\tan\varphi = \frac{X_L}{R_L} \qquad \text{or} \qquad \varphi = \arctan\left(\frac{X_L}{R_L}\right)$$

[fo_lwinkl, 1, en_US]

where:

R_L	Resistance of the line to be protected
X_L	Reactance of the line to be protected

EXAMPLE

110 kV overhead line 150 mm² with the data

$R'_1 = 0.19\ \Omega/km$

$X'_1 = 0.42\ \Omega/km$

You calculate the setting value for the line angle as follows:

$$\tan\varphi = \frac{X_L}{R_L} = \frac{X'_1}{R'_1} = \frac{0.42\ \Omega/km}{0.19\ \Omega/km} = 2.21$$

[fo_tan_phi, 1, en_US]

$$\arctan(2.21) = 65.7°$$

[fo_arctan_phi, 1, en_US]

Parameter: Kr and Kx

- Default setting **(_:16921:104) Kr** = ***1.00***
- Default setting **(_:16921:105) Kx** = ***1.00***

The **Kr** and **Kx** parameters are used to set the residual compensation factors as scalar values. The **Kr** and **Kx** parameters are relevant for the **Fault locator** function.

Calculate the setting values for the parameters **Kr** and **Kx** from the line data as follows:

Resistance ratio	Reactance ratio
$Kr = \frac{R_{gnd}}{R_L} = \frac{1}{3} \cdot \left(\frac{R_0}{R_1} - 1 \right)$	$Kx = \frac{X_{gnd}}{X_L} = \frac{1}{3} \cdot \left(\frac{X_0}{X_1} - 1 \right)$

where:

R_0	Zero-sequence system resistance of the line
X_0	Zero-sequence system reactance of the line
R_1	Positive-sequence system resistance of the line
X_1	Positive-sequence system reactance of the line

This data can either be used for the entire line or as length-related values, since the quotients are length-independent. You can calculate the data both from the primary values and from the secondary values.

EXAMPLE

110-kV overhead line 150 mm² with the data:

R_1/s	0.19 Ω/km positive-sequence system resistance
X_1/s	0.42 Ω/km positive-sequence system reactance
R_0/s	0.53 Ω/km zero-sequence system resistance
X_0/s	1.19 Ω/km zero-sequence system reactance
s	Line length

You receive the following setting values for the parameters **Kr** and **Kx**:

$$k_r = \frac{R_{Gnd}}{R_L} = \frac{1}{3} \cdot \left(\frac{R_0}{R_1} - 1\right) = \frac{1}{3} \cdot \left(\frac{0.53\ \Omega/km}{0.19\ \Omega/km} - 1\right) = 0.60$$

[fo_kr, 1, en_US]

$$k_x = \frac{X_{Gnd}}{X_L} = \frac{1}{3} \cdot \left(\frac{X_0}{X_1} - 1\right) = \frac{1}{3} \cdot \left(\frac{1.19\ \Omega/km}{0.42\ \Omega/km} - 1\right) = 0.61$$

[fo_kx, 1, en_US]

Parameter: K0 and Angle (K0)

- Default setting **(_:16921:118) K0** = ***1.000***
- Default setting **(_:16921:150) Angle (K0)** = ***0.00°***

NOTE

The visibility of the **K0** and **Angle (K0)** parameters depends on the selected setting format of the residual compensation factors. The parameters **K0** and **Angle (K0)** are only visible if you have set the parameter **Set. format residu. comp.** = ***K0*** for the device. You can find the parameter **Set. format residu. comp.** in the DIGSI 5 project tree under **Name of the device** → **Settings** → **Device settings**.

The **K0** and **Angle (K0)** parameters are used to set the complex grounding-resistance factor.

Make sure that the line angle is set correctly because the device needs the line angle for calculation of the compensation components from the K0 factor. The complex grounding-resistance factor is defined by the absolute value and the angle. You can calculate the complex grounding-resistance factor from the line data as follows:

$$K_0 = \left|\frac{\underline{Z}_{Gnd}}{\underline{Z}_L}\right| = \left|\frac{1}{3} \cdot \left(\frac{\underline{Z}_0}{\underline{Z}_1} - 1\right)\right|$$

[fo_K01, 1, en_US]

where:

$\underline{Z}_0$	(Complex) zero-sequence impedance
$\underline{Z}_1$	(Complex) positive-sequence impedance

This data can either be used for the entire line or as length-related values, since the quotients are length-independent. You can calculate the data both from the primary values and from the secondary values.

For overhead lines, you can use the values for the calculation because the angles of the zero-sequence system and the positive-sequence system differ only slightly. For cables, however, significant angular differences can occur, as the following example illustrates.

EXAMPLE

110-kV single-conductor liquid-filled cable 3 · 185 mm² Cu with the data:

$\underline{Z}_1/s$	$0.408 \cdot e^{j73^\circ}$ Ω/km positive-sequence impedance
$\underline{Z}_0/s$	$0.632 \cdot e^{j18.4^\circ}$ Ω/km zero-sequence impedance
s	Line length

The values for calculation of the grounding-resistance factor **K0** are:

$$\frac{\underline{Z}_0}{\underline{Z}_1} = \frac{0.632}{0.408} \cdot e^{j(18.4^\circ - 73^\circ)} = 1.55 \cdot e^{-j\,54.6^\circ} = 1.55 \cdot (0.579 - j\,0.815) = 0.898 - j\,1.263$$

[fo_1_k0, 1, en_US]

$$k_0 = \left|\frac{1}{3} \cdot \left(\frac{\underline{Z}_0}{\underline{Z}_1} - 1\right)\right| = \left|\frac{1}{3} \cdot (0.898 - j\,1.263 - 1)\right| = \left|\frac{1}{3} \cdot (-0.102 - j\,1.263)\right|$$

[fo_2_k0, 1, en_US]

The setting value of the parameter **K0** is calculated from:

$$k_0 = \left|\frac{1}{3} \cdot \sqrt{(-0.102^2) + (-1.263^2)}\right| = 0.42$$

[fo_3_k0, 1, en_US]

When determining the angle, take note of the quadrant of the result. The following table lists the quadrants and the angle range obtained from the operational signs of the real and imaginary parts of **K0**.

Real Part	Imaginary Part	tan Phi (K0)	Quadrant/Range		Calculation Method
+	+	+	I	0° to 90°	arc tan (|Im| / |Re|)
+	-	-	IV	-90° to 0°	–arc tan (|Im| / |Re|)
-	-	+	III	-90° to -180°	arc tan (|Im| / |Re|) –180°
-	+	-	II	+90° to +180°	–arc tan (|Im| / |Re|) +180°

In this example, the following setting value for the **Angle (K0)** parameter is obtained:

$$\varphi(K_0) = \arctan\left(\frac{1.263}{0.102}\right) - 180° = -94.6°$$

[fo_phi_K0, 1, en_US]

Parameter: Blocking of the auto. recl.

- Default setting **(_:16921:120) Blocking of the auto. recl.** = ***no***

With the parameter **Blocking of the auto. recl.**, with inhomogeneous lines, you can block the **Automatic reclosing** function for faults on individual line sections, for example, on cable sections.

NOTE

The parameter **Blocking of the auto. recl.** is only visible, if you have instantiated the function block **Blk by FtLc. #** in the **Automatic reclosing** function.

You can find the function block **Blk by FtLc. #** in the DIGSI 5 library in the FG **Circuit breaker** → **Automatic reclosing function** → **Bocking by fault locator**.

Parameter Value	Description
no	The **Fault locator plus** function has no impact on the **Automatic reclosing** function.
yes	The **Fault locator plus** function blocks the **Automatic reclosing** function. The blocking only functions if the function block (FB) **Blk by FtLc. #** is instantiated in the **Automatic reclosing** function. The parameter **(_:102) Min. dead time of blocking** is in the FB. Set the parameter **Min. dead time of blocking** to the smallest dead time of all instantiated AREC cycles.

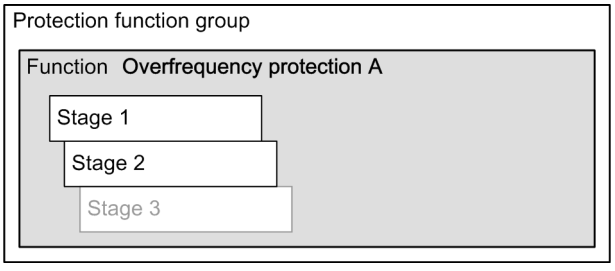
6.51 Overfrequency Protection

6.51.1 Overview of Functions

The **Overfrequency protection** function (ANSI 81O):

- Detect overfrequencies in electrical power systems or machines
- Monitor the frequency band and output failure indications
- Disconnect generating units when the power frequency is critical
- Provide additional turbine protection if the speed limiter fails

Frequency deviations are caused by an unbalance between the active power generated and consumed. Overfrequency is caused by load shedding (island network), power system disconnection or disturbances of the frequency controller. Overfrequency implies a risk of self excitation of machines which are connected to long lines without load.



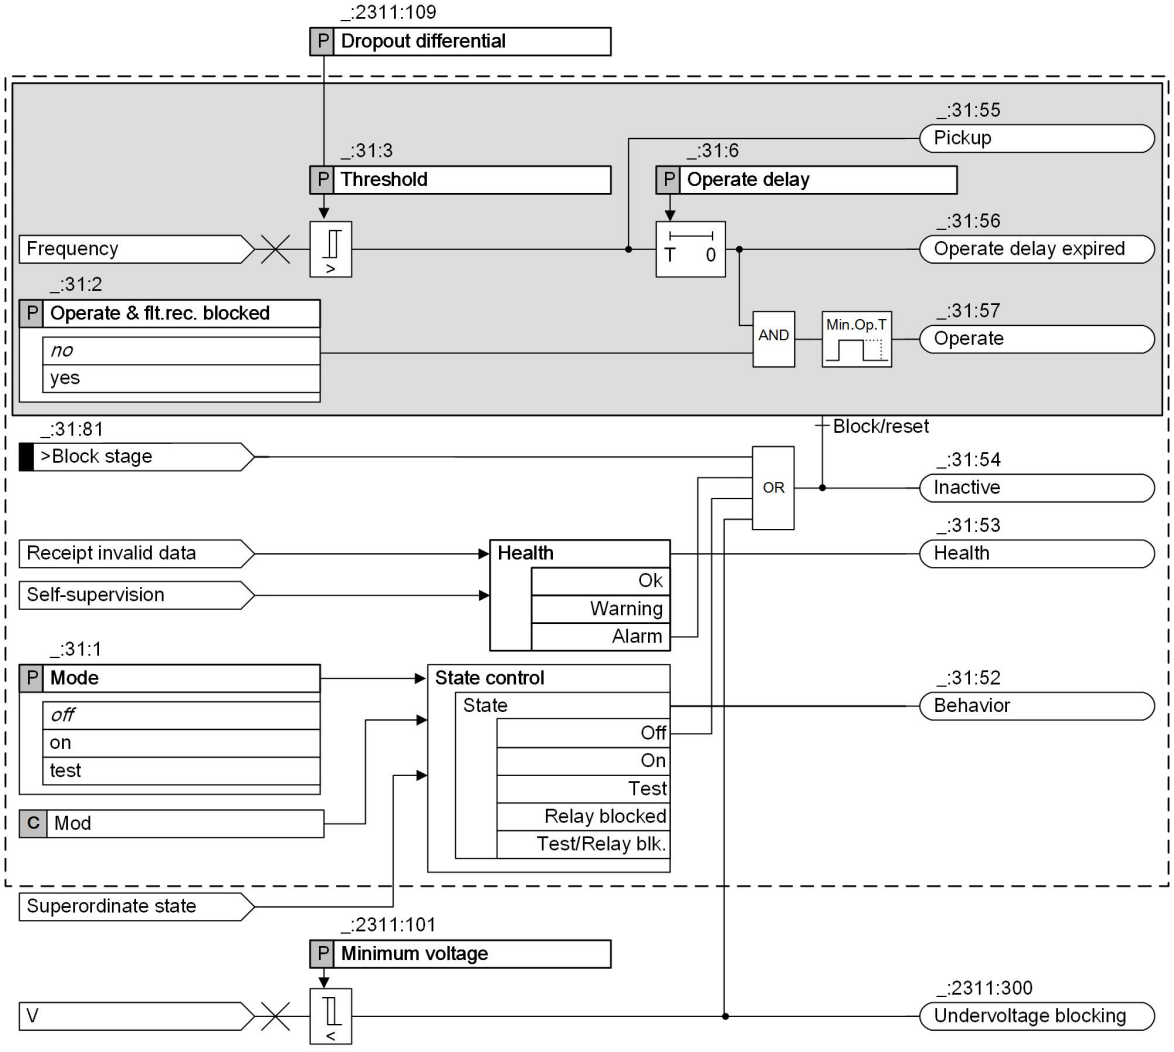
Overfrequency protection is available in two functional configurations (selectable from the DIGSI functions library). The functional configurations differ in the frequency measurement method they use.

6.51.2 Structure of the Function

The **Overfrequency protection** function is used in protection function groups, which are based on voltage measurement.

The overfrequency protection function comes with 2 factory-set stages. A maximum of 3 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.

The parameters **`Dropout differential`** and **`Minimum voltage`** are set for all stages.



[dw_stofqp, 1, en_US]

Figure 6-596 Structure/Embedding of the Function

6.51.3 Overfrequency-Protection Stage

Logic of a Stage

[lo_stofqp, 2, en_US]

Figure 6-597 Logic Diagram of the Overfrequency-Protection Stage

Frequency-Measurement Method

Underfrequency protection is available in 2 functional configurations. These work with different frequency-measurement methods. You select the frequency-measurement method in dependence of the application.

- Angle-difference method (method A):

  The angle-difference method determines the phasor of the positive-sequence voltage in multiphase systems. In the case of 1-phase connection, it always processes the phasor of the connected voltage. Since the change of angle of the voltage phasor over a given time interval is proportional to the frequency change, the current frequency can be derived from it.

- Filtering method (method B):

  The filtering method processes the instantaneous voltage values and determines the current frequency using a suitable combination of filters. The frequency-protection function selects automatically the largest voltage as the measurand. In a multiphase connection, the phase-to-phase voltage is always the largest. If in a multiphase connection the selected voltage is no longer available, the function changes over automatically to the next maximum voltage. The function can even operate with just one voltage.

Both methods of measurement are characterized by a high measuring accuracy combined with a short response time. Disturbance values such as harmonics, high frequency disturbances, phase-angle jumps during switching operations and compensation processes due to power swings are effectively suppressed.

NOTE

The angle difference method (method A) requires the sampling-frequency tracking.

If you use the angle difference method as method of measurement, ensure that sampling-frequency tracking is active (see *3.3.2 Sampling-Frequency Tracking*).

Functional Measured Value

The angle-difference method provides the following measured value:

Measured Value	Description
f	Frequency calculated with the angle-difference method

Behavior on Leaving the Operating Range

The sampling-frequency tracking makes a wide frequency operating range possible. If the stage has picked up before leaving the frequency operating range and the measuring voltage is higher than the set minimum voltage, the pickup is maintained. A dropout of the pickup is only possible by means of a blocking.

Blocking the Stage

In the event of blocking, a picked-up stage will be reset. The following blocking options are available for the stage:

- Externally or internally via the logical binary input *>Block stage*
- Internally when the voltage drops below the **Minimum voltage**

6.51.4 Application and Setting Notes

Frequency-Measurement Method

The frequency measurement method is selected with the functional configuration from the DIGSI functions library. The letter at the end of the function name describes the method of measurement.

Redundant solutions can be implemented by combining 2 different methods of frequency measurement. You can implement a **2-out-of-2 decision** by connecting the operate indications of both functions in a CFC with a logical AND gate. This increases the reliability of protection.

Frequency-Measurement Method	Description
Angle difference method (method A)	Select this method of measurement if the frequency protection stage is used for the protection of machines.
Filtering method (method B)	Select this method of measurement if the frequency protection stage is used in an electrical power system.

Parameter: Threshold

- Recommended setting value **(_:31:3) Threshold** = ***51.50 Hz*** for f_{rated} = 50 Hz

With the parameter **Threshold**, you define the pickup threshold of the overfrequency protection stage in dependence of the application. 51.50 Hz is a typical warning threshold in 50-Hz systems.

Parameter: Operate delay

- Recommended setting value **(_:31:6) Operate delay** = ***10 s***

With the parameter **Operate delay**, you set the stage so that overfunctions due to disturbing influences (for example, switching operations) are avoided. Fairly high time delays are sufficient for warning indications.

Parameter: Minimum voltage

- Recommended setting value **(_:2311:101) Minimum voltage** = **37.500 V**

For the **Undervoltage blocking**, Siemens recommends 65 % of the rated voltage of the protected object as the setting value.
Calculate the secondary or primary setting value with the phase-to-ground voltage, that is, $V_{rated}/\sqrt{3}$.
For V_{rated} = 100 V secondary, the setting value of the **Minimum voltage** is calculated as follows:

$$\text{Minimum voltage} = 0.65 \cdot V_{rated} = 0.65 \cdot \frac{100\ \text{V}}{\sqrt{3}} = 37.500\ \text{V}$$

[fo_minimal voltage A, 1, en_US]

In the angle-difference method, the setting value relates to the positive-sequence system.

NOTE

If in DIGSI you switch over the settings view of the parameters to ***Percent***, the phase-to-phase value of the rated voltage is the reference value for the **Minimum voltage** in both methods of measurement.

Parameter: Dropout differential

- Recommended setting value **(_:2311:109) Dropout differential** = ***20 mHz***

Due to the high-precision frequency measurement, the recommended setting value for the **Dropout differential** can remain at 20 mHz. For a later dropout of the stage, increase the setting value of the dropout differential. For example, if the pickup value (parameter **Threshold**) of the stage is set to 51.5 Hz and the **Dropout differential** to 100 mHz, the stage will drop out at 51.4 Hz.

Setting example for the overfrequency protection for generators

If the overspeed limiter does not function properly, the overfrequency protection issues an additional alarm indication. Overspeeding can be caused by load shedding or by a disturbance of the speed limiter (for example, in an island network).
One possible frequency limit could be 1.03 f_{rated}. If the machine does not recover, it can be shut down with a 2nd stage of, for example, 1.08 f_{rated}. To avoid overfunctions, you can set a sufficient time delay for the warning indication or tripping.
For this application, 2 stages of the overfrequency protection are used. The following table shows a setting suggestion.

Stage	Caused by	Setting Values		
		At f_{rated} = 50 Hz	At f_{rated} = 60 Hz	Delay
f1>	Warning or disconnection	51.50 Hz	61.80 Hz	20.00 s
f2>	Shutdown	54.00 Hz	64.80 Hz	5.00 s

NOTE

This table shows one example of a possible frequency protection setting. The setting values can differ depending on the application.

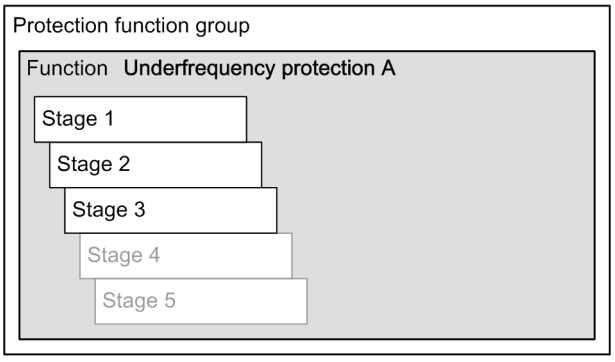
6.52 Underfrequency Protection

6.52.1 Overview of Functions

The **Underfrequency protection** function (ANSI 81U) is used to:

- Detect underfrequencies in electrical power systems or machines
- Monitor the frequency band and output failure indications
- Decouple power systems
- Load shedding to ensure power system stability and protect motors
- Disconnect generating units when the power system frequency is critical (for example, $f < 0.95\ f_{rated}$)

Frequency deviations are caused by an unbalance between the active power generated and consumed. Underfrequency is caused by an increase of the consumers' active power demand or by a decrease of the power generated. These conditions occur in the case of power system disconnection, generator failure, or disturbances of the power and frequency controller.



Underfrequency protection is available in 2 functional configurations (selectable from the DIGSI functions library). The functional configurations differ in the frequency measurement method they use.

6.52.2 Structure of the Function

The **Underfrequency protection** function is used in protection function groups, which are based on voltage measurement.

The **Underfrequency protection** function comes with 3 factory-set stages. A maximum of 5 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.

The parameters **`Dropout differential`** and **`Minimum voltage`** are set for all stages.

6.52.3 Underfrequency-Protection Stage

Logic of a Stage

[lo_stuf_qp, 3, en_US]

Figure 6-599 Logic Diagram of the Underfrequency-Protection Stage

Frequency-Measurement Method

Underfrequency protection is available in 2 functional configurations. These work with different frequency-measurement methods. You select the frequency-measurement method in dependence of the application.

- Angle-difference method (method A):
  The angle-difference method determines the phasor of the positive-sequence voltage in multiphase systems. In the case of 1-phase connection, it always processes the phasor of the connected voltage. Since the change of angle of the voltage phasor over a given time interval is proportional to the frequency change, the current frequency can be derived from it.
- Filtering method (method B):
  The filtering method processes the instantaneous voltage values and determines the current frequency using a suitable combination of filters. The frequency-protection function selects automatically the largest voltage as the measurand. In a multiphase connection, the phase-to-phase voltage is always the largest. If in a multiphase connection the selected voltage is no longer available, the function changes over automatically to the next maximum voltage. The function can even operate with just one voltage.

Both methods of measurement are characterized by a high measuring accuracy combined with a short response time. Disturbance values such as harmonics, high frequency disturbances, phase-angle jumps during switching operations and compensation processes due to power swings are effectively suppressed.

NOTE

The angle difference method (method A) requires the sampling-frequency tracking.

If you use the angle difference method as method of measurement, ensure that sampling-frequency tracking is active (see *3.3.2 Sampling-Frequency Tracking*).

Behavior on Leaving the Operating Range

Sampling-frequency tracking makes an additional frequency operating range possible. If the stage has picked up before leaving the frequency operating range and the measuring voltage is higher than the set minimum voltage, the pickup is maintained. A dropout of the pickup is only possible by means of a blocking.

Blocking the Stage

In the event of blocking, a picked-up stage will be reset. The following blocking options are available for the stage:

- Via the binary input signal *>Block stage* from an external or internal source
- Internally when the voltage drops below the **Minimum voltage**

6.52.4 Application and Setting Notes

Frequency-Measurement Method

The frequency measurement method is selected with the functional configuration from the DIGSI functions library. The letter at the end of the function name describes the method of measurement.

Redundant solutions can be implemented by combining 2 different methods of frequency measurement. You can implement a **2-out-of-2 decision** by connecting the operate indications of both functions in a CFC with a logical AND gate. This increases the security of protection.

Method of Measurement	Description
Angle-difference method (method A)	Select this method of measurement if the frequency protection stage is used for the protection of machines.
Filtering method (method B)	Select this method of measurement if the frequency protection stage is used in an electrical power system.

Parameter: Threshold

- Recommended setting value **(_:61:3) Threshold** = ***49.80 Hz*** for f_{rated} = 50 Hz

With the parameter **Threshold**, you define the pickup threshold of the underfrequency protection stage in dependence of the application. 49.8 Hz is a typical warning threshold in 50-Hz systems.

Parameter: Operate delay

- Recommended setting value **(_:61:6) Operate delay** = ***10.00 s***

With the parameter **Operate delay**, you set the stage so that overfunctions due to disturbing influences (for example switching operations) are avoided. Fairly high time delays are sufficient for warning indications.

Parameter: Minimum voltage

- Recommended setting value **(_:2311:101) Minimum voltage** = **37.500 V**

For the **Undervoltage blocking**, Siemens recommends 65 % of the rated voltage of the protected object as the setting value.

Calculate the secondary or primary setting value with the phase-to-ground voltage, that is, $V_{rated}/\sqrt{3}$.

For V_{rated} = 100 V secondary, the setting value of the **Minimum voltage** is calculated as follows:

$$\text{Minimum voltage} = 0.65 \cdot V_{rated} = 0.65 \cdot \frac{100\ \text{V}}{\sqrt{3}} = 37.500\ \text{V}$$

[fo_minimal voltage A, 1, en_US]

In the angle-difference method, the setting value relates to the positive-sequence system.

NOTE

If in DIGSI you switch over the settings view of the parameters to ***Percent***, the phase-to-phase value of the rated voltage is the reference value for the **Minimum voltage** in both methods of measurement.

Parameter: Dropout differential

- Recommended setting value **(_:2311:109) Dropout differential** = ***20 mHz***

Due to the high-precision frequency measurement, the recommended setting value for the **Dropout differential** can remain at 20 mHz. If in your application you wish a subsequent dropout of the tripping stage, then increase the setting value of the dropout differential. For example, if the pickup value (parameter **Threshold**) of the tripping stage is set to 49.8 Hz and the **Dropout differential** to 100 mHz, the stage will drop out at 49.9 Hz.

Setting Example of Underfrequency Protection for Generators

Underfrequency protection provides an additional protection for the turbine. It has the task of ensuring the demand of a power plant by a timely decoupling from the electrical power system. After the decoupling from the electrical power system, the turbo set controller sets the generator unit to the rated speed, so that the demand can continue to be supplied with rated frequency.

Turbo-generators can operate permanently at as little as 95 % of the rated frequency. This requires the apparent power to be reduced by the same factor. A decrease of the frequency leads not only to a higher current consumption by the inductive loads but is also a hazard to stable operation.

The decoupling from the electrical power system is initiated without delay at 0.95 f_{rated}. After the decoupling, the power-plant unit has to recover. If it does not, the turbine is stopped for its own protection. In the turbine, underfrequency can lead to resonances and inadmissible strains of the turbine blades. You can delay the tripping in order to give the speed controllers sufficient time for a response.

The frequency value to be set depends on the specifications of the power plant operator or the turbine manufacturer (speed monitoring). It is approx. 0.94 f_{rated}.

For this application, 3 stages of the underfrequency protection are used. The following table shows a setting suggestion.

Stage	Caused by	Setting Values		
		At f_{rated} = 50 Hz	At f_{rated} = 60 Hz	Delay
f1<	Warning	49.80 Hz	59.80 Hz	10.00 s
f2<	Decoupling from power system	47.50 Hz	57.00 Hz	0.00 s
f3<	Shutdown	47.00 Hz	56.40 Hz	10.00 s

NOTE

This table shows one example of a possible frequency protection setting. The setting values can differ depending on the application and the turbine.

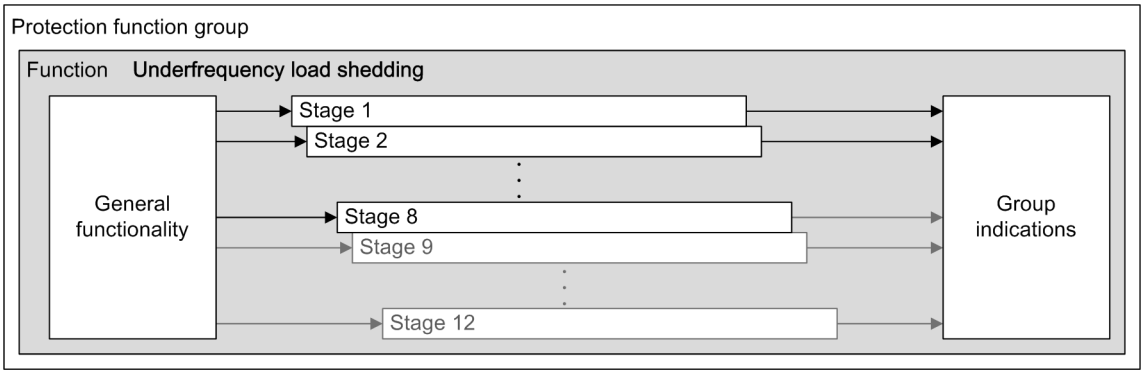
6.53 Underfrequency Load Shedding

6.53.1 Overview of Functions



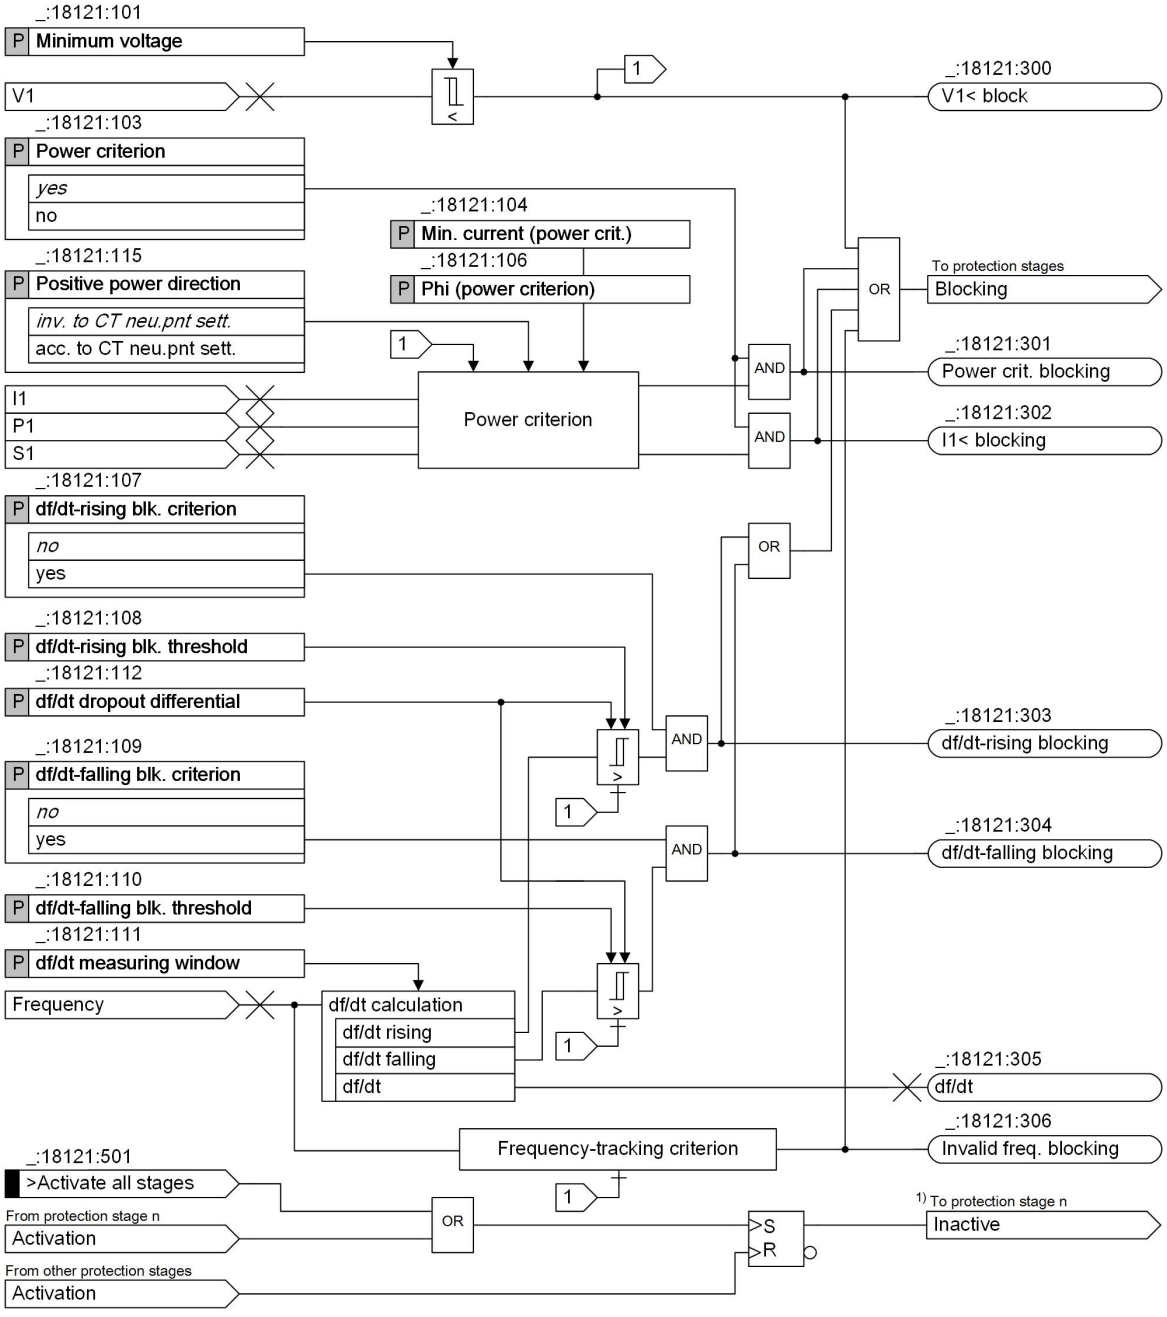
The **Underfrequency load shedding** function:

- Detects underfrequencies in the electrical power systems
- Switches off the medium-voltage busbar or feeders that consume active power to stabilize the frequency
- Maintains operations for the medium-voltage busbar or feeders that generate active power

6.53.2 Structure of the Function

The **Underfrequency load shedding** function can be used in the **Voltage/Current 3-phase** function group and in the **Line** function group.

The **Underfrequency load shedding** function comes factory-set with 8 stages. A maximum of 12 stages can be operated simultaneously within the function. These stages are identical in structure.



[dw_load shedding_structure, 1, en_US]

Figure 6-600 Structure/Embedding of the Function

6.53.3 General Functionality

6.53.3.1 Description

Logic

[lo_UFLS_general functionality, 2, en_US]

Figure 6-601 Logic Diagram of the General Functionality

(1) n means the number of the protection stage.

Measurands

The general functionality requires the following input measurands:

- Positive-sequence voltage V1
- Positive-sequence current I1
- Positive-sequence system apparent power S1
- Positive-sequence system active power P1
- Frequency

S1 and P1 are both calculated from V1 and I1. The frequency is calculated from V1.

The frequency and the frequency change rate df/dt are calculated via the angle difference algorithm. For more information, see *6.51.3 Overfrequency-Protection Stage*.

Undervoltage Blocking

The frequency of the **Underfrequency load shedding** function is calculated from the positive-sequence voltage V1. In order to obtain a reliable and accurate frequency calculation result, the magnitude of V1 is monitored. If the magnitude of V1 is smaller than the **`Minimum voltage`**, all the protection stages are blocked and the *V1< block* indication is issued.

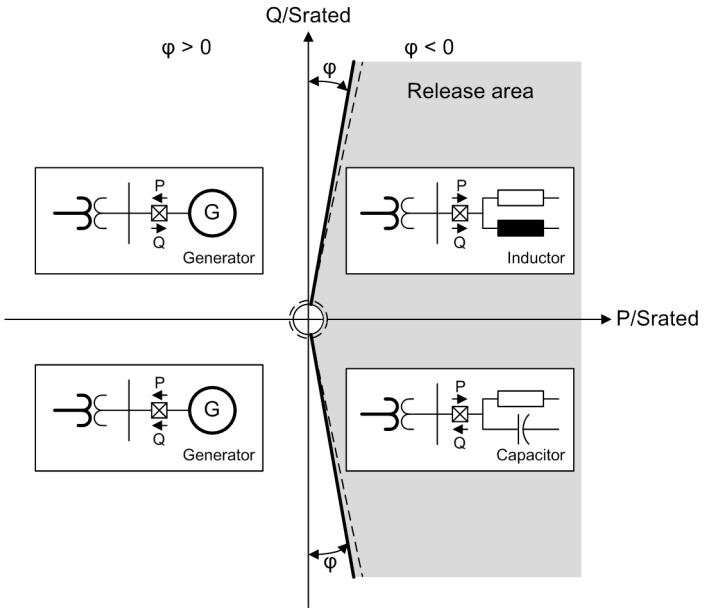
Power Criterion

If a feeder delivers active power towards the busbar, or if the medium-voltage busbar delivers active power to the high-voltage busbar, it is meaningless to switch off this feeder or the medium-voltage busbar during the load-shedding process. The power criterion determines the power-flow direction and includes this information as a blocking criterion into the load-shedding decision of all protection stages.

The parameter **`Positive power direction`** defines the positive active-power flow direction of the function in relation to the standard forward direction of the protection functionality. For more information, see *6.53.3.2 Application and Setting Notes*.

In the following figures, if the power flow is located in the release area which is marked in gray, the protection stages are released. In the remaining area, the protection stages are blocked.

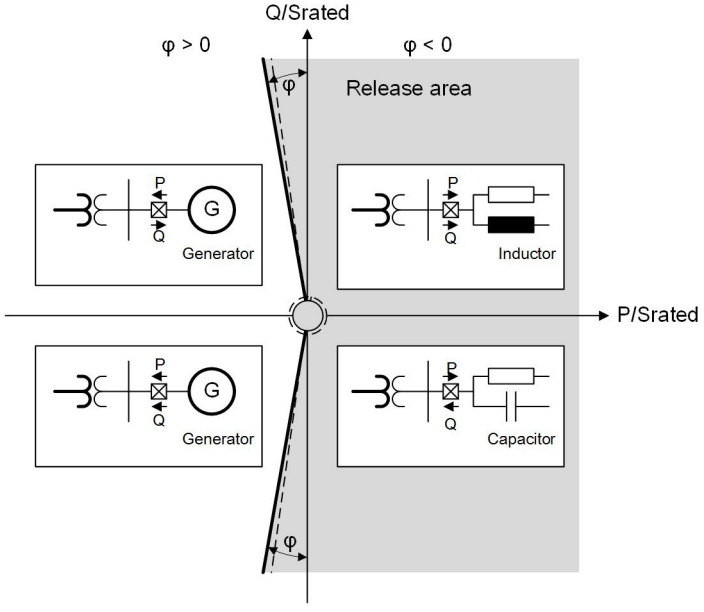
The release area is configured via the following parameters:



- The parameter **`Phi (power criterion)`** defines the area which limits the range of the power angle.
- The parameter **`Min. current (power crit.)`** defines the minimum positive-sequence current that must be present to calculate the active power in a reliable way. In the following figures, the minimum current is indicated as the circle whose center is the origin of the coordinates.

The power criterion is checked only when the following 2 conditions are fulfilled:

- The positive-sequence current I1 exceeds the threshold **`Min. current (power crit.)`**, that is, I1 is out of the circle in the following figures.
- The undervoltage blocking is not fulfilled, that is, the magnitude of V1 is not smaller than the **`Minimum voltage`**.



The dashed lines in the figures show the dropout characteristics. The dropout differential of the power angle is 1°.

The symbol φ in the following figures represents the setting value of the parameter **`Phi (power criterion)`**.

[dw_load_shedding_power_crit<0, 1, en_US]

Figure 6-602 Power-Criterion Checking at **Phi (power criterion)** ≤ 0

[dw_load shedding_power_crit>0, 2, en_US]

Figure 6-603 Power-Criterion Checking at **Phi (power criterion)** > 0 (according to VDE-AR-N 4142:2020-04)

The power criterion contains the check of the current criterion and of the power-angle criterion.

You can determine whether to check the power criterion or not by setting the **Power criterion** parameter. The power criterion is carried out only when the **Power criterion** parameter is set to ***yes***.

The working method of the current criterion and of the power-angle criterion differ at **Phi (power criterion)** ≤ 0 and **Phi (power criterion)** > 0.

For **Phi (power criterion)** ≤ 0, the power criterion is checked as follows:

- When the positive-sequence current I1 falls below the **Min. current (power crit.)**, the current criterion is not fulfilled and the *I1< blocking* indication is issued. Therefore, all the protection stages are blocked and the power-angle criterion is not considered.
- When I1 exceeds the **Min. current (power crit.)** and the power angle is out of the release area, the *Power crit. blocking* indication is issued and all the protection stages are blocked.

For **Phi (power criterion)** > 0, the power criterion is checked as follows:

- When I1 falls below the **Min. current (power crit.)**, all the protection stages are released and the power-angle criterion is not considered.
- When I1 exceeds the **Min. current (power crit.)** and the power angle is out of the release area, the *Power crit. blocking* indication is issued and all the protection stages are blocked.

df/dt Blocking

If the change rate of df/dt is too high, the **Underfrequency load shedding** function may not be applicable anymore.

The df/dt blocking comprises the df/dt-rising blocking and the df/dt-falling blocking.

The df/dt-rising criterion and the df/dt-falling criterion can be individually switched on or off. These 2 df/dt criteria are operative only when the magnitude of the positive-sequence voltage V1 is greater than the **Minimum voltage**:

- The df/dt-rising blocking takes place when the df/dt-rising value exceeds the setting value of the parameter **df/dt-rising blk. threshold**. It is signaled via the indication *df/dt-rising blocking*.
- The df/dt-falling blocking takes place when the df/dt-falling value exceeds the setting value of the parameter **df/dt-falling blk. threshold**. It is signaled via the indication *df/dt-falling blocking*.

Frequency-Tracking Criterion

The frequency-tracking criterion is only checked when no undervoltage blocking is given.

The frequency of the **Underfrequency load shedding** function is calculated via the angle difference algorithm, which requires the sampling-frequency tracking to be active (see *3.3.2 Sampling-Frequency Tracking*). If the sampling-frequency tracking is inactive, all the protection stages are blocked and the signal *Invalid freq. blocking* is issued.

Activating/Deactivating Protection Stages

The mechanism of exclusive stage activation is described in *Exclusive Stage Activation, Page 1611*.

Functional Measured Value

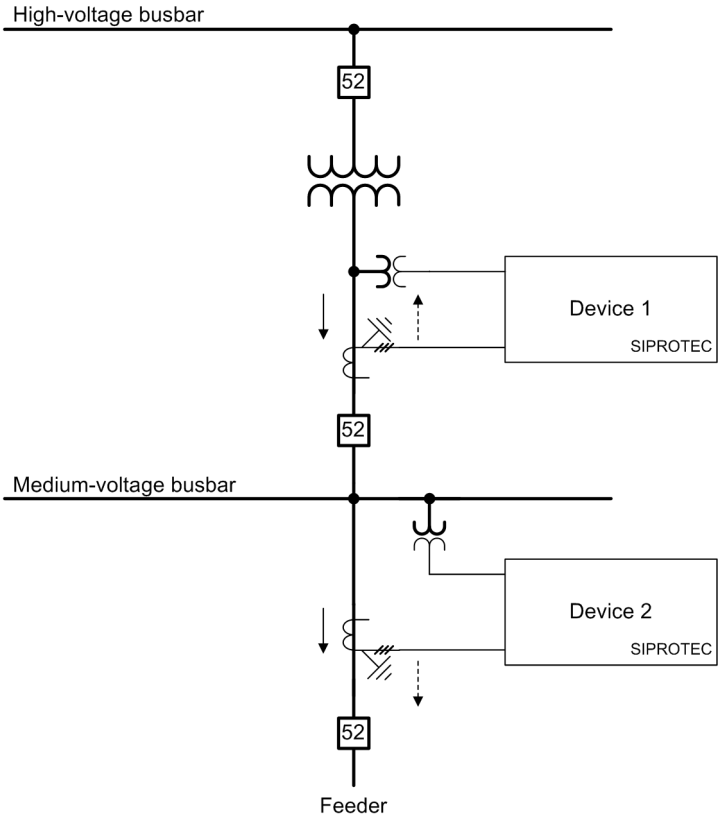
Value	Description
df/dt	Calculated rate of frequency change

6.53.3.2 Application and Setting Notes

Parameter: Minimum voltage

- Default setting **(_:18121:101) Minimum voltage** = *0.700 p.u.*

If the magnitude of V1 is smaller than the **Minimum voltage**, all protection stages are blocked.



The **Minimum voltage** parameter is set as a per-unit value related to the rated voltage of the connected voltage measuring point. Siemens recommends using the default setting.

Parameter: Positive power direction

- Default setting **(_:18121:115) Positive power direction** = *inv. to CT neu.pnt sett.*

With the **Positive power direction** parameter, you define the positive active-power flow direction of the function in relation to the standard forward direction of the protection functionality.

The following figure shows 2 application scenarios of protection devices with the **Underfrequency load shedding** function.

[dw_UFLS_positive power direction, 1, en_US]

Figure 6-604 Application Scenarios

Dotted arrow: Standard forward direction of the protection functionality
Solid arrow: Positive active-power flow direction

The standard forward direction of the protection functionality is from the busbar to the protected object which is the transformer for device 1 or the feeder for device 2. The standard forward direction of the protection functionality is configured via the **(_:8881:116) Neutr.point in dir.of ref.obj** parameter of the measuring point I-3ph (see chapter *6.1.5 Application and Setting Notes for Measuring-Point Current 3-Phase (I-3ph)*). For the load-shedding function, the positive active-power flow direction can differ from the standard forward direction of the protection functionality, such as for device 1. To adapt the function to this condition, the **Positive power direction** parameter is used. With the **Positive power direction** parameter, you can set the positive active-power flow direction either to the same as or to the inverse of the standard forward direction.

- For device 1, set the **Positive power direction** parameter to ***inv. to CT neu.pnt sett.***. Then, the positive active-power flow direction of the power criterion is opposite to the standard forward direction of the protection functionality. Consequently, the **Underfrequency load shedding** function sheds the medium-voltage busbar when the positive power-flow direction is from the high-voltage busbar to the medium-voltage busbar.
- For device 2, set the **Positive power direction** parameter to ***acc. to CT neu.pnt sett.***. Then, the positive active-power flow direction of the power criterion is the same as the standard forward direction of the protection functionality. Consequently, the **Underfrequency load shedding** function sheds the feeder when the positive power-flow direction is from the medium-voltage busbar to the feeder.

Parameter: Power criterion, Phi (power criterion), Min. current (power crit.)

- Default setting **(_:18121:103) Power criterion** = ***yes***
- Default setting **(_:18121:106) Phi (power criterion)** = ***-5°***
- Default setting **(_:18121:104) Min. current (power crit.)** = ***0.050 p.u.***

The power criterion evaluates the power-flow direction as a blocking criterion for the protection stages.

- With the **Power criterion** parameter, you configure whether to apply the power criterion or not.

  If a feeder can deliver active power towards the busbar, or if the medium-voltage busbar can deliver active power to the high-voltage busbar, Siemens recommends using the power criterion to exclude the feeder or the medium-voltage busbar from being shed under this condition. If a feeder or the medium-voltage busbar is always consuming active power, the power criterion is not required.
- With the **Phi (power criterion)** parameter, you decide whether the protection stage is blocked or released in the case of low active-power flow. If the active-power flow is low, the determined active power-flow direction is not always reliable.

  For **Phi (power criterion)** ≤ 0, the protection stage is released for a clear forward active power-flow direction. If the active power-flow direction is not reliable, the protection stages are blocked. For **Phi (power criterion)** > 0, the behavior is the contrary.

  The **Phi (power criterion)** parameter can be set depending on your philosophy.
- With the **Min. current (power crit.)** parameter, you set the minimum positive-sequence current threshold to achieve a reliable active-power criterion result. The **Min. current (power crit.)** parameter is set as a per-unit value related to the rated current of the connected current measuring point. Siemens recommends using the default setting.

Parameter: df/dt-rising blk. criterion, df/dt-rising blk. threshold, df/dt-falling blk. criterion, df/dt-falling blk. threshold

- Default setting **(_:18121:107) df/dt-rising blk. criterion** = ***no***
- Default setting **(_:18121:108) df/dt-rising blk. threshold** = ***1.0 Hz/s***
- Default setting **(_:18121:109) df/dt-falling blk. criterion** = ***no***
- Default setting **(_:18121:110) df/dt-falling blk. threshold** = ***3.0 Hz/s***

If the change rate of df/dt is too high, the **Underfrequency load shedding** function may not be applicable anymore.

With the parameters **df/dt-rising blk. criterion** and **df/dt-falling blk. criterion**, you determine whether to check the df/dt-rising blocking and the df/dt-falling blocking.

With the parameters **df/dt-rising blk. threshold** and **df/dt-falling blk. threshold**, you set the threshold rates of df/dt-rising and df/dt-falling.

Parameter: df/dt measuring window

- Default setting **(_:18121:111) df/dt measuring window** = ***5 periods***

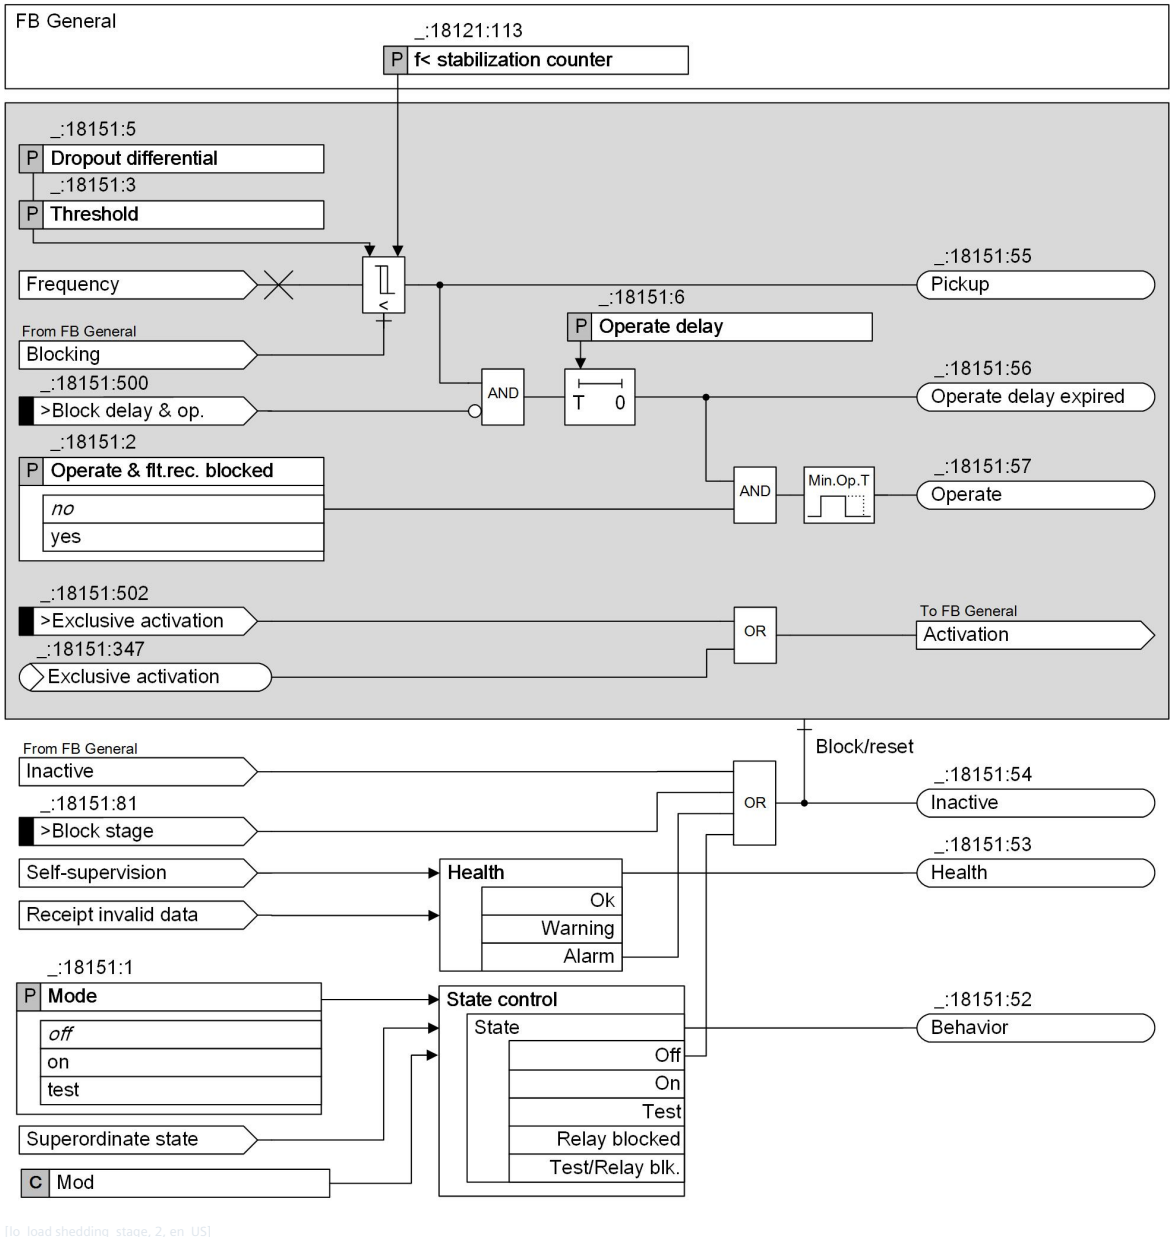
With the **df/dt measuring window** parameter, you optimize the measuring accuracy or the pickup time of the function.

The default setting provides the maximum measuring accuracy. If you do not have specific requirements for a decreased pickup time, Siemens recommends using the default setting.

For a non-sensitive setting (high threshold value), you can set the **df/dt measuring window** parameter to a value which is smaller than ***5 periods***.

Parameter: df/dt dropout differential

- Default setting **(_:18121:112) df/dt dropout differential** = ***0.1 Hz/s***



With the **df/dt dropout differential** parameter, you define the dropout threshold of the parameters **df/dt-rising blk. threshold** and **df/dt-falling blk. threshold**.

The default setting is a reasonable value. Siemens recommends using the default setting.

6.53.4 Stage Description

6.53.4.1 Description

Logic of the Stage

[lo_load shedding_stage, 2, en_US]

Figure 6-605 Logic Diagram of the Underfrequency Load Shedding Stage

Pickup and Operate

If the following 3 conditions are all fulfilled, a **Pickup** indication is issued:

- The frequency value drops below the **Threshold**.
- The **Blocking** input from the function block **General** is inactive.
- The preceding 2 conditions are fulfilled during the configured number of frequency measurement cycles (cycle time = 10 ms). You can set the number with the parameter **f< stabilization counter**.

If the **Pickup** signal is maintained during the **Operate delay** time, an **Operate** indication is issued.

Exclusive Stage Activation

A load-shedding schema defines in which order feeders (power consumers) are disconnected. To not discriminate power consumers, this order is changed regularly. The mechanism of exclusive stage activation supports this order change efficiently.

Even though multiple protection stages are instantiated and their **Mode** parameters are set to *on*, you can only activate one stage at a time via the exclusive stage activation in an **Underfrequency load shedding** function.

The exclusive stage activation comprises the following input signals:

- The SPS signal *>Exclusive activation* which is offered in the protection stage.
- The SPC signal *Exclusive activation* which is offered in the protection stage.
  This SPC signal allows the exclusive stage activation from a station controller.
- The SPS signal *>Activate all stages* which is offered in the function block **General**.

The protection stage which receives the newest SPS signal *>Exclusive activation* or SPC signal *Exclusive activation* remains active and all other stages are deactivated. If 2 or more protection stages simultaneously receive the SPS signals *>Exclusive activation* and/or the SPC signals *Exclusive activation*, only the protection stage with the largest stage number is activated.

If the SPS signal *>Activate all stages* is activated, the exclusive stage activation is reset, that is, all protection stages whose **Mode** parameters are set to *on* become active again.

After a normal device restart (reset), the statuses of the protection stages which were influenced by the SPS signal *>Exclusive activation* or the SPC signal *Exclusive activation* are still maintained.

After an initial startup, the exclusive stage activation is reset.

EXAMPLE

Configured protection stages:	Protection stages 1 to 8
Protection stages whose **Mode** parameters are set to *on*:	Protection stages 1 to 8

The following cases occur in sequence:

- **Case 1:**
  Scenario: In the protection stage 1, the SPS signal *>Exclusive activation* or the SPC signal *Exclusive activation* is activated.
  Result: The protection stage 1 remains active and stages 2 to 8 are deactivated.
- **Case 2:**
  Scenario: In the protection stage 2, the SPS signal *>Exclusive activation* or the SPC signal *Exclusive activation* is activated.
  Result: The protection stage 2 is activated, the stage 1 is deactivated, and stages 3 to 8 remain deactivated.
- **Case 3:**
  Scenario: The SPS signal *>Activate all stages* is activated.
  Result: The protection stages 1 to 8 are activated.

- **Case 4:**
  Scenario: In the protection stages 2 to 4, the SPS signal *>Exclusive activation* or the SPC signal *Exclusive activation* is activated simultaneously.
  Result: The protection stage 4 is activated and the other stages are deactivated.
- **Case 5:**
  Scenario: A normal device restart (reset) occurs.
  Result: After the device restart, the protection stage 4 remains activated and the other stages remain deactivated.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- Via the binary input signal *>Block stage* from an external or internal source
- Via the *Inactive* input from the function block **General**

Behavior on Leaving the Operating Range

The sampling frequency tracking makes a wide frequency-operating range possible. If the stage has picked up before leaving the frequency-operating range, the pickup is maintained. The **Pickup** signal is reset when a blocking condition becomes active.

6.53.4.2 Application and Setting Notes

Parameter: Threshold

- Default setting **(_:18151:3) Threshold** = ***49.00 Hz*** for f_{rated} = 50 Hz

With the **Threshold** parameter, you define the underfrequency pickup value of the stage. The specific value depends on the application and the total number of the stages applied in parallel.

Parameter: Operate delay

- Default setting **(_:18151:6) Operate delay** = ***0.10 s***

Set the **Operate delay** parameter for the specific application.

Parameter: Dropout differential

- Default setting **(_:18151:5) Dropout differential** = ***20 mHz***

With the **Dropout differential** parameter, you define the dropout threshold. For example, if you set the **Threshold** to 49.00 Hz and the dropout differential to 20 mHz, the stage drops out at 49.02 Hz.

Due to the high-precision frequency measurement, the setting value can remain at the default value of 20 mHz.

Parameter: Operate & flt.rec. blocked

- Default setting **(_:18151:2) Operate & flt.rec. blocked** = ***no***

With the **Operate & flt.rec. blocked** parameter, you can block the operate indication, the fault recording, and the fault log.

Parameter: f< stabilization counter

- Default setting **(_:18121:113) f< stabilization counter** = ***6***

You can configure the **f< stabilization counter** parameter in the function block **General**.

With the **f< stabilization counter** parameter, you set the number of measurement cycles in which the measured frequency value must be lower than the frequency threshold to meet the pickup condition. With this setting, you can optimize the pickup-condition reliability versus the pickup time.

The measuring cycle time is 10 ms. With the default setting of ***6***, the pickup time is the sum of the inherent frequency measuring time (approx. 10 ms to 30 ms) plus the 6 times measuring repetition of 60 ms, which is 70 ms to 90 ms in total.

In order to avoid a wrong pickup in case of a phase jump, Siemens recommends setting the value of the **f< stabilization counter** parameter not below 5.

6.53.5 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General				
_:18121:101	General:Minimum voltage		0.300 p.u. to 0.900 p.u.	0.700 p.u.

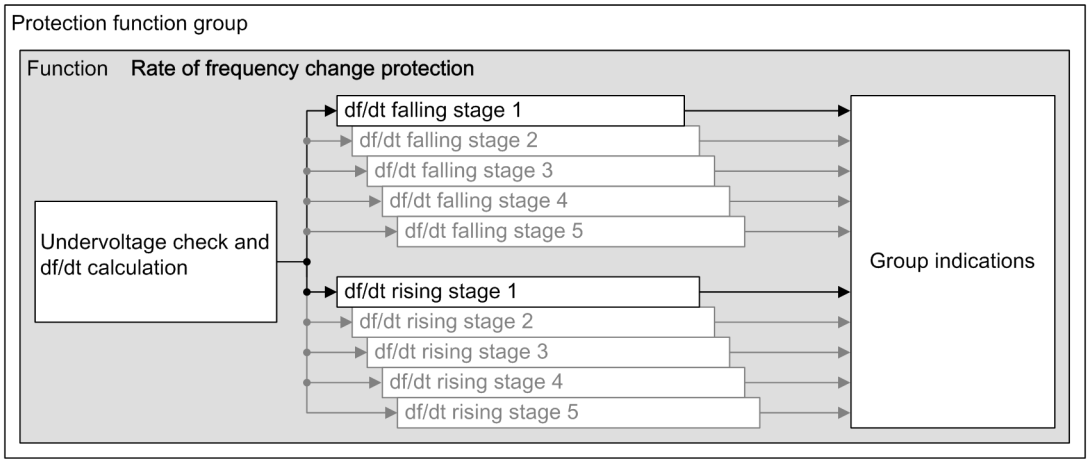
6.54 Rate of Frequency Change Protection

6.54.1 Overview of Functions

The function **Rate of frequency change protection** is used to:

- Detect a frequency change quickly
- Prevent the system from not secure states caused by unbalance between the generated and consumed active power
- Network decoupling
- Load shedding

6.54.2 Structure of the Function



The function **Rate of frequency change protection** can be used in protection function groups containing a 3-phase voltage measurement.

2 function block types are available:

- **df/dt rising**
- **df/dt falling**

The function **Rate of frequency change protection** is preconfigured by the manufacturer with 1 df/dt rising stage and 1 df/dt falling stage. A maximum of 5 df/dt rising stages and 5 df/dt falling stages can operate simultaneously within the function. Both of the function block types are similar in structure.

Undervoltage check and df/dt calculation are general functionalities and take place on the function level. All stages use these general functionalities.

[dw_dfdt 01, 1, en_US]

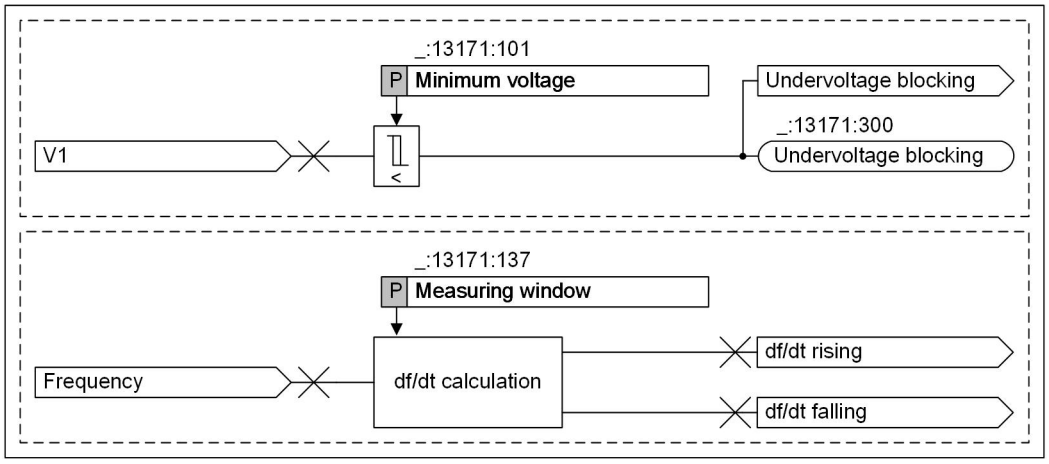


Figure 6-606 Structure/Embedding of the Function

6.54.3 General Functions (Undervoltage Test, df/dt Calculation)

6.54.3.1 Description

Logic

The following figure represents the logic of undervoltage check and df/dt calculation. It applies to all types of stages.

[lo_dfdtgf, 2, en_US]

Figure 6-607 Logic Diagram of General Functionality

Measurand

This function uses the frequency calculated via the angle difference algorithm.

For more information, refer to chapter *6.51.3 Overfrequency-Protection Stage*.

The frequency difference is calculated over a settable time interval (default setting: 5 periods).

The ratio between the frequency difference and the time difference reflects the frequency change which can be positive or negative.

A stabilization counter works to avoid overfunction. This counter is increased if the set threshold value is exceeded. If the value drops below the threshold value, the counter is reset immediately. The counter is set to 8 internally and is activated at each half system cycle.

Undervoltage Blocking

If the measuring voltage drops below the **`Minimum voltage`**, the **Rate of frequency change protection** is blocked because precise frequency values cannot be calculated anymore.

Functional Measured Value

Value	Description
df/dt	Calculated rate of frequency change

6.54.3.2 Application and Setting Notes

Parameter: `Minimum voltage`

- Recommended setting value **`(_:13171:101) Minimum voltage`** = ***`37.500 V`***

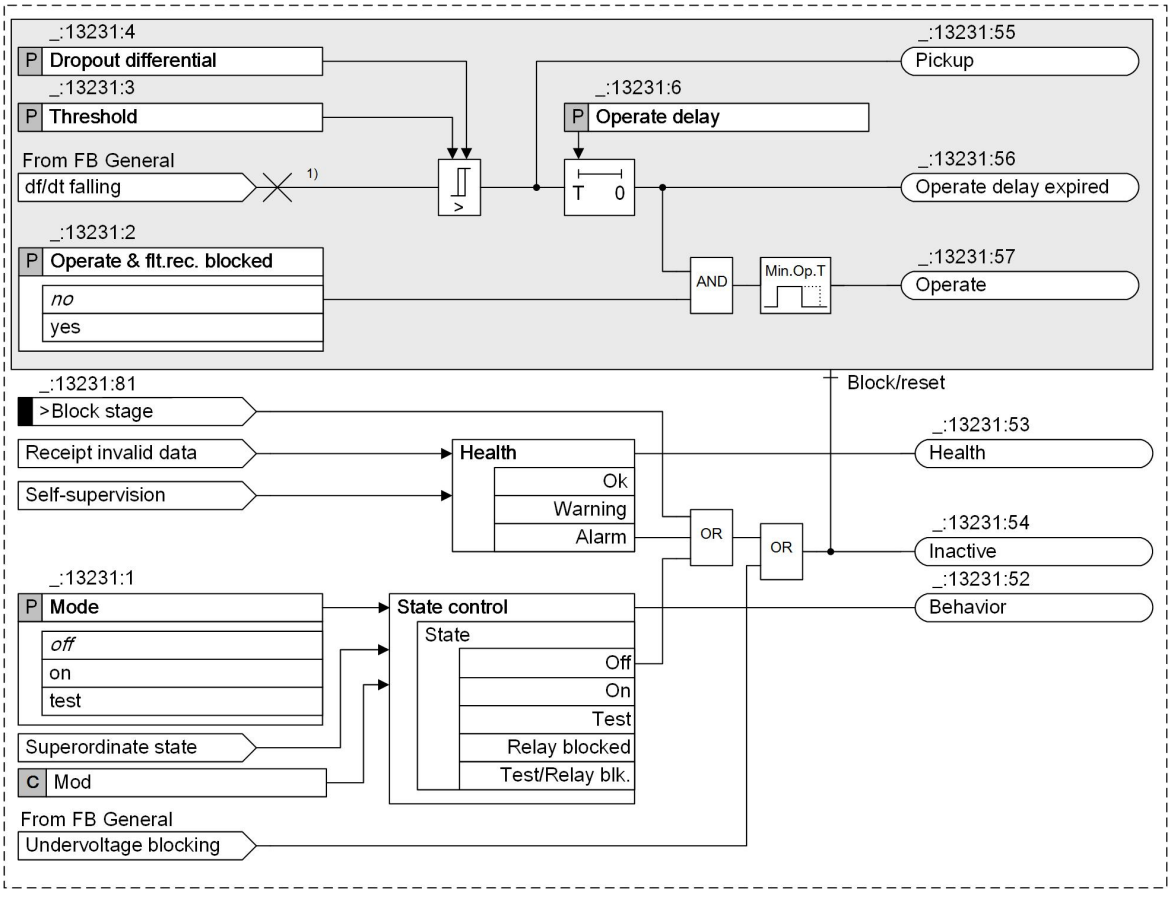
For the **Undervoltage blocking**, 65 % of the rated voltage of the protected object is recommended.

The method of measurement uses the phasor of the positive-sequence voltage. When determining the setting value, keep in mind that the absolute value of the sound positive-sequence voltage is equal to the absolute value of the phase-to-ground voltage. The default setting is referred to this value.

Parameter: `Measuring window`

- Default setting **`(_:13171:137) Measuring window`** = ***`5 periods`***

You can use the **`Measuring window`** parameter to optimize the measuring accuracy or the pickup time of the function. For information regarding pickup time and measuring accuracy, refer to the technical data.



The default setting provides maximum measuring accuracy. If you do not have specific requirements for a decreased pickup time, Siemens recommends using the default setting.

The default setting is a reasonable compromise between measuring accuracy and pickup time. For a non-sensitive setting (high threshold value), you can set the parameter **Measuring window** to a smaller value.

6.54.4 Stage Description

6.54.4.1 Description

Logic of the Stage

[lo_dfdt_st_2, en_US]

Figure 6-608 Logic Diagram of Rate of Frequency Change Protection

(1) For the stage type **df/dt rising**, the value **df/dt rising** is used.

Frequency Rising/Falling

The stage **df/dt falling** is used to detect frequency falling and the stage **df/dt rising** is used to detect frequency rising.

You set the threshold value as an absolute value. You define the frequency-change direction via the selected stage type.

Blocking of the Stage

The following blockings reset the picked up stage completely:

- Via the binary input signal *>Block stage*
- Via the undervoltage blocking when the voltage drops below the **Minimum voltage**

6.54.4.2 Application and Setting Notes

Parameter: `Threshold`

- Default setting **`(_:13231:3) Threshold`** = ***`3.000 Hz/s`***

The pickup value depends on the application and is determined by power-system conditions. In most cases, a network analysis will be necessary. A sudden disconnection of loads leads to a surplus of active power. The frequency rises and causes a positive frequency change. On the other hand, a failure of generators leads to a deficit of active power. The frequency drops and results in a negative frequency change.

The following relations can be used as an example for estimation. They apply for the change rate at the beginning of a frequency change (approximate 1 s).

$$\frac{df}{dt} = -\frac{f_{rated}}{2H} \cdot \frac{\Delta P}{S_{rated}}$$

Where:

f_{rated}	Rated frequency
ΔP	Active power change $\Delta P = P_{Consumption} - P_{Generation}$
S_{rated}	Rated apparent power of the machines
H	Inertia constant

Typical data for H:

For hydro generators (salient-pole machines)	H = 1.5 s to 6 s
For turbine-driven generators (non-salient pole rotors)	H = 2 s to 10 s
For industrial turbine-driven generators	H = 3 s to 4 s

EXAMPLE

f_{rated} = 50 Hz
H = 3 s
Case 1: $\Delta P/S_{rated}$ = 0.12
Case 2: $\Delta P/S_{rated}$ = 0.48
Case 1: df/dt = -1 Hz/s
Case 2: df/dt = -4 Hz/s

Parameter: `Operate delay`

- Default setting **`(_:13231:6) Operate delay`** = ***`1.00 s`***

You can use the **`Operate delay`** parameter to avoid overfunction due to disturbing influences (for example, switching operations). If the protection function is supposed to respond quickly, set the **`Operate delay`** parameter to 0 s.

For monitoring small changes (< 1 Hz/s), a small time delay is useful to avoid overfunctioning.

Parameter: `Dropout differential`

- Recommended setting value **`(_:13231:4) Dropout differential`** = ***`0.10 Hz/s`***

You can use the **`Dropout differential`** parameter to define the dropout value. The recommended value is ***`0.10 Hz/s`***.

NOTE

In case of power-system incidents, especially in case of transmission incidents and influence of voltage-stabilizing measures via power-electronic components (reactive-power compensation through SVC), the magnitude and the phase angle of the voltage can change. Sensitive settings can lead to overfunction. Therefore, it is reasonable to block the **Rate of Frequency Change Protection** if other protection functions, for example, residual voltage or negative-sequence voltage, pick up. To do this, use the blocking input *>Block stage* and connect it via CFC.

6.54.4.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General				
_:13171:101	General:Minimum voltage		3.000 V to 175.000 V	37.500 V
_:13171:137	General:Measuring window		2 periods to 5 periods	5 periods
df/dt falling1

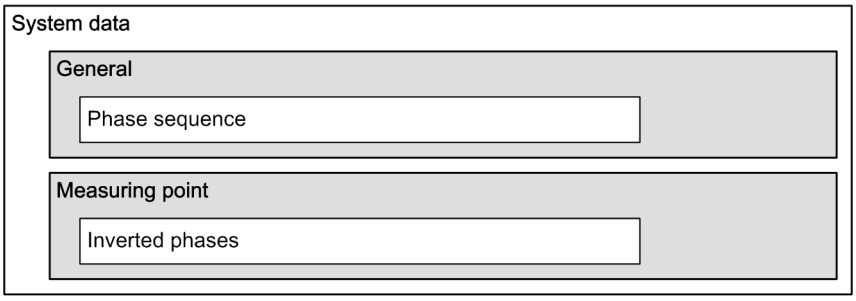
6.55 Phase-Sequence Switchover

6.55.1 Overview of Functions

The **Phase-sequence reversal** function enables correct execution of the protection of the device and supervision functions, independently of the phase sequence of the phases in a system or system section.

The phase sequence is set via parameters. You can select between the phase sequences ***ABC*** or ***ACB***.

Binary inputs also provide the option of switching over the phase sequence with respect to the parameter setting. For example, in pumped-storage hydropower plants with motor or motor/generator operation you temporarily change the direction of rotation by changing over the phase sequence.



The phase sequence has an effect on calculation of the positive-sequence system and negative-sequence system values and on calculation of phase-to-phase values. A phase-rotation reversal therefore has an effect on all protection and supervision functions that use these values.

You can change the phase sequence in 2 ways via binary inputs.

- Change over the phase sequence for the entire device.
  In doing so, all 3-phase measuring points are switched over. All analog inputs are therefore affected (for example current and voltage inputs simultaneously).
- Change over the phase sequence per measuring point.
  In doing so, only the activated measuring points are switched over. The other measuring points remain unaffected.

6.55.2 Structure of the Function

The **Phase-sequence switchover** function is integrated in the **Power-system data**. You will find the signals in the DIGSI 5 project tree under **Name of the device** → **Settings**. There you will find the parameter for setting the phase sequence and the binary inputs via which you can influence a change in the phase sequence.

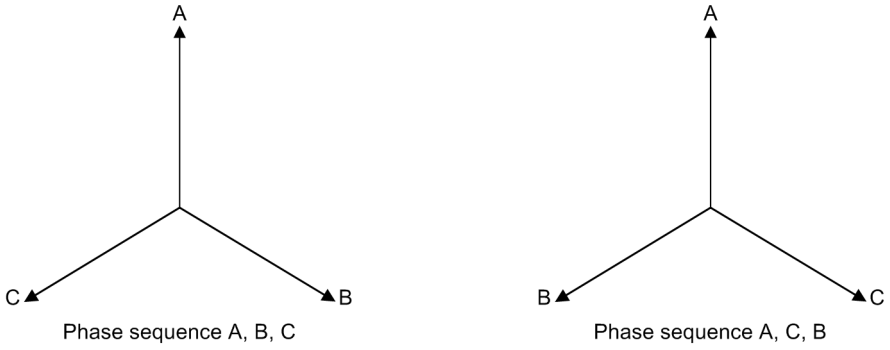
[dw_ph_rein, 1, en_US]

Figure 6-609 Structure/Embedding of the Function

6.55.3 Function Description

General

The phase sequence of the system is set in the device via the **`Phase sequence`** parameter. You will find the signals in the DIGSI 5 project tree under **Name of the device** → **Settings** → **Power-system data** → **General**. There are 3 methods to change the phase sequence for different operational requirements.



- Changing the phase sequence via the setting parameter.
  - **Note**: With version V7.50 and higher, this setting parameter is a reset parameter. If the parameter is changed and transmitted to the device, the device performs a startup. The parameter change affects all 3-phase measuring points. If the device is in operation and if measurands are present at the measuring points, perform a parameter change carefully since this affects all measuring points.

- With the binary signal *>Phs-rotation reversal*, you change over the phase sequence of all measuring points.
- With the binary signal *>Invert Phases*, you change over the phase sequence per measuring point.
  The **Inverted phases** parameter available for each measuring point is used to set which phases at the measuring point must be swapped. The parameter can be found at each 3-phase measuring point.

The 2 binary-signal mechanisms are explained separately below.

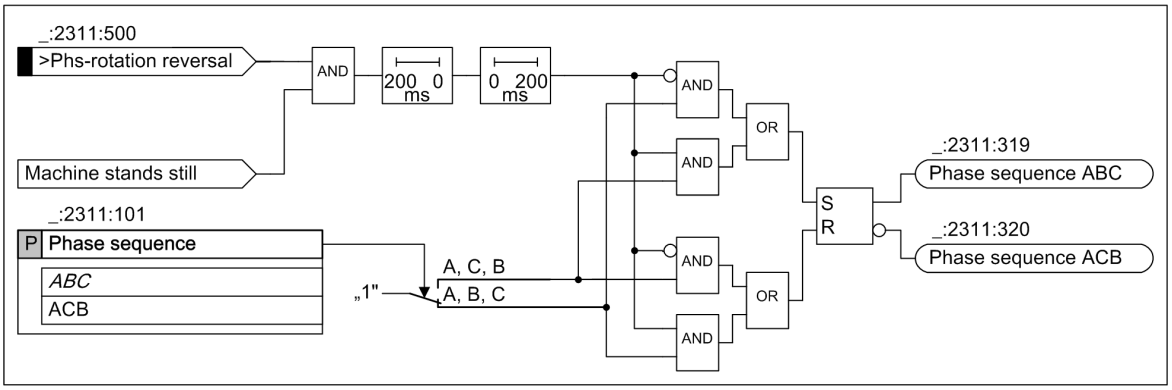
Switchover of the Phase Sequence of All Measuring Points

The direction of rotation of the currents and voltages depends on the phase sequence. The following drawing shows the vector definitions for the 2 phase sequences.

[dw_ph_rdrf, 1, en_US]

Figure 6-610 Vector with Different Phase Sequences

The phase sequence of a system or a system section is defined when parameterizing via the **Phase sequence** parameter. The setting parameter acts on all measuring points.



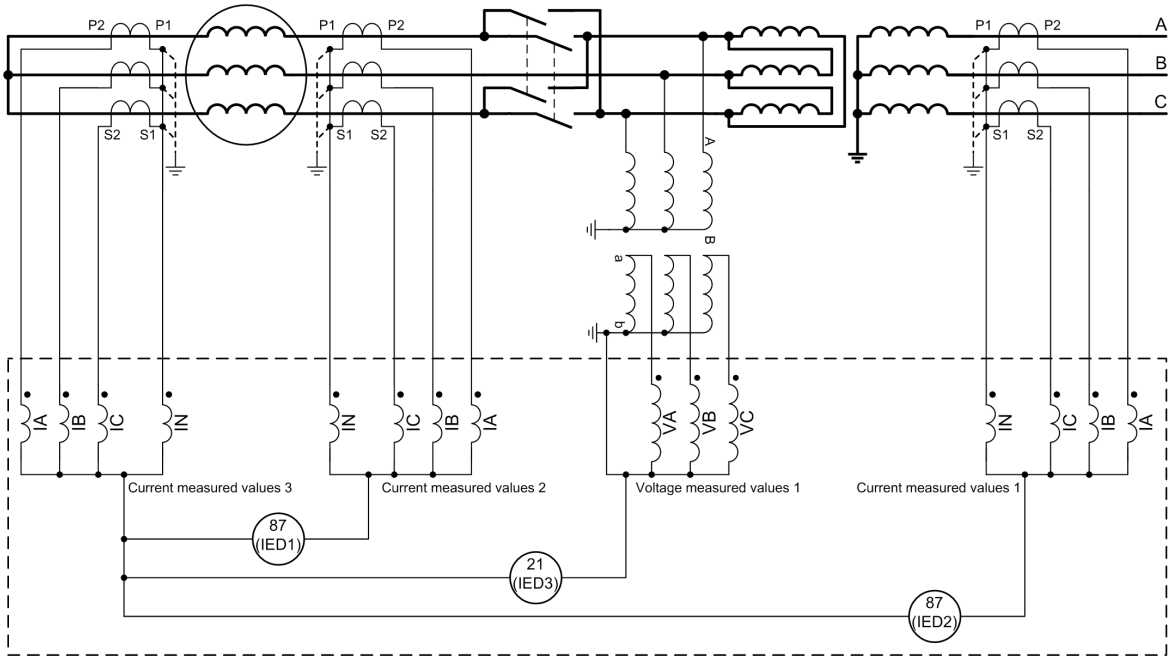
The operationally induced switchover between the phase sequence ***ABC*** and the phase sequence ***ACB*** is initiated via the binary input *>Phs-rotation reversal*. This switches over the phase sequence simultaneously at all 3-phase measuring points.

The following image shows a logic diagram for determining the current phase assignment and switchover. The indications shown on the right show the present phase sequence. If the phase sequence is set via the **Phase sequence** parameter to ***ABC***, activation of the binary input will result in a switchover to the phase sequence ***ACB***.

NOTE

The switchover of the phase sequence is only authorized for a time at which no measured values are pending. The switchover command must be present for at least 200 ms. The change of phase sequence is only permissible when the machine is at standstill. If the current and voltage values of all 3-phase measuring points are below 5 % of the rated variables, this is recognized as machine standstill.

A renewed machine standstill must be detected for a resetting of the phase sequence to the set preferred position.



[dw_phrpsys1, 2, en_US]

Figure 6-611 Phase Sequence Switchover

Changing Over the Phase Sequence per Measuring Point

A switchover of the phase sequence per measuring point can also be necessary for operational reasons. This switchover enables proper behavior of the protection equipment, for example at the transition from generator operation to motor operation (pump operation).

The following example shows an application in a pumped storage plant. The switchover of the phase sequence (change in rotational direction) realizes the transition there from generator operation to motor operation. Which phases and measuring points are changed over depends on the conditions in the system.

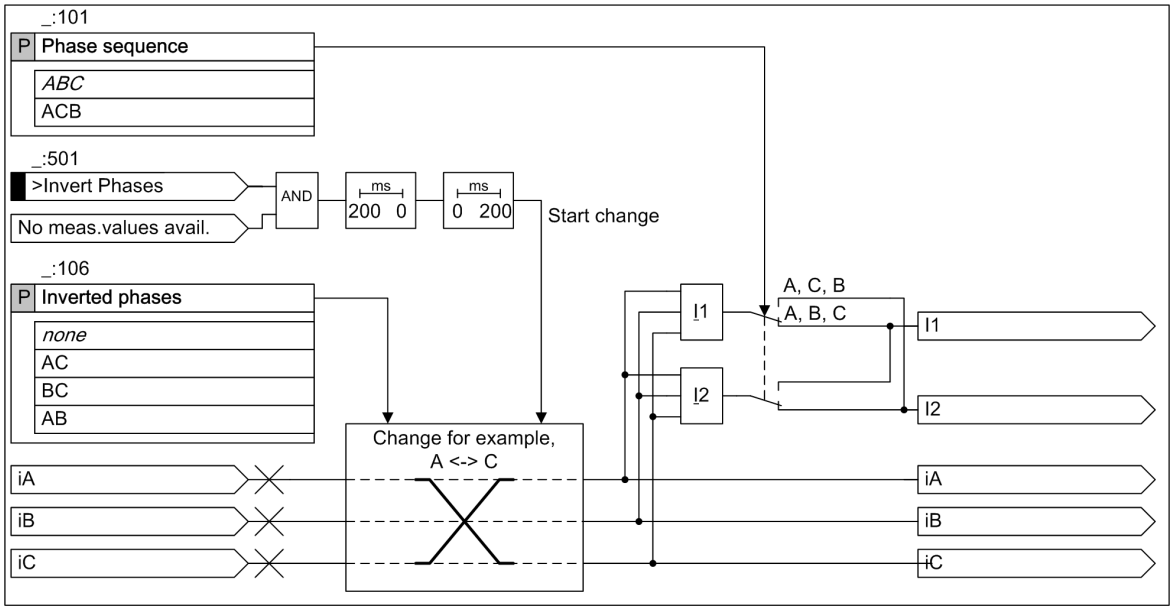
[dw_phrapp, 2, en_US]

Figure 6-612 Application Example for Phase-Rotation Reversal in a Pump Station

The example shows 2 differential protection devices (IED1 and IED2) and an impedance protection (IED3) with the connected measuring points.

The phase sequence is insignificant for the differential protection of IED1, as the protected object is not affected by the switchover option of the phase sequence.

The phase sequence is also relevant to the differential protection of IED2, as the protected object extends beyond the switchover option.



The phase sequence is also relevant to the impedance protection (IED3). Depending on the switch position, the voltage measured values 1 and the current measured values 3 have a different phase sequence.

The phase sequence of the system is set in the device via the **Phase sequence** parameter for generator operation. The **Inverted phases** parameter is used to set which phase is swapped for the relevant measuring point. The swap is communicated to the measuring point via the binary input signal *>Invert Phases*. The changed phase sequence is then included for calculation of the measurands at the measuring point.

In accordance with *Figure 6-612* the phase sequence is set to ***ABC***. A is swapped with C in motor operation. The **Inverted phases** parameter must be set to ***AC*** for the measuring points of current measured values 2 and current measured values 3. As a result, the phase assignment for the differential protection IED2 and the impedance protection IED3 is correct. The positive-sequence and negative-sequence current is calculated correctly.

The following logic diagram shows the principle for determining the present phase assignment and measured variables with the example of currents.

The switchover of the phase sequence is only authorized for a time at which no measured values are pending at the selected measuring points. The switchover command must be present for at least 200 ms. The change in the phase sequence is only implemented if the measurands at the measuring points that are to be switched are under 5 % of the rated variables. If the currents of the measuring points of current measured values 2 and current measured values 3 of the example fall below 5 % of their rated variables, the switchover is released and the set phases are switched with active binary input.

[lo_phrgph, 1, en_US]

Figure 6-613 Measured Values for Changed-Over Phases

6.55.4 Application and Setting Notes

Parameter: Phase sequence

- Default setting **(_:101) Phase sequence** = ***ABC***

ABC	Phase sequence A, B, C
ACB	Phase sequence A, B, C

Parameter: Inverted phases

- Default setting **(_:106) Inverted phases** = ***none***

none	No phase exchange
AC	Phase A changed over with phase C

BC	Phase B changed over with phase C
AB	Phase C changed over with phase B

NOTE

If you change the setting value of the parameter **Inverted phases**, consider the following:
The device can take the new setting value only if the binary input signal *>Invert Phases* is not active.

Input signal: *>Phs-rotation reversal*

The *>Phs-rotation reversal* binary input is used to switch between the ***ABC*** phase sequence and the ***ACB*** phase sequence. The switchover direction depends on the setting of the **Phase sequence** parameter. In doing so, the phase sequence of all 3-phase measuring points is changed. Changing of the phase-rotation reversal via the binary input is only possible if no measurands (< 5 % of the rated variables) are present at all 3-phase measuring points.

Input signal: *>Invert Phases*

The binary input *>Invert Phases* is used to activate the setting of the parameter **Inverted phases**. In doing so, the phase sequence of the selected measuring point is changed. Changing of the phase sequence via the binary input is only possible if no measurand (< 5 % of the rated variables) is present at the respective 3-phase measuring point.

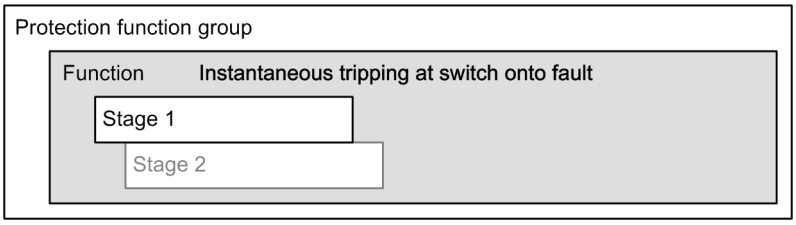
6.56 Instantaneous Tripping at Switch onto Fault



6.56.1 Overview of Functions

The **Instantaneous tripping at switch onto fault** function serves for immediate tripping when switching onto a fault.

The function does not have its own measurement and must be linked to another protection function with the pickup (measurement).

6.56.2 Structure of the Function

The function **Instantaneous tripping at switch onto fault** can be used in all protection function groups. The function is preconfigured with 1 stage. A maximum of 2 tripping stages can be operated simultaneously within the function. The tripping stages have an identical structure.

[dw_strsto, 1, en_US]

Figure 6-614 Structure/Embedding of the Function

6.56.3 Stage Description

Logic of the Stage

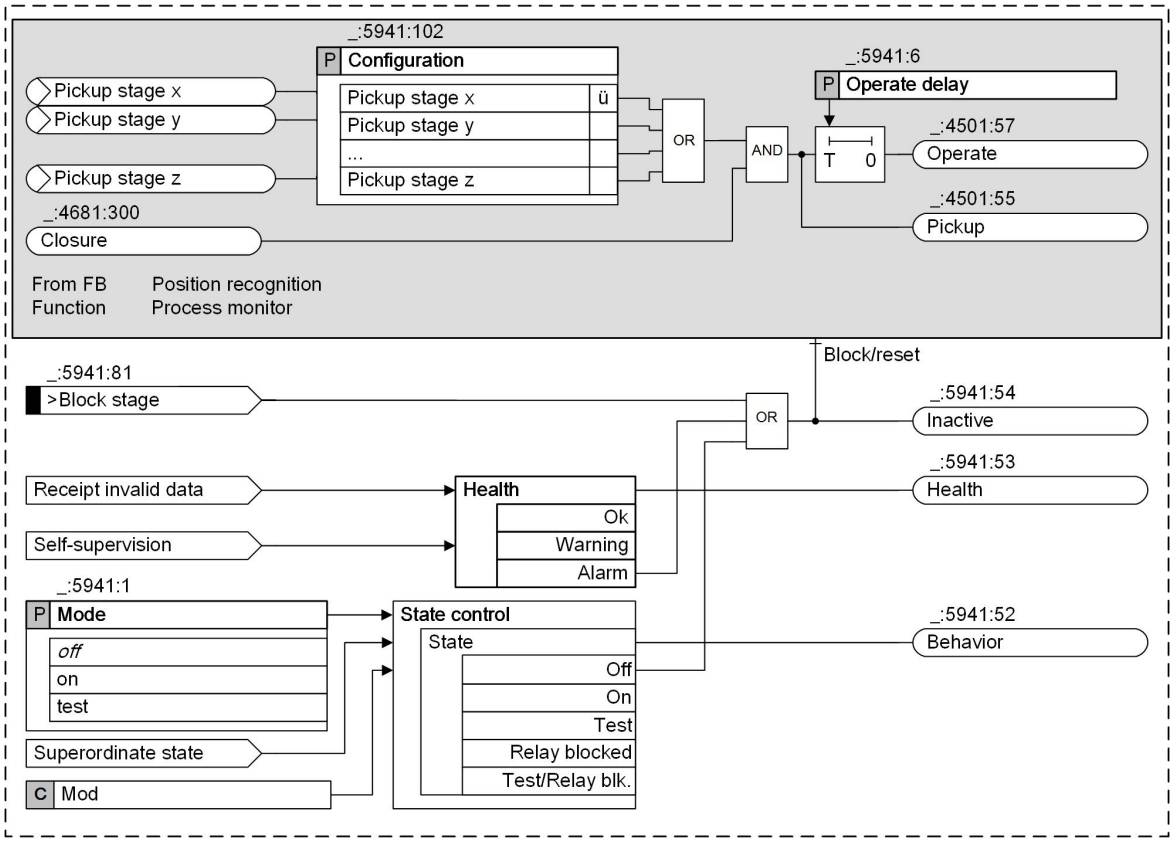


Figure 6-615 Logic Diagram of the Stage Instantaneous Tripping at Switch onto Fault

Connection of the Stage

The stage is intended to initiate instantaneous tripping when switching onto a fault. To do this, the stage must be connected to one or more pickups from protection functions or protection stages, for example, to pickup of an overcurrent-protection stage. That is, the stage of the **Instantaneous tripping at switch onto fault** function does not have its own measuring function but requires the pickup of another protection function or protection stage to pick up.

The stage is active only if switching is pending or executed (refer to *6.23 Overcurrent Protection, Phases*).

NOTE

If a protection stage picks up and tripping is blocked by the **Inrush-current detection** function, the **Instantaneous tripping at switch onto fault** function does not pick up. In this case there is no fault recording either.

Despite this, if a fault recording is necessary, you can activate it with the parameter **`(_:114) Start flt.rec`** of the **Inrush-current detection** function (refer to *6.68.1 Inrush-Current Detection*).

6.56.4 Application and Setting Notes

Parameter: Configuration

- Default setting **`(_:5941:102) Configuration`** = ***`no stage`***

The **Configuration** parameter is used to define the pickup of a protection function or protection stage that the **Instantaneous tripping at switch onto fault** function uses to respond.
Normally, the pickups of protection functions and stages with high fault current are selected:

- Overcurrent protection (phase and ground)
- Directional overcurrent protection (phase and ground)
- Ground-fault protection for grounded systems

A specific protection stage is generally used. This can be one of the protection stages provided for the protection application, which itself trips with a delay. An additional protection stage with settings optimized for this use case, for example, increased threshold value and blocking of self-tripping, can also be used.

Parameter: Operate delay

- Recommended setting value **(_:5941:6) Operate delay** = ***0.00 s***

When switching onto a fault, the tripping should usually be instantaneous. The tripping delay is therefore set to 0.

6.56.5 Settings

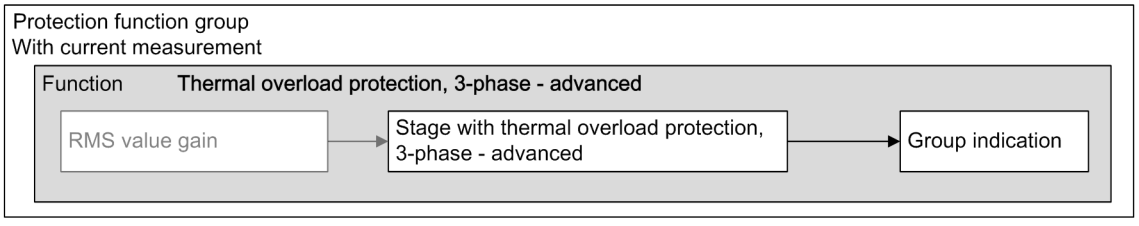
6.57 Thermal Overload Protection, 3-Phase - Advanced

6.57.1 Overview of Functions

The **Thermal overload protection, 3-phase – advanced** function (ANSI 49) is used to:



- Protect the equipment (motors, generators, transformers, capacitors, overhead lines, and cables) against thermal overloads
- Monitor the thermal state of motors, generators, transformers, capacitors, overhead lines, and cables

6.57.2 Structure of the Function

The **Thermal overload protection, 3-phase – advanced** function is used in protection function groups with current measurement.

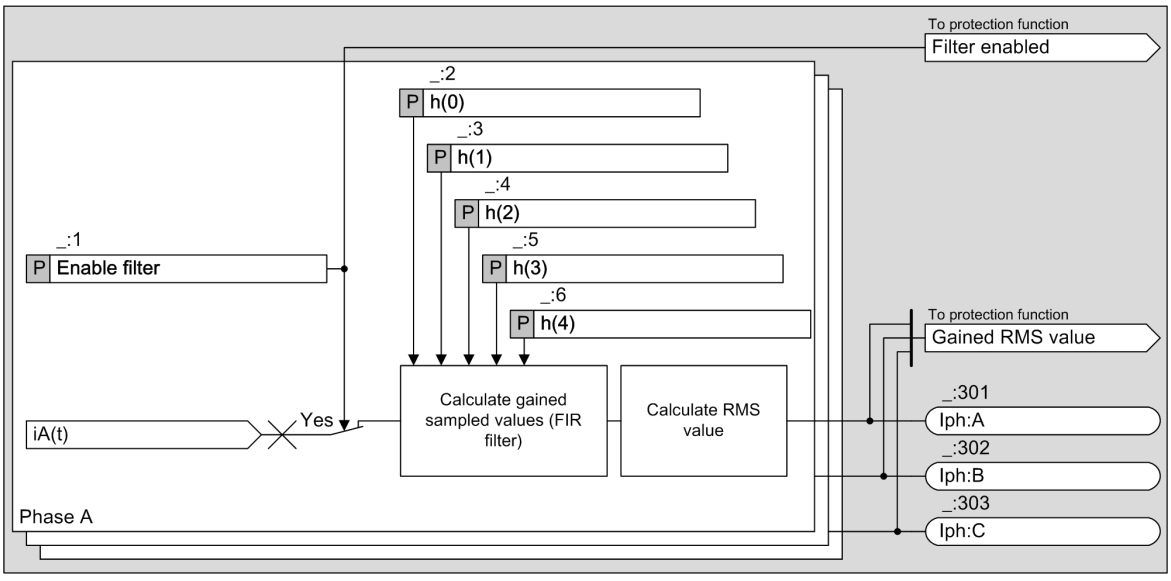
The function is preconfigured by the manufacturer with 1 **Thermal overload protection, 3-phase – advanced** stage.

The non-preconfigured function block **Filter** can optionally be applied to gain the RMS value used by the **Thermal overload protection, 3-phase – advanced** stage.

[dw_TOLP_with_filter_stage, 2, en_US]

Figure 6-616 Structure/Embedding of the Function

6.57.3 Filter for RMS Value Gain



6.57.3.1 Description

The function block **Filter** can be used to adapt the RMS value for 2 means:

- To gain harmonics in a defined way. Higher harmonics can stress the protected object thermally more than lower harmonics. This is the case for reactors applied in AC filters. In addition, the amplitude attenuation of higher frequencies due to the anti-aliasing filter of the device is automatically compensated by the filter
- To only compensate the amplitude attenuation of higher frequencies by the device (due to the anti-aliasing filter)

The filter gain (amplitude response) is realized by a 9-order FIR filter.

Logic

[lo_tolp_filter_stage, 1, en_US]

Figure 6-617 Logic Diagram of the Function Block Filter

The FIR filter gains the 8-kHz sampled values according to the set filter coefficients. Afterwards the RMS value is calculated. The symmetrical 9-order filter coefficients are set via the respective parameters **h(0)**, **h(1)**, **h(2)**, **h(3)** and **h(4)**.

NOTE

A FIR-filter configuration tool is provided as an auxiliary PC tool. With this PC tool, the coefficients h(0), h(1), h(2), h(3), h(4) of the FIR filter are generated according to the required gain factors (amplitude response). The tool can be obtained from the SIPROTEC download area. For more information about the tool, refer to the tool help function.

The gained RMS value is delivered to the protection stages only when the function block **Filter** is instantiated and the parameter **Enable filter** is set as ***yes*** . Otherwise, the normal RMS value is used.

Functional Measured Values

Values	Description	Primary	Secon-dary	% Referenced to
Iph:A	Filtered RMS measured value of current A	kA	A	Parameter **Rated current**
Iph:B	Filtered RMS measured value of current B	kA	A	Parameter **Rated current**
Iph:C	Filtered RMS measured value of current C	kA	A	Parameter **Rated current**

You can find the parameter **Rated current** in the **FB General** of function groups where the **Thermal overload protection, 3-phase - advanced** function is used.

If the parameter **Enable filter** is set to ***no***, the function values are shown as ---.

6.57.3.2 Application and Setting Notes

Parameter: Enable filter

- Default setting **(_:1) Enable filter** = ***no***.

With the parameter **Enable filter**, you set whether the **Filter** is enabled.

Parameter Value	Description
yes	If gained RMS values should be used in one of the protection stages, set parameter **Enable filter** = ***yes***.
no	If no gained RMS values are needed, set the parameter **Enable filter** = ***no***.

Parameter: `h(0),h(1),h(2),h(3),h(4)`

- Default setting **(_:2) h(0)** = ***0.000***
- Default setting **(_:3) h(1)** = ***0.000***
- Default setting **(_:4) h(2)** = ***0.000***
- Default setting **(_:5) h(3)** = ***0.000***
- Default setting **(_:6) h(4)** = ***1.000***

With the default value of the coefficients, the filter has no effect and no gain is applied.

If the filter shall be applied to adapt the RMS value calculation to a specific protection object such as a reactor, the reactor manufacturer has to provide the required amplitude response (gain factors) for the reactor. To determine the coefficients h(0) to h(4) for the FIR filter, you must enter the gain factors into the auxiliary PC tool which is available in the SIPROTEC download area. The 5 required coefficients are generated by the tool. They have to be entered manually as settings to configure the filter. The amplitude attenuation of higher frequencies due to the anti aliasing filter of the device is automatically taken into account and compensated by the filter.

To only compensate the attenuation of higher frequencies by the device, set the following coefficients in the filter.

Rated Frequency	Filter Coefficients for Only Compensating the Device Amplitude Attenuation
50 Hz	h(0) = -0.002 h(1) = -0.012 h(2) = 0.045 h(3) = -0.110 h(4) = 1.151
60 Hz	h(0) = -0.005 h(1) = -0.020 h(2) = 0.058 h(3) = -0.128 h(4) = 1.170

6.57.3.3 Settings

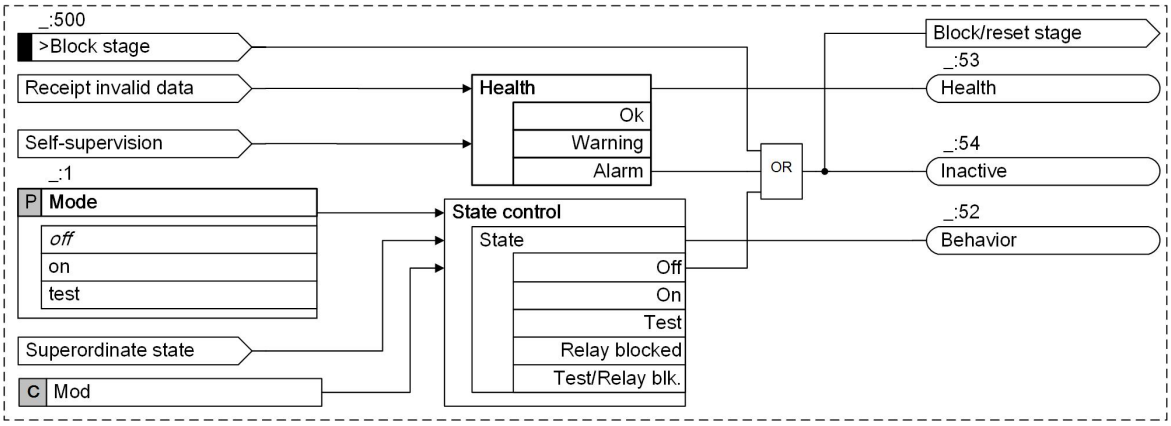
6.57.4 Stage with Thermal Overload Protection, 3-Phase - Advanced



6.57.4.1 Description

Logic

[lo_tolp_with_filter_stage, 2, en_US]

Figure 6-618 Logic Diagram of the Thermal Overload Protection, 3-Phase - Advanced Stage

[lo_stage_control_TOLP, 2, en_US]

Figure 6-619 Logic Diagram of the Stage Control

RMS-Value Selection

The protection function supports 2 kinds of RMS measurement:

- Normal RMS value
- Gained RMS value from the function block **Filter**

The gained RMS value is automatically used if the function block **Filter** is configured and the filter has been enabled.

NOTE

When the function block **Filter** is applied, only one current measuring point I-3ph is allowed to be connected to the 3-phase current interface of the function group.

Thermal Replica

The protection function calculates the overtemperature from the phase currents based on a thermal single-body model according to the thermal differential equation with

$$I_{p.u.}^2 = \tau_{th} \frac{d\theta}{dt} + \theta - \theta_{Amb}$$

[fo_diffgl-170914, 2, en_US]

With the following standardization:

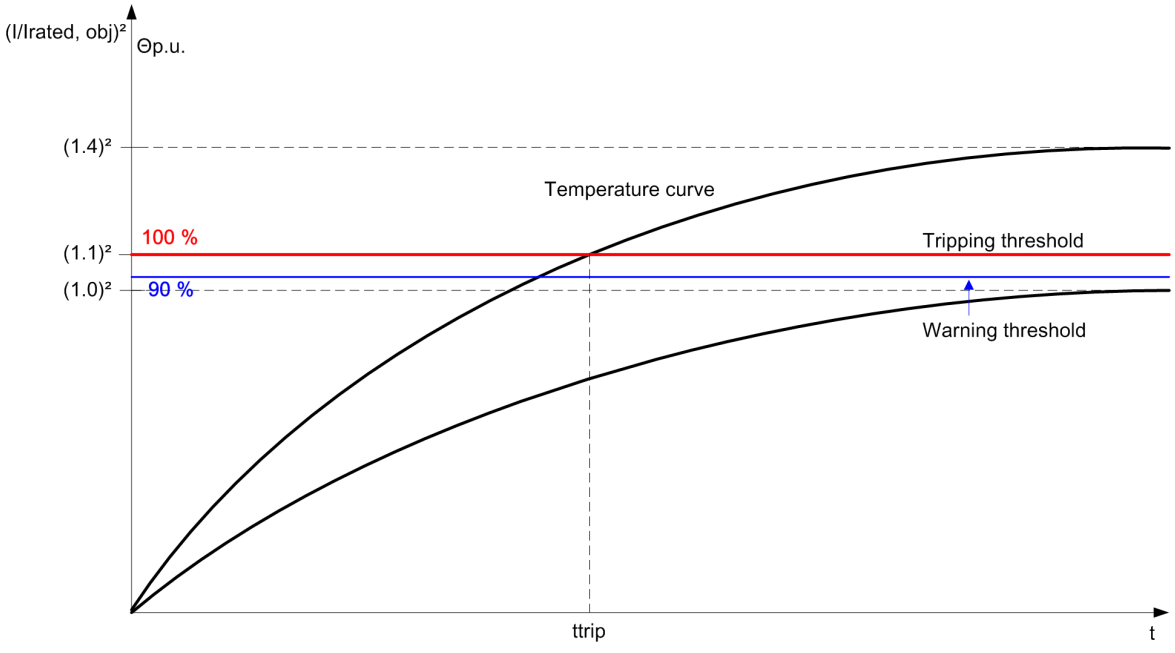
$$I_{p.u.} = \frac{I}{I_{max}} = \frac{I}{K \cdot I_{rated\ ,obj.}} \qquad \theta = \frac{\vartheta}{\vartheta_{max}} = \frac{\vartheta}{K^2 \cdot \Delta\vartheta_{rated\ ,obj.}}$$

$$\tau_{th} = R_{th} \cdot C_{th} \qquad \theta_{Amb} = \frac{\vartheta_{Amb} - 40\ °C}{\vartheta_{max}} = \frac{\vartheta_{Amb} - 40\ °C}{K^2 \cdot \Delta\vartheta_{rated\ ,obj.}}$$

[fo_normie_01, 3, en_US]

Θ	Current overtemperature, in relation to the final temperature at a maximum permissible phase current k $I_{rated, obj}$
Θ_{Amb}	Standardized ambient temperature, where ϑ_{Amb} describes the coupled ambient temperature. The coupled ambient temperature ϑ_{Amb} can be the measured ambient temperature or the ambient temperature preset using the **`Default temperature`** parameter.
$\Delta\vartheta_{rated\ obj}$	Overtemperature of the protected object set at rated current

τ_{th}	Thermal time constant (temperature rise/cooling) of the protected object
k	This factor indicates the maximum continuous permissible phase current. The factor refers to the rated current of the protected object ($k = I_{max}/I_{rated, obj}$)
$I_{rated, obj}$	Rated current of the protected object



At the same time, $I_{rated, obj}$ is the rated current of the assigned protected object side:

- In the case of transformers, the rated current of the winding to be protected, which the device calculates from the set rated apparent power and rated voltage, is decisive.
- The uncontrolled winding forms the basis in the case of transformers with voltage control
- In the case of generators, motors and reactors, the rated current, which the device calculates from the set rated apparent power and rated voltage, is decisive.
- In the case of lines, nodes and busbars, the rated current of the protected object is set directly

In a steady state, the solution to the thermal differential equation is an e-function whose asymptote represents the final overtemperature Θ_{end}. The time constant τ_{th} determines the rise. After reaching an initial adjustable overtemperature threshold Θ_{warn} (**`Threshold thermal warn.`**), a warning indication is given.

If the overtemperature limit Θ_{Off} (tripping overtemperature) is exceeded, an operate indication is immediately issued and the equipment disconnected from the power supply. This threshold is specified at 100 % and corresponds to the final temperature set at a flowing permissible continuous current (I_{max}).

Figure 6-620 shows the temperature rise at different overload currents and the supervision thresholds.

[dw_temp_ve, 1, en_US]

Figure 6-620 Temperature History for Different Overload Currents (**`K-factor`** = ***`1.1`***)

The overtemperature is calculated separately for each phase. The current overtemperature can be obtained from the operational measured values. It is shown in percent. An indication of 100 % means that the thermal threshold has been reached. The maximum overtemperature of the phases is regarded as the tripping temperature. This means that the highest of the 3 phase currents is always assumed.

The analysis of the RMS values of the currents over a broad frequency band also includes the harmonic components. These harmonic components contribute to the temperature rise of the equipment.

If the flowing current falls below an adjustable minimum current **`Imin cooling`** , the **`Cooling time constant`** is activated.

Operate Curve

If the ambient temperature is not measured and set to 40°C, you can get the operate curve as following:

$$t = \tau_{th} \cdot \ln \frac{\left(\frac{I}{k \cdot I_{rated,obj.}}\right)^2 - \left(\frac{I_{preload}}{k \cdot I_{rated,obj.}}\right)^2}{\left(\frac{I}{k \cdot I_{rated,obj.}}\right)^2 - 1}$$

[fo_auslos, 1, en_US]

t	Operate time
τ_{th}	Time constant
I	Measured load current
$I_{preload}$	Preload current
k	Setting factor according to VDE 0435 part 3011 or IEC 60255-149 (K factor)
$I_{rated, obj}$	Rated current of the protected object

Ambient Temperature

This function takes the ambient temperature into consideration. The reference temperature of the thermal model is 40 °C.

Compared to the reference temperature, a different ambient temperature leads to different results.

- The ambient temperature is smaller than the reference temperature.

  If the ambient temperature is smaller than the reference temperature, the thermal limit increases. This means that the persistent maximum permissible current increases and results in a higher actual K factor.
- The ambient temperature is larger than the reference temperature.

  If the ambient temperature is larger than the reference temperature, the thermal limit decreases. This means that the persistent maximum permissible current decreases and results in a lower actual K factor.

The ambient temperature can be measured with an RTD (Resistance Temperature Detector) element and can influence the thermal limit dynamically. Alternatively, a higher or lower ambient temperature can be considered statically with the parameter **`Default temperature`**, which results in a lower or higher actual K factor compared to the parameter that corresponds to an ambient temperature of 40 °C.

So, the parameter **`Default temperature`** is a fixed value to describe the ambient temperature if no sensor is connected or it is the value to be considered if the temperature sensor is defective. The parameter **`Minimal temperature`** parameter limits the coupled ambient temperature. If the measured ambient temperature is lower than the minimum temperature, the minimum temperature is processed in the thermal model.

To calculate the actual K factor depending on the ambient temperature, the value of the parameter **`Temperature rise at Irated`** is required.

The ambient temperature is measured by an external RTD unit or by an IO111 module and provided by the functions **RTD unit Ether.**, **RTD unit serial**, or **Temperature module IO111** of the function group **Analog unit**. When using the parameter **`Temperature sensor`** , the respective temperature sensor can be selected.

If the temperature measurement is faulty, for example, due to an open circuit between the device and the RTD unit, the health state of the function **Thermal overload protection, 3-phase – advanced** changes to *Warning*. In this case, the process continues with either the temperature measured last or the value set under the parameter **`Default temperature`**, depending on which value is higher.

Current Influence

The thermal replica based on the single-body model applies with limitations to high overcurrent situations (short circuits, motor startup currents). To avoid an overfunction of the overload protection, the thermal replica must be influenced for overcurrents (exceeding $\mathbf{I}_{threshold}$). You can select between 2 strategies for this:

- Freezing of the thermal memory
- Limitation of the input current for the thermal replica to the set current. The temperature rise is thereby **retarded** at high currents.

Warning Thresholds

The thermal warning threshold issues a warning indication before the tripping threshold (tripping temperature) is reached. In this way, for example, a load can be reduced in sufficient time and a disconnection avoided. At a normal **K-factor** of ***1.1***, a thermal memory value of 83 % sets in at continuously flowing rated current.

Apart from the thermal warning threshold, the overload protection also has a current-warning threshold. This current-warning threshold can signal an overload current in sufficient time before the overtemperature value has reached the warning or tripping threshold.

Dropout of Tripping

Once the thermal memory has fallen below the setting value of the **Dropout threshold operate** , the trip command is canceled upon tripping. In contrast, the current-warning threshold and the thermal warning threshold are reduced at a fixed dropout threshold (see Technical Data).

Behavior in the Event of Auxiliary-Voltage Failure

The behavior of the thermal replica can be controlled upon auxiliary-voltage failure via the setting parameter **Storage of thermal replica** . You can save the thermal state for a time of 500 min. Once the supply voltage returns, the thermal replica continues to function with the saved thermal state.

If the thermal replica is not saved, it will be reset to 0 upon failure of the auxiliary voltage.

Resetting the Thermal Map

You can reset the thermal memory via the binary input indication **>Reset thermal replica** . The thermal memory will then have a 0 value. A reparameterization will also lead to resetting the thermal memory.

Emergency Start

Depending on the operating conditions, tripping can be blocked or closure enabled despite the permissible thermal limits being exceeded. Upon activation of the binary input signal **>Emergency start** , tripping is blocked and closure enabled. This does not affect the state of the thermal memory. After the input **>Emergency start** disappears, the blocking remains in effect for the set **Emerg. start T overtravel** .

Blocking the Function

Blocking will cause a picked up function to be reset. The tripping function can be blocked externally or internally by the binary input signal **>Block stage** .

All indications then drop out and the thermal memory is set to the value 0.

Blocking Closure

The signal **Block close** can be used to prevent closure of the protected object at a high thermal load. The signal is set if the tripping overtemperature is exceeded, and canceled if the temperature falls below the dropout threshold.

Functional Measured Values

Values	Description	Primary	Secondary	% Referenced to
(_:601:305) Time until trip	Expected time until tripping	s	s	s
(_:601:304) Time until close	Time until close release	s	s	s
(_:601:306) Overload phase A	Thermal measured values of the phases	%	%	Tripping temperature
(_:601:307) Overload phase B				
(_:601:308) Overload phase C				

Values	Description	Primary	Secondary	% Referenced to
(_:601:309) Overload maximum	Thermal measured value of the overload protection	%	%	Tripping temperature
(_:601:310) Equival. current phs A	Current measured value which serves as basis for the overload measured value	A	A	Rated operating current of the primary values
(_:601:311) Equival. current phs B				
(_:601:312) Equival. current phs C				
(_:601:313) Equival. current max.	Maximum current measured value which serves as basis for the overload measured value	A	A	Rated operating current of the primary values

6.57.4.2 Application and Setting Notes

Motors and generators as well as transformers are at risk from longer-lasting overloads. The overload protection has a thermal operate curve, which can be adapted to the overload capacity of the equipment that is to be protected.

Parameter: Threshold current warning

- Default setting **(_:101) Threshold current warning** = ***1.000 A*** at I_{rated} = 1 A

Set the threshold to the maximum permissible continuous current ($I_{max, perm}$). This results in the same setting value as for the **K-factor**.

Parameter: Threshold thermal warn.

- Default setting **(_:104) Threshold thermal warn.** = ***90 %***

The default setting can be left at a **K-factor**, of ***1.1***, as the thermal memory results for 83 % at continuously flowing rated current. The calculation uses the rule of three: 100 % corresponds to (**K-factor**)^2 and x % corresponds to 1^2.

$$\frac{\Theta}{\Theta_{off}} = \frac{100\ \%}{k^2} = 83\ \%$$

[fo_warnsc_2, en_US]

At a **K-factor** of 1.05, the thermal memory for rated current is already 91 % filled. Increase the **Threshold thermal warn.** to 95 %.

Parameter: Dropout threshold operate

- Default setting **(_:105) Dropout threshold operate** = ***90 %***

The **Dropout threshold operate** parameter is used to drop out pickup and tripping when the value drops below this threshold. A setting on the order of magnitude of the warning threshold is recommended. You can select a lower setting value for special applications, desired additional cooling or longer blocking of closing.

Note that the calculation of the operational measured value **Time until close** refers to this value.

Parameter: Emerg. start T overtravel

- Default setting **(_:112) Emerg. start T overtravel** = ***300 s***

The **Emerg. start T overtravel** parameter is used to set the time for which blocking of the tripping has to remain active after an outgoing binary input signal **>Emergency start**. With an outgoing input signal, the load on the protection object is removed. The emergency start T-overtravel must be set long enough to allow the thermal memory to fall below the dropout threshold after cooling. Select a time on the order of magnitude of the **Cooling time constant**. In the example, 105 min (6300 s) have been assumed.

Parameter: K-factor

- Default setting **(_:106) K-factor** = ***1.10***

The **K-factor** parameter is used to describe the limiting value for the maximum permissible continuous load. The rated current $I_{rated, obj}$ of the protected object (motors, generators, transformers) is the basic current for the overload detection. If motors are designed according to temperature class F and operated according to temperature class B, selection of the 1.1 times rated current (**K-factor** = ***1.1***) is always permissible. In the case of transformers, **K factors** of **1.15** to maximum **2.1** can also occur.

You can determine the **K-factor** on the basis of the thermally permissible continuous current $I_{max, perm.}$:

$$K-factor = \frac{I_{max,perm.}}{I_{rated,obj.}}$$

[fo_tolp_kf, 2, en_US]

NOTE

The thermally permissible continuous current for the protected object is known from relevant tables, from the thermal limit curves or from the specifications of the manufacturer!

EXAMPLE

Motor and transformer with the following data

Continuous permissible current: $I_{max\ perm.} = 1.1\ I_{rated\ motor}$

Rated current of the motor: $I_{rated\ motor} = 1100$ A

Selected **K factor** of 1.1

Parameter: Thermal time constant

- Default setting **(_:110) Thermal time constant** = ***900 s***

The **Thermal time constant** parameter is used to define the tripping characteristics of the stage.

NOTE

The **Thermal time constant** is specified by the machine manufacturer.

For motors, for instance, it is on the order of magnitude of 10 to 30 min. Deviations are possible. A **Thermal time constant** of ***15.12 min*** is a customary value in practice.

If, on the other hand, the **Thermal time constant** is not known, but only an operate curve is available, the time constant can also be concluded from this. Define the **K-factor** for this by calculating the maximum permissible overcurrent or assuming the **K-factor** (**K-factor** = ***1.1***). The operate time for a current value (for example, 1.5 $I_{rated, obj.}$) is read off from the operate curve. The current value must be close to the overload current value.

The operate curves are indicated for both the cold and warm state. The operate curve for the **cold** state is recommended for calculating the time constant.

Use the formula for the operate time to calculate the **Thermal time constant** parameter. It must be converted according to the time constant τ_{th}. For the cold-operation case, set the previous current to 0 ($I_{previous\ load} = 0$).

$$t = \tau_{th} \cdot \ln\left[\frac{\frac{1}{k^2}\left(\frac{I}{I_{rated\ ,obj.}}\right)^2 - \frac{1}{k^2}\left(\frac{I_{preload}}{I_{rated\ ,obj.}}\right)^2}{\frac{1}{k^2}\left(\frac{I}{I_{rated\ ,obj.}}\right)^2 - 1}\right]$$

[fo_konsmt, 2, en_US]

EXAMPLE

For the asynchronous motor

K factor = 1.1

Characteristic curve class 10 according to ANSI: At 1.5 $I/I_{rated, obj}$, a required operate time of 700 s is derived from the characteristic curve.

The **Thermal time constant** can therefore be calculated:

$$700\ s = \tau_{th} \cdot \ln \frac{\frac{1}{1.1^2}\left(\frac{1.5\, I_{rated,obj.}}{I_{rated,obj.}}\right)^2}{\frac{1}{1.1^2}\left(\frac{1.5\, I_{rated,obj.}}{I_{rated,obj.}}\right)^2 - 1} = \tau_{th} \cdot 0.772$$

[fo_konsta_01, 2, en_US]

This results in a setting value of 907 s for the **Thermal time constant**.

Parameter: Cooling time constant

- Default setting **(_:111) Cooling time constant** = ***3600 s***

The **Cooling time constant** parameter is used to define the cooling characteristics of the thermal stage. If the machines come to a standstill and hence self-cooling (for instance, via the fan impeller) is absent, the cooling will take considerably longer. Standstill sensing is performed via the current. For the **Cooling time constant**, 7 times the time of the thermal time constant 6350 s (105 min) is selected. This is a customary value in practice.

NOTE

The **Cooling time constant** is a multiple of the thermal time constant and can be taken from the motor data.

Parameter: Imax thermal

- Default setting **(_:107) Imax thermal** = ***2.5 A*** at I_{rated} = 1 A

The **Imax thermal** parameter allows you to set the threshold current for the **Behav. at I> Imax therm.** parameter. If you calculate with relatively long start times for motors (longer than 25 s), the current limiting must be reduced to 2 $I/I_{rated, obj}$.

Parameter: Imin cooling

- Default setting **(_:108) Imin cooling** = ***0.500 A***

When defining the minimum current **Imin cooling**, you can use the no-load current for orientation. If no data is available, set 0.05 $I/I_{rated, obj}$. If the current falls below this value, there is an automatic switchover to the **Cooling time constant**.

Parameter: Temperature rise at Irated

- Default setting **(_:109) Temperature rise at Irated** = ***70 K***

Consider this parameter only if the ambient temperature is not 40 °C or if you use a sensor for the measurement of the ambient temperature.

At an ambient temperature of 40 °C, if the equipment operates continuously with the rated current, the temperature rise is 70 K. Here, the rated current refers to the protected object. You can find the temperature value in the technical data of the equipment or measure it. If you use a temperature sensor when measuring

at the rated current, deduct the actual ambient temperature or the coolant temperature from the measured value.

When selecting the setting value, you can also use the specified temperature class for orientation. Usually, you will find the overtemperature expressed in Kelvin (K), which can be accepted as is. If the absolute temperature is given, the ambient temperature must be deducted. As a rule, this is 40 °C.

The overtemperature at maximum permissible current (***ϑmax***) and the **`Temperature rise at Irated`** (***ϑrated,obj.***) can be converted by using the following formula:

$$k^2 = \left(\frac{\Delta\vartheta_{max}}{\Delta\vartheta_{rated\ ,obj.}} \right)$$

[fo_ueb_for_Irated, 3, en_US]

EXAMPLE:

Temperature class **B** for continuous operation: permissible overtemperature = 80 K

From this, a temperature for I_{rated} of 120 °C (80 K + 40 °C) can be derived when using a temperature sensor for the measurement.

Temperature class **F** as thermal limiting value: permissible overtemperature = 105 K.

From this, a maximum temperature of 145 °C (105 K + 40 °C) derives.

From these values, the K factor can be derived:

$$k^2 = \frac{\Delta\vartheta_{max\ ,Obj.}}{\Delta\vartheta_{rated\ ,Obj.}} = \frac{105\ K}{80\ K} = 1.31 \qquad \rightarrow\ k = 1.146$$

[fo_bsp_kfaktor, 3, en_US]

If you select a setting value of 1.1 for the **`K-factor`**, your selection can be considered as conservative.

NOTE

For electrical machines, the limits can vary depending on the type of coolant.

Consult the machine manufacturer to agree on a setting value for the overtemperature.

Parameter: **`Storage of thermal replica`**

- Default setting **`(_:113) Storage of thermal replica`** = ***`no`***

If a continuous auxiliary voltage for the bay units is ensured, the bay default setting can be retained.

Parameter: **`Behav. at I> Imax therm.`**

- Default setting **`(_:114) Behav. at I> Imax therm.`** = ***`current limiting`***

The **`Behav. at I> Imax therm.`** parameter is used to select the process by which the function reacts to short-circuit currents. To prevent premature tripping of the overload protection at low time constants, high preloading and high short-circuit currents, the thermal replica can be modified. As overcurrent due to a starting of the motor also leads to a certain heating of the stator winding, limiting the input current is recommended for machines.

Parameter Value	Description
`current limiting`	The input currents are limited to the value set in the **`Imax thermal`** parameter. If the measured current exceeds the set current value, the limited current value is supplied to the thermal replica. An advisable current threshold is approx. 2 to 2.5 $I_{rated, obj}$.
`freeze therm. rep.`	If input currents exceed the **`Imax thermal`** parameter, the thermal replica will be frozen for the time the parameter is exceeded. This parameter value is provided to enable compatibility with **older products**!

Parameter: `Temperature sensor`

- Default setting **`(_:44) Temperature sensor`** = ***none***

With the **`Temperature sensor`** parameter, you determine which temperature sensor to use to detect the ambient temperature.

A temperature sensor is used to measure the ambient temperature of the protected object and to feed it to the device via an RTD unit (RTD = Resistance Temperature Detector) or via an IO111 module. The function **Thermal overload protection, 3-phase – Advanced** receives the measured temperature value via the functions **RTD unit Ether.** or **RTD unit Serial** or **Temperature module IO111** from the function group **Analog units**.

Parameter: `Default temperature`

- Default setting **`(_:118) Default temperature`** = ***40 °C***

The **`Default temperature`** defines the ambient temperature under the following conditions:

- No temperature sensor for measuring the ambient temperature is connected.
- The temperature measurement is faulty and the last measured temperature value is less than the **`Default temperature`**.

The actual K factor which defines the thermal limit of the function **Thermal overload protection, 3-phase – Advanced** is influenced by the parameter **`Default temperature`**. For the default value ***40 °C***, the persistent maximum permissible current equals to K times the $I_{rated,\ motor}$. A lower or higher **`Default temperature`** results in a higher or lower actual K factor. Siemens recommends using the default setting.

Parameter: `Minimal temperature`

- Default setting **`(_:117) Minimal temperature`** = ***-20 °C***

If the measured ambient temperature drops below the set value, the set value is assumed as the ambient temperature. If the overload protection works with a prespecified outside temperature, and this temperature drops below the value set in the **`Minimal temperature`** parameter, the **`Minimal temperature`** is also used.

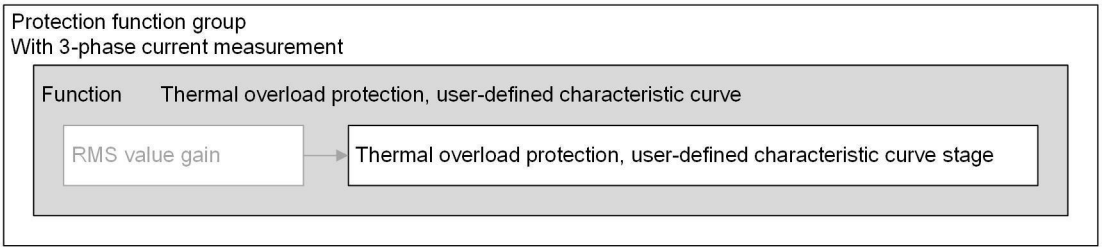
6.58 Thermal Overload Protection, User-Defined Characteristic Curve

6.58.1 Overview of Functions

The **Thermal overload protection, user-defined characteristic curve** function (ANSI 49) is used to:



- Protect the equipment (motors, generators, and transformers) against thermal overloads
- Realize a manufacturer specific overload characteristic curve for specific equipment, for example, shunt reactors
- Monitor the thermal state of motors, generators, and transformers

6.58.2 Structure of the Function

The **Thermal overload protection, user-defined characteristic curve** function is used in protection function groups with 3-phase current measurement.

The function comes factory-set with 1 **Thermal overload protection, user-defined characteristic curve** stage.

The non-preconfigured function block **Filter** can optionally be applied to gain the RMS value used by the **Thermal overload protection, user-defined characteristic curve** stage.

[dw_TOLP_user_curve_str, 2, en_US]

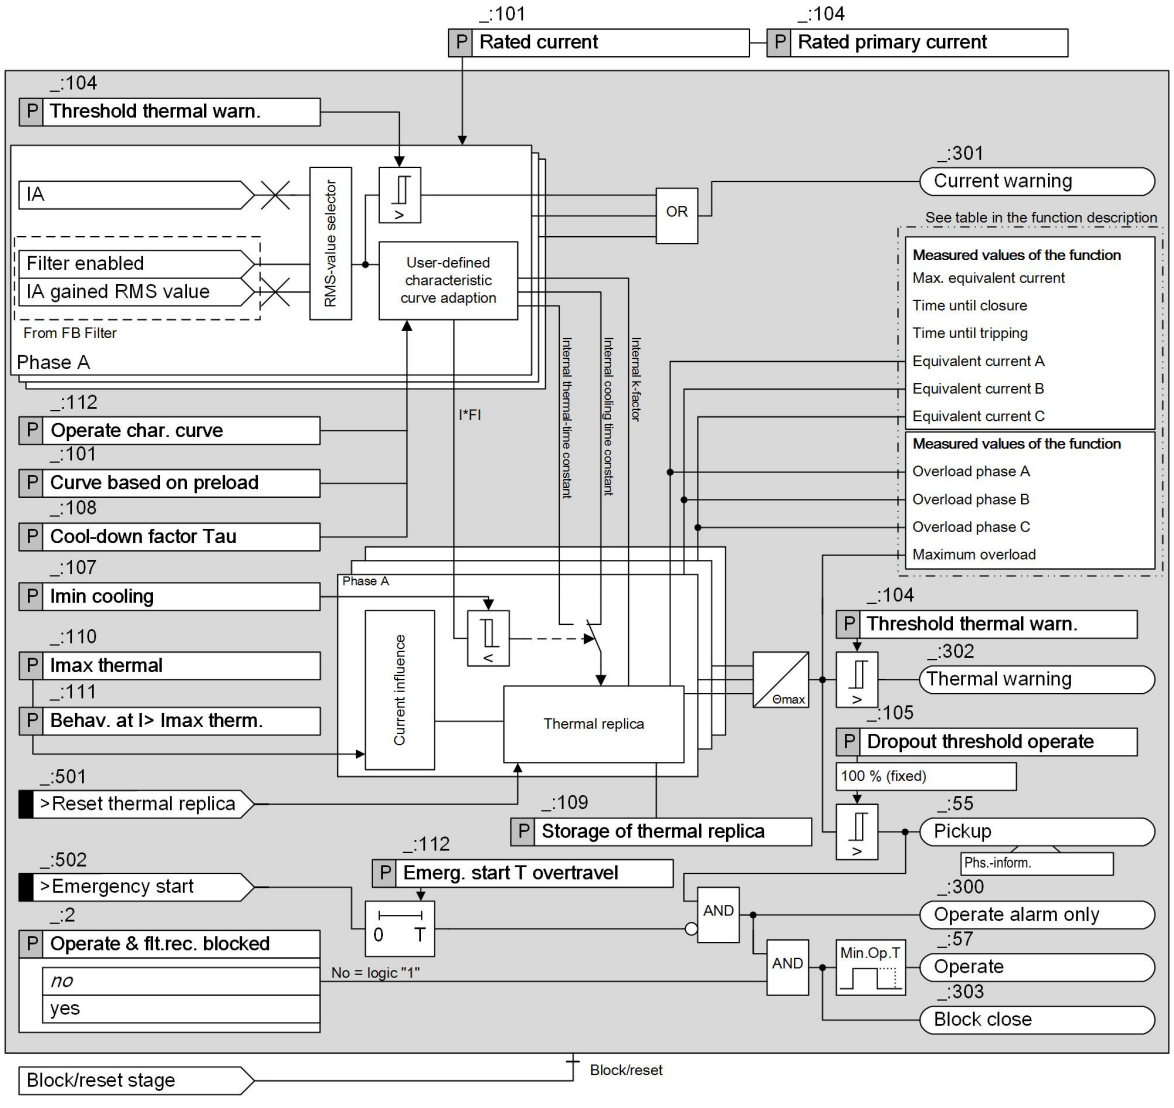


Figure 6-621 Structure/Embedding of the Function

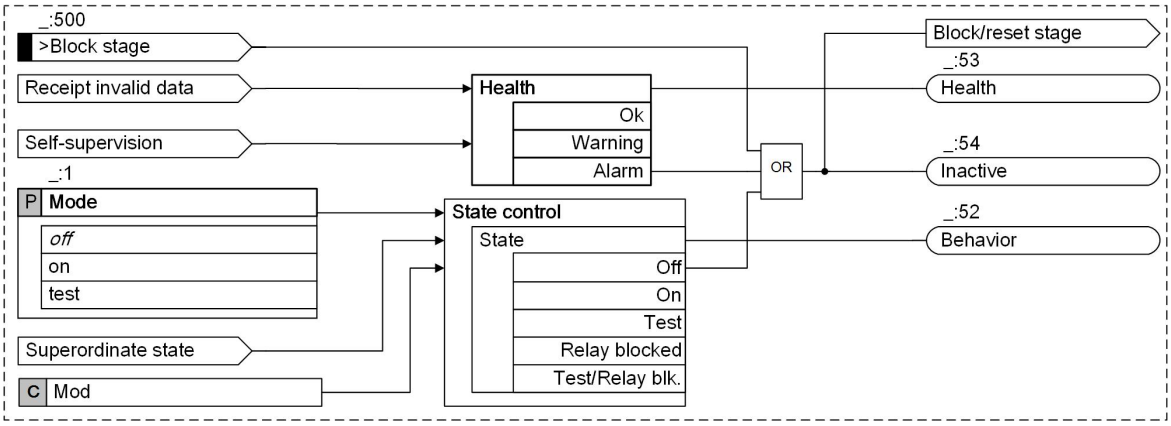
6.58.3 Function Description

Filter for RMS Value Gain

You can find more information about the function block **Filter** in chapter *6.23.3 Filter for RMS Value Gain*.

Logic



[lo_tolp_user_curve_stage, 2, en_US]

Figure 6-622 Logic Diagram of the Thermal Overload Protection, User-Defined Characteristic Curve Function

(1) The **(_:101) Rated current** parameter is from the protected object.

(2) The **(_:104) Rated primary current** parameter is from the used current transformer.

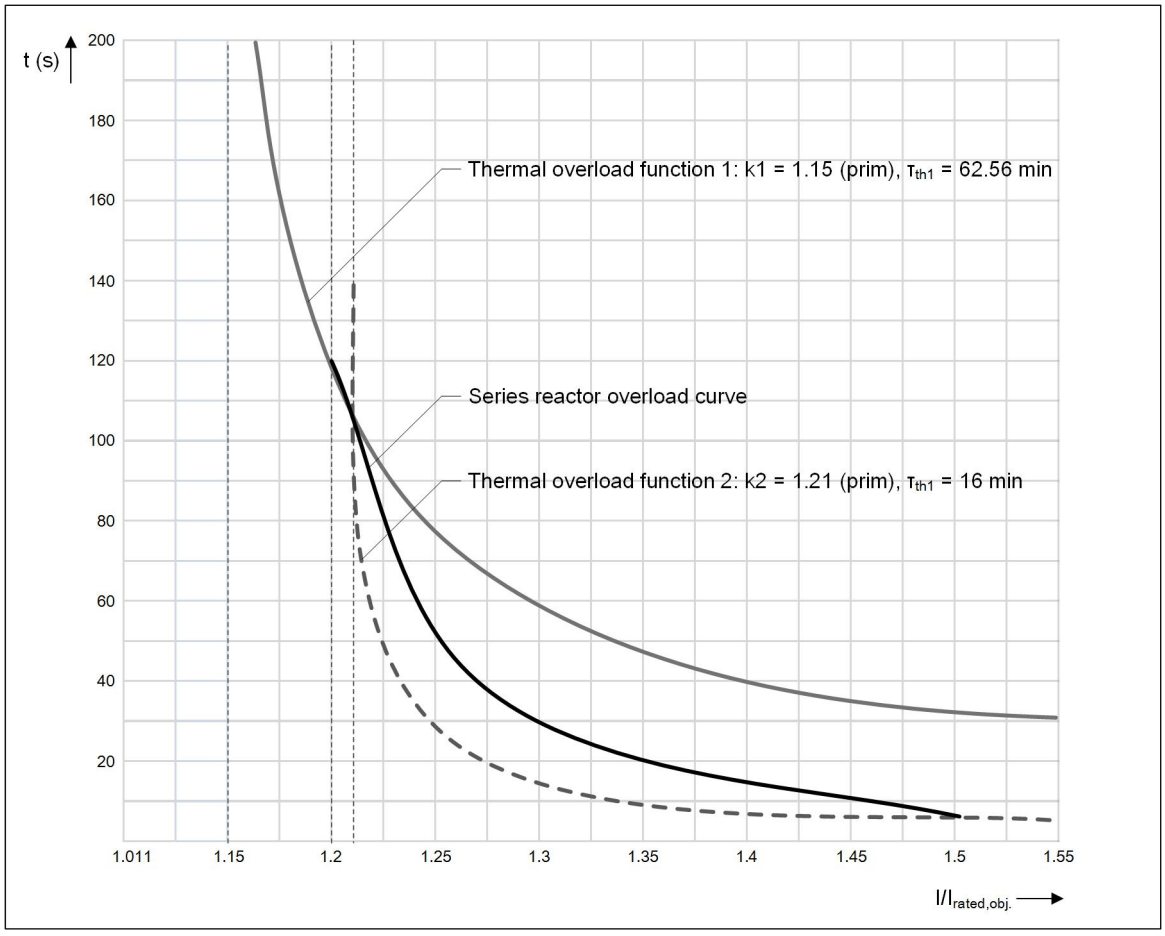
[lo_stage_control_TOLP, 2, en_US]

Figure 6-623 Logic Diagram of the Stage Control

RMS-Value Selection

The protection function supports 2 kinds of RMS measurement:

- Normal RMS value
- Gained RMS value from the function block **Filter**



The gained RMS value is automatically used if the function block **Filter** is configured and the filter has been enabled.

NOTE

When the function block **Filter** is applied, only one current measuring point I-3ph is allowed to be connected to the 3-phase current interface of the function group.

User-Defined Characteristic Curve

For specific equipment (for example, shunt reactors and transformers) or for special applications, the manufacturer specifies an overload characteristic curve. This curve cannot be described accurately with a single-body model so that deviations can occur. The following figure shows an example of a predefined overload characteristic curve and 2 standard characteristic curves based on the single-body model.

[dw_TOLP_user_curve_characteristic, 2, en_US]

Figure 6-624 User-Defined Characteristic Curve with Replica of Standard Characteristics

The calculation is identical to the realization of the standard **Thermal overload protection, 3-phase - advanced** function. You can find more information in the function description **Thermal overload protection, 3-phase - advanced** starting from chapter *6.57.1 Overview of Functions*.

The main deviations are as follows:

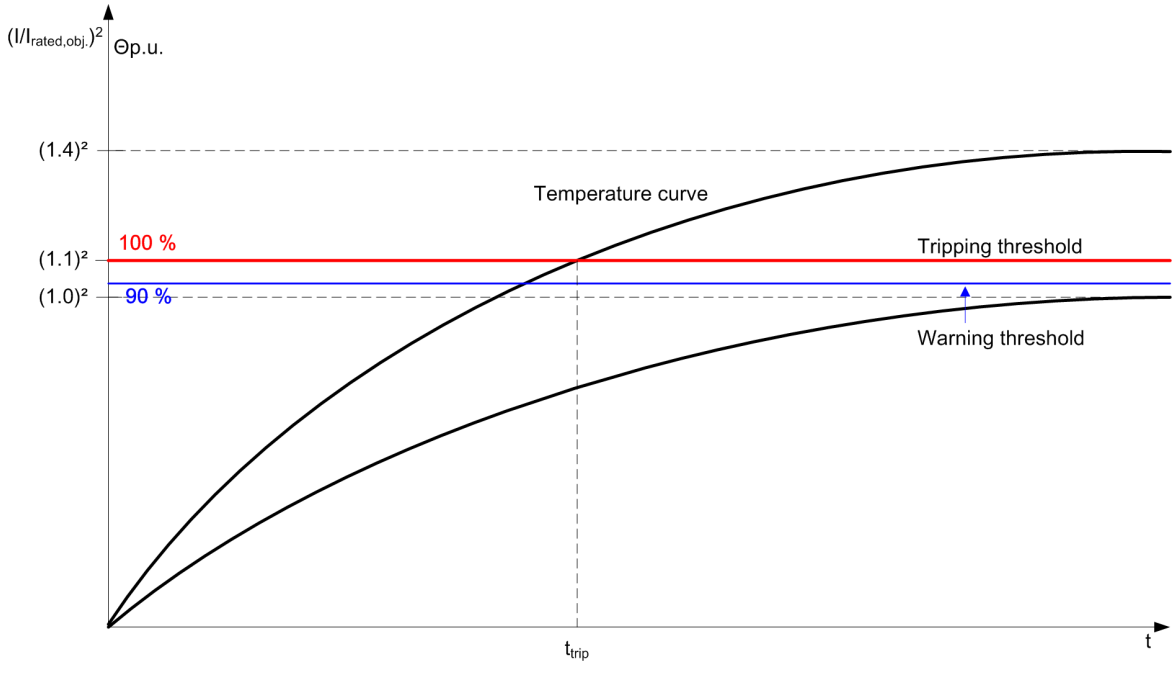
- The thermal characteristic is set with a flexible characteristic ($t_{trip} = f(I/I_{rated,obj})$).
  - The first point of the characteristic curve is important and is used to calculate the internal k-Factor. To meet the applications with a minimum internal k-Factor value of 1.001, the minimum $I/I_{rated,obj}$ value of 1.011 can be set as the first point of the characteristic curve.
  - The point at $I/I_{rated,obj} = 1.5$ is used to calculate the internal thermal time constant. If there is no point at $I/I_{rated,obj} = 1.5$, the point which is the closest to $I/I_{rated,obj} = 1.5$ from $I/I_{rated,obj} = 1.1$ is used to calculate the internal thermal time.
  - The points are set according to the maximum permissible load current.
- The **`Curve based on preload`** parameter describes for which thermal preload the user-defined characteristic curve is valid. Normally, such a curve is given for protected objects under rated load.
- The **`Cool-down factor Tau`** parameter is used for the determination of the cooling time constant. The set factor is multiplied with the internal calculated time constant.
- The thermal model is based on a constant ambient temperature of 40 °C. It cannot be corrected via the external measurement.

Thermal Replica

The protection function calculates the overtemperature from the phase currents on the basis of a thermal single-body model according to the thermal differential equation with

$$I_{p.u.}^2 = \tau_{th} \frac{d\theta}{dt} + \theta$$

[fo_tolp_diffgl, 1, en_US]



With the following standardization:

$$I_{p.u.} = \frac{I}{I_{max}} = \frac{I}{K \cdot I_{rated\ ,obj.}} \quad \theta = \frac{\vartheta}{\vartheta_{max}} = \frac{\vartheta}{K^2 \cdot \Delta\vartheta_{rated\ ,obj.}}$$

$$\tau_{th} = R_{th} \cdot C_{th}$$

[fo_tolp_normie, 1, en_US]

Θ	Current overtemperature, in relation to the final temperature at a maximum permissible phase current k $I_{rated, obj}$
$\Delta\vartheta_{rated\ obj}$	Overtemperature of the protected object set at rated current
τ_{th}	Thermal time constant (temperature rise/cooling) of the protected object. The value is calculated internally.
K	This factor indicates the maximum continuous permissible phase current. The factor refers to the rated current of the protected object ($K = I_{max}/I_{rated, obj}$) and is calculated internally.
$I_{rated, obj}$	Rated current of the protected object

[dw_TOLP_temperature, 1, en_US]

Figure 6-625 Temperature History for Different Overload Currents (**K-factor** = ***1.1***)

The overtemperature is calculated separately for each phase. The current overtemperature can be obtained from the operational measured values. It is shown in percent. An indication of 100 % means that the thermal threshold has been reached. The maximum overtemperature of the phases is regarded as the tripping temperature. This means that the highest of the 3 phase currents is always assumed.

The analysis of the RMS values of the currents over a broad frequency band also includes the harmonic components. These harmonic components contribute to the temperature rise of the equipment.

Current Influence

The thermal replica based on the single-body model applies only with limitations to high overcurrent situations (short circuits, motor startup currents). To avoid an overfunction of the overload protection, the thermal replica must be influenced in case of overcurrents (exceeding $I_{threshold}$). You can select between 2 strategies for this:

- Freezing of the thermal memory
- Limitation of the input current for the thermal replica to the set current. The temperature rise is thereby **retarded** at high currents.

Warning Thresholds

The thermal warning threshold issues a warning indication before the tripping threshold (tripping temperature) is reached. In this way, for example, a load can be reduced in sufficient time and a disconnection can be avoided. If the first setting value of the user-defined characteristic curve is set to 1.1 of the rated current, a thermal memory value of 83 % is set to the continuously flowing rated current.

Apart from the thermal warning threshold, the overload protection also has a current-warning threshold. This current-warning threshold can signal an overload current in sufficient time before the overtemperature value has reached the warning or tripping threshold.

Dropout of Tripping

Once the thermal memory has fallen below the setting value of the **Dropout threshold operate**, the trip command is cancelled upon tripping. In contrast, the current-warning threshold and the thermal warning threshold are reduced at a fixed dropout threshold (see Technical Data).

Behavior in the Event of Auxiliary-Voltage Failure

The behavior of the thermal replica can be controlled upon auxiliary-voltage failure via the setting parameter **Storage of thermal replica**. You can save the thermal state for a time of 500 min. Once the supply voltage returns, the thermal replica continues to function with the saved thermal state.

If the thermal replica is not saved, it will be reset to 0 upon failure of the auxiliary voltage.

Resetting the Thermal Memory

You can reset the thermal memory via the binary input indication **>Reset thermal replica**. The thermal memory will then have a 0 value.

Emergency Start

Depending on the operating conditions, tripping can be blocked or closure enabled despite the permissible thermal limits being exceeded. Upon activation of the binary input signal **>Emergency start**, tripping is blocked and closure enabled. This does not affect the state of the thermal memory. After the input **>Emergency start** disappears, the blocking remains in effect for the set **Emerg. start T overtravel**.

Blocking the Function

Blocking will cause a picked up function to be reset. The tripping function can be blocked externally or internally by the binary input signal **>Block stage**.

All indications then drop out and the thermal memory is not calculated.

Blocking Closure

The signal **Block close** can be used to prevent closure of the protected object at a high thermal load. The signal is set if the tripping overtemperature is exceeded, and cancelled if the temperature falls below the dropout threshold.

Functional Measured Values

Values	Description	Primary	Secondary	% Referenced to
(_:601:305) Time until trip	Expected time until tripping	s	s	s

6.58.4 Application and Setting Notes

Motors and generators as well as transformers are at risk from long-lasting overloads. You can adapt the given overload characteristic curve to the user-defined characteristic curve with the **Thermal overload protection, user-defined characteristic curve** function. You can find the predefined characteristic curve in the chapter *12.52 Thermal Overload Protection, User-Defined Characteristic Curve*.

When setting the parameters, consider the following:

- The settings for the used current transformer (primary values and secondary values) must be set correctly in the power system.
- The rated values for the protected object must be correct in the used function group.

Parameter: `Threshold current warning`

- Recommended setting value **`(_:101) Threshold current warning`** = ***`1.1 A`*** at I_{rated} = 1 A

Set the threshold to the maximum permissible continuous current ($I_{max, perm}$). This results in the same setting value as for the first value of the user-defined characteristic curve.

Parameter: `Threshold thermal warn.`

- Recommended setting value **`(_:104) Threshold thermal warn.`** = ***`90 %`***

If the first value of the user-defined characteristic curve is 1.1 of the rated current, the default setting can be left. The thermal memory results for 83 % at continuously flowing rated object current.

If the first value of the user-defined characteristic curve is 1.05 of the rated object current, the thermal memory for rated current is already 91 % filled. Increase the **`Threshold thermal warn.`** to 95 %.

Parameter: `Dropout threshold operate`

- Recommended setting value **`(_:105) Dropout threshold operate`** = ***`90 %`***

The **`Dropout threshold operate`** parameter is used to drop out pickup and tripping when the value drops below this threshold. A setting on the order of magnitude of the warning threshold is recommended. You can select a lower setting value for special applications, desired additional cooling or longer blocking of closing.

Note that the calculation of the operational measured value **`Time until close`** refers to this value.

Parameter: Emerg. start T overtravel

- Default setting **(_:112) Emerg. start T overtravel** = ***300 s***

The **Emerg. start T overtravel** parameter is used to set the time for which blocking of the tripping has to remain active after an outgoing binary input signal **>Emergency start**. With an outgoing input signal, the load on the protected object is removed. The emergency start T-overtravel must be set long enough to allow the thermal memory to fall below the dropout threshold after cooling. Select a time on the order of magnitude of the **Cooling time constant**. In the example, 5 min (300 s) have been assumed.

Parameter: Imax thermal

- Recommended setting value **(_:107) Imax thermal** = ***2.5 A*** at I_{rated} = 1 A

The **Imax thermal** parameter allows you to set the threshold current for the **Behav. at I> Imax therm.** parameter. If you calculate with relatively long start times for motors (longer than 25 s), the current limiting must be reduced to 2 $I/I_{rated, obj}$.

Parameter: Imin cooling

- Recommended setting value **(_:108) Imin cooling** = ***0.5 A*** at I_{rated} = 1 A

When defining the minimum current **Imin cooling**, you can use the no-load current for orientation. If no data is available, set 0.5 $I/I_{rated, obj}$. If the current falls below this value, the internal thermal time constant τ automatically switches to the internal cooling time constant with the **Cool-down factor Tau** parameter.

Parameter: Storage of thermal replica

- Recommended setting value **(_:113) Storage of thermal replica** = ***no***

If a continuous auxiliary voltage for the bay units is ensured, the default setting can be retained.

Parameter: Behav. at I> Imax therm.

- Recommended setting value **(_:114) Behav. at I> Imax therm.** = ***current limiting***

The **Behav. at I> Imax therm.** parameter is used to select the process by which the function reacts to short-circuit currents. To prevent premature tripping of the overload protection at low time constants, high preloading and high short-circuit currents, the thermal replica can be modified. As overcurrent due to a starting of the motor also leads to a certain heating of the stator winding, limiting the input current is recommended for machines.

Parameter Value	Description
current limiting	The input currents are limited to the value set in the **Imax thermal** parameter. If the measured current exceeds the set current value, the limited current value is supplied to the thermal replica. An advisable current threshold is approx. 2 to 2.5 $I_{rated, obj}$.
freeze therm. rep.	If input currents exceed the **Imax thermal** parameter, the thermal replica will be frozen for the time the parameter is exceeded.

Parameter: Curve based on preload

- Default value **(_:101) Curve based on preload** = ***100 %***

The **Curve based on preload** parameter is used for a certain load case. In most cases, it applies for an operation under rated conditions. For that, it is assumed that rated current is flowing permanently. This is referred to as warm condition. In this case, the default setting 100 % is applied.

Thus, the thermal behavior is also correct for different preloads.

For cases without preload or cold condition, set the parameter to 0 %.

Parameter: **Cool-down factor Tau**

- Default value **(_:108) Cool-down factor Tau** = *7.0*

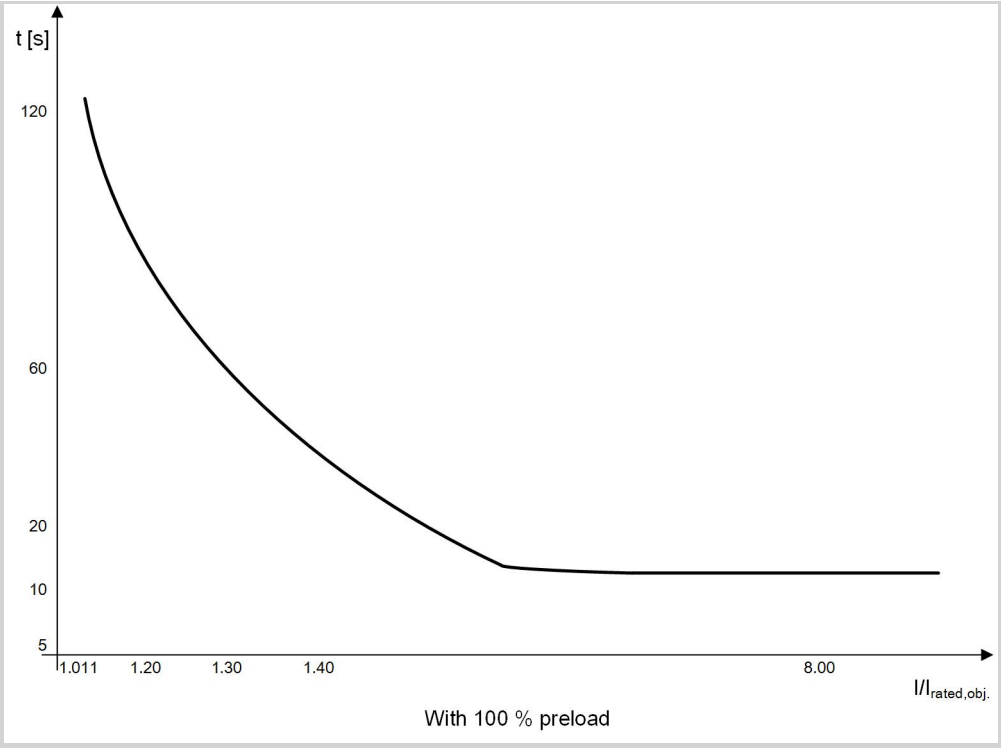
If the current becomes lower than the setting value of the **Imin cooling** parameter, you can set the **Cool-down factor Tau** parameter to calculate the internal cooling time constant.

Parameter: **Operate char. curve**

- Default value **Operate char. curve** = *1.1 p.u., 600.00 s*

With the **Operate char. curve** parameter, you define the characteristic curve in a tabular form with ordered normalized current values and associated normalized time values.

When setting the parameter, consider the following:



- Set the current value as per-unit value with the rated current of the protected object as reference.
- Set the time value in seconds.
- Enter the values in continuous order.

EXAMPLE

With the following 12 points, you can get a user-defined characteristic curve as shown in the following figure.

Table 6-21 User-Defined Points

I / I_{obj}	t (s)
1.16	120.00
1.21	96.00
1.25	76.00
1.28	62.00
1.35	48.00
1.42	37.50
1.48	33.50

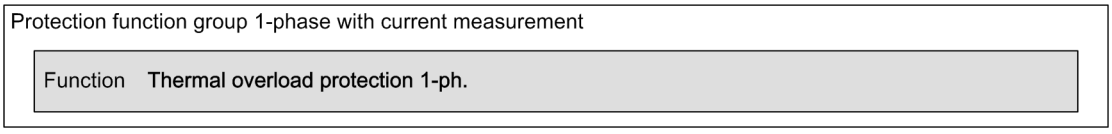
6.59 Thermal Overload Protection, 1-Phase



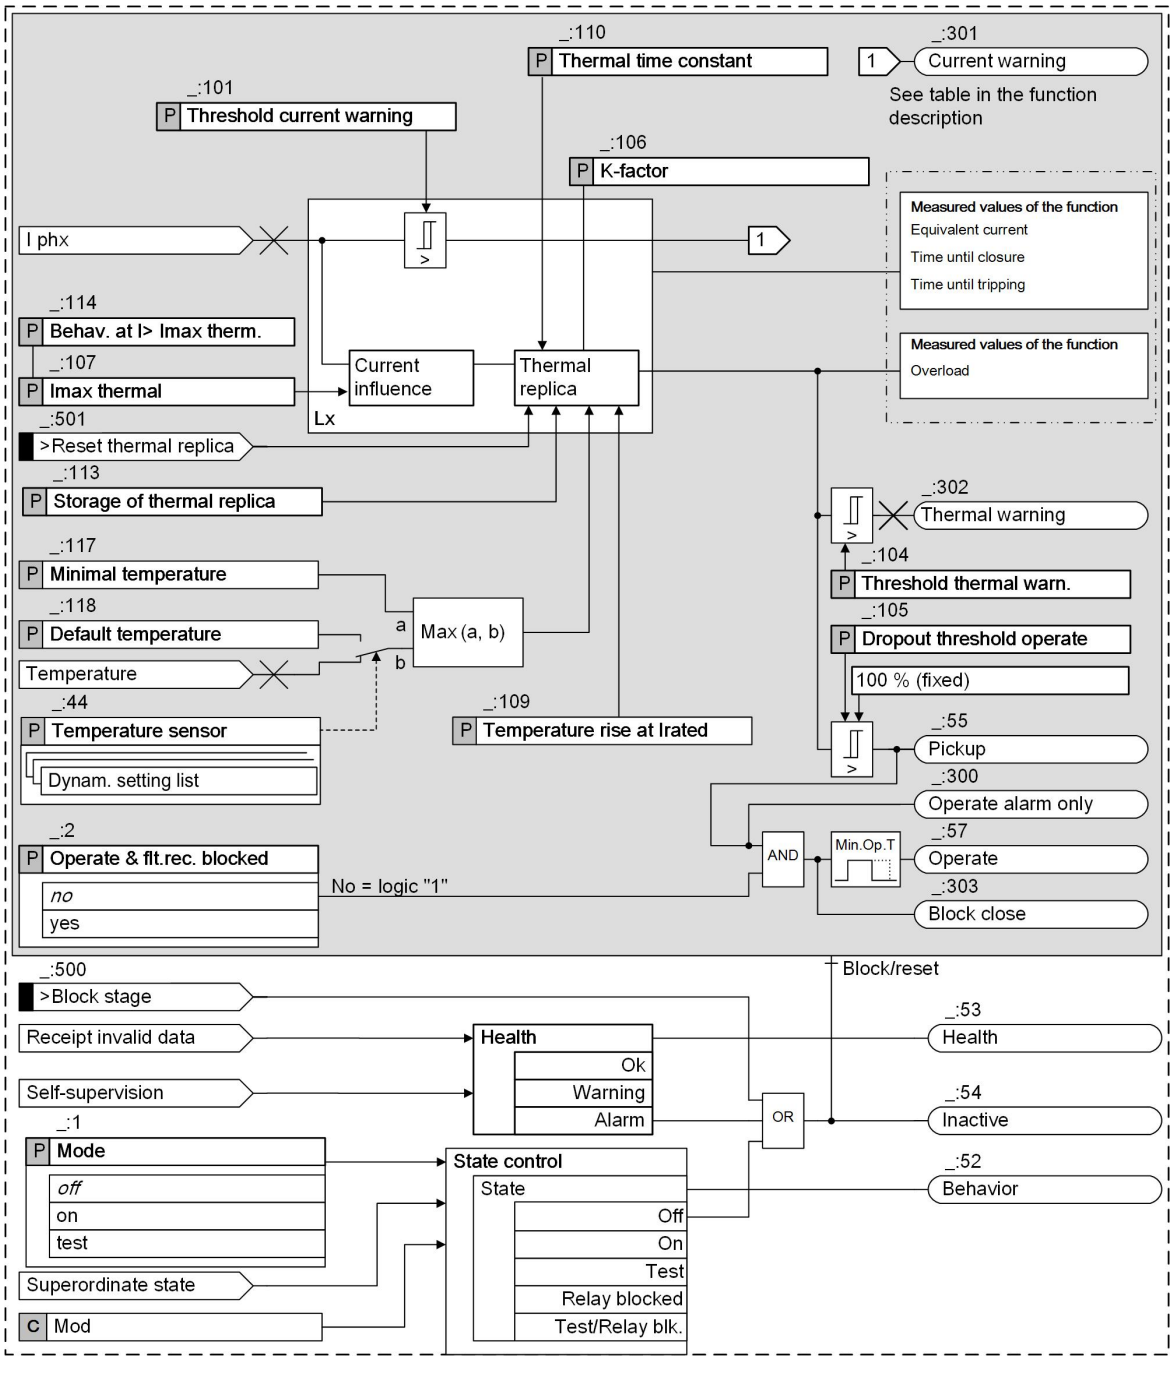
6.59.1 Overview of Functions

The **Thermal overload protection 1-phase** function (ANSI 49) is used to:

- Protect the equipment (reactors or resistors in the neutral point of a transformer) from thermal overload

6.59.2 Structure of the Function

The **Thermal overload protection 1-phase** function is used in 1-phase protection function groups with current measurement.
The **Thermal overload protection, 1-phase** function is steplessly preconfigured.



{dw_tolp1p, 2, en_US}

Figure 6-627 Structure/Embedding of the Function

6.59.3 Function Description

Logic

[lo_tolp_1p, 3, en_US]

Figure 6-628 Logic Diagram of the Thermal Overload Protection Function

Thermal Replica

The protection function calculates the overtemperature from the current flowing in the protected object (for example, reactor or resistance in the transformer neutral point) on the basis of a thermal single-body model according to the thermal differential equation with

$$I_{p.u.}^2 = \tau_{th} \frac{d\Theta}{dt} + \Theta - \Theta_V$$

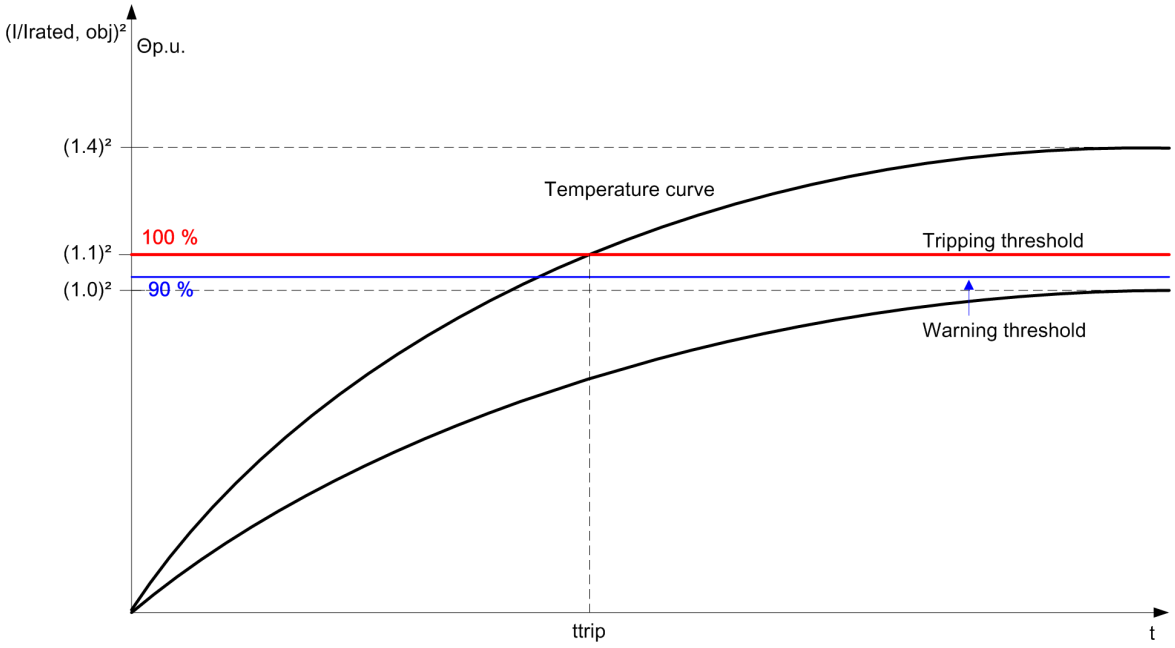
[fo_diffgl, 2, en_US]

With the following standardization:

$$I_{p.u.} = \frac{I}{I_{max}} = \frac{I}{k \cdot I_{rated,obj.}} \qquad \Theta = \frac{\vartheta}{\vartheta_{max}} = \frac{\vartheta}{k^2 \cdot \Delta\vartheta_{rated,obj.}}$$

$$\tau_{th} = R_{th} \cdot C_{th} \qquad \Theta_V = \frac{\vartheta_{Amb} - 40\,°C}{\vartheta_{max}} = \frac{\vartheta_{Amb} - 40\,°C}{k^2 \cdot \Delta\vartheta_{rated,obj.}}$$

[fo_normie, 2, en_US]



Θ	Current overtemperature, in relation to the final temperature at a maximum permissible current k $I_{rated,obj}$
Θ_V	Standardized ambient temperature, where ϑ_{Amb} describes the coupled ambient temperature. The coupled ambient temperature ϑ_{Amb} can be the measured ambient temperature or the ambient temperature preset using the **`Default temperature`** parameter.
$\Delta\vartheta_{rated,obj}$	Overtemperature of the protected object set at rated current
τ_{th}	Thermal time constant (temperature rise/cooling) of the protected object
k	This factor indicates the maximum continuous permissible phase current. The factor refers to the rated current of the protected object ($k = I_{max}/I_{rated,obj}$)
$I_{rated,obj}$	Rated current of the protected object

At the same time, $I_{rated,obj}$ is the rated current of the protected object.

In a steady state, the solution to the thermal differential equation is an e-function whose asymptote represents the final overtemperature Θ_{end}. The time constant τ_{th} determines the rise. After reaching an initial adjustable overtemperature threshold Θ_{warn} (**`Threshold thermal warn.`**), a warning indication is given.

If the overtemperature limit Θ_{Off} (tripping overtemperature) is exceeded, an operate indication is immediately issued and the equipment disconnected from the power supply. This threshold is specified at 100 % and corresponds to the final temperature set at a flowing permissible continuous current (I_{max}).

Figure 6-629 shows the temperature rise at different overload currents and the supervision thresholds.

[dw_temp_ve, 1, en_US]

Figure 6-629 Temperature History for Different Overload Currents (**K-factor** = ***1.1***)

The current overtemperature can be obtained from the operational measured values. It is shown in percent. An indication of 100 % means that the thermal tripping threshold has been reached.

The analysis of the RMS value of the current over a broad frequency band also includes the harmonic components. These harmonic components contribute to the temperature rise of the equipment.

Operate Curve

If the ambient temperature is not measured and set to 40°C, you get the following operate curve:

$$t = \tau_{th} \cdot \ln \frac{\left(\frac{I}{k \cdot I_{rated,obj.}}\right)^2 - \left(\frac{I_{preload}}{k \cdot I_{rated,obj.}}\right)^2}{\left(\frac{I}{k \cdot I_{rated,obj.}}\right)^2 - 1}$$

[fo_auslos, 1, en_US]

t	Operate time
τ_{th}	Time constant
I	Measured load current
$I_{preload}$	Preload current
k	Setting factor according to VDE 0435 part 3011 or IEC 60255-149 (K factor)
$I_{rated,obj}$	Rated current of the protected object

Ambient Temperature

This function can take the ambient temperature into consideration The reference temperature of the thermal model is 40 °C. If the ambient temperature drops below the reference temperature, the thermal limit increases. The equipment can be stressed more. If the ambient temperature is higher, the conditions change.

The **Default temperature** parameter can be used to fix or measure the ambient temperature. The **Minimal temperature** parameter limits the coupled ambient temperature. If the measured ambient temperature is lower than the minimum temperature, the minimum temperature is processed in the thermal model.

The ambient temperature refers to the overtemperature of the protected object, which sets itself at the rated current (parameter **Temperature rise at Irated**).

The measured ambient temperature is measured by an external RTD unit (RTD = Resistance Temperature Detector) or by an IO111 module and provided by the functions **RTD unit Ether.**, **RTD unit serial**, or **Temperature module IO111** of the function group **Analog unit**. When using the **Temperature sensor** parameter, the respective temperature sensor can be selected.

If the temperature measurement is disrupted, for example, due to an open circuit between the device and the RTD unit, the health state of the **Thermal overload protection, 1-phase** function changes to *warning*. In this case, the process continues with either the temperature measured last or the value set under the **Default temperature** parameter, whichever value is the highest.

Current Influence

The thermal replica based on the single-body model applies with limitations to high overcurrent situations (short circuits). To avoid an overfunction of the overload protection, the thermal replica must be influenced for overcurrents (exceeding $\mathbf{I}_{\text{limit}}$). You can select between 2 strategies for this:

- Freezing of the thermal memory
- Limitation of the input current for the thermal replica to the set current. The temperature rise is thereby **retarded** at high currents.

Warning Thresholds

The thermal warning threshold issues a warning indication before the tripping threshold (tripping temperature) is reached. In this way, for example, a load can be reduced in sufficient time and a disconnection avoided. At a normal **K-factor** of ***1.1***, a thermal memory value of 83 % sets in at continuously flowing rated current.

Apart from the thermal warning threshold, the overload protection also has a current-warning threshold. This current-warning threshold can signal an overload current in sufficient time before the overtemperature value has reached the warning or tripping threshold.

Dropout of Tripping

Once the thermal memory has fallen below the setting value of the **Dropout threshold operate**, the trip command is cancelled upon tripping. In contrast, the current-warning threshold and the thermal warning threshold are reduced at a fixed dropout threshold (see technical data).

Behavior in the Event of Auxiliary-Voltage Failure

The behavior of the thermal replica can be controlled upon auxiliary-voltage failure via the **Storage of thermal replica** parameter. You can save the thermal state for a down time of 500 min. If the supply voltage returns, the thermal replica continues to function with the saved thermal state.

If the thermal replica is not saved, it will be reset to 0 upon failure of the auxiliary voltage.

Resetting the Thermal Map

You can reset the thermal memory via the binary input indication **>Reset thermal replica**. The thermal memory will then have a 0 value. A reparameterization will also lead to resetting the thermal memory.

Blocking the Function

Blocking will cause a picked up function to be reset. The function can be blocked externally or internally by the binary input signal **>Block stage**.

All indications then drop out and the thermal memory is set to the value 0.

Blocking Closure

The signal **Block close** can be used to prevent closure of the protected object at a high thermal load. The signal is set if the tripping overtemperature is exceeded, and cancelled if the temperature falls below the dropout threshold.

Functional Measured Values

Measured Value	Description
(_:310) Equival. current	Besides the thermal measured values in percent, the equivalent current is also issued as a thermal current-measured value (A or kA). The current equivalent is the primary current, which corresponds to the thermal measured value in percent, assuming steady-state conditions.
(_:304) Time until close	The **Time until close** is the expected time until it is possible for the protected object for reclosure. The calculation of this value is based on the assumption of constant currents. The thermal replica has then fallen below the setting value of the dropout threshold.
(_:305) Time until trip	The **Time until trip** is the expected time until tripping (100 % value exceeded) occurs. The calculation of this value is based on the assumption of constant currents.
(_:306) Overload	The value **Overload** indicates the current temperature of the protected object in percent. Tripping occurs if 100 % is exceeded.

6.59.4 Application and Setting Notes

Parameter: Threshold current warning

- Recommended setting value **(_:101) Threshold current warning** = ***1.1 A*** for I_{rated} = 1 A

Set the threshold to the maximum permissible continuous current ($I_{max, perm}$). This results in the same setting value as for **K-factor**.

Parameter: Threshold thermal warn.

- Recommended setting value **(_:104) Threshold thermal warn.** = ***90 %***

The default setting can be left at a **K-factor** of 1.1, because the thermal memory sets itself to 83 % at continuously flowing rated current. The calculation uses the rule of three: 100 % corresponds to (**K-factor**)^2 and x % corresponds to 1^2.

$$\frac{\Theta}{\Theta_{off}} = \frac{100\ \%}{k^2} = 83\ \%$$

[fo_warmsc, 2, en_US]

At a **K-factor** of 1.05, the thermal memory for rated current is 91 % filled. Increase the **Threshold thermal warn.** to 95 %.

Parameter: Dropout threshold operate

- Recommended setting value **(_:105) Dropout threshold operate** = ***90 %***

The **Dropout threshold operate** parameter is used to cancel pickup and tripping when the value drops below this threshold. A setting on the order of magnitude of the warning threshold is recommended. You can select a lower setting value for special applications, desired additional cooling, or longer blocking of switching on.
The calculation of the operational measured value **Time until close** refers to this value.

Parameter: K-factor

- Recommended setting value **(_:106) K-factor** = ***1.1***

The **K-factor** parameter is used to describe the limiting value for the maximum permissible continuous load. The rated current $I_{rated, obj}$ of the protected object (for example, resistance) is the basic current for overload sensing.
You can determine **K-factor** on the basis of the thermally permissible continuous current $I_{max, perm.}$:

$$K\text{-factor} = \frac{I_{max,perm.}}{I_{rated,obj.}}$$

[fo_tolp_kf, 2, en_US]

NOTE

The thermally permissible continuous current for the protected object is known from relevant tables or from the specifications of the manufacturer!

Siemens recommends using the default value as it is a typical value for many applications.

Parameter: Thermal time constant

- Default value **(_:110) Thermal time constant** = ***900 s (15 min)***

The **Thermal time constant** parameter is used to define the operate curve of the stage. If no time constant is given, you can derive it from other values.

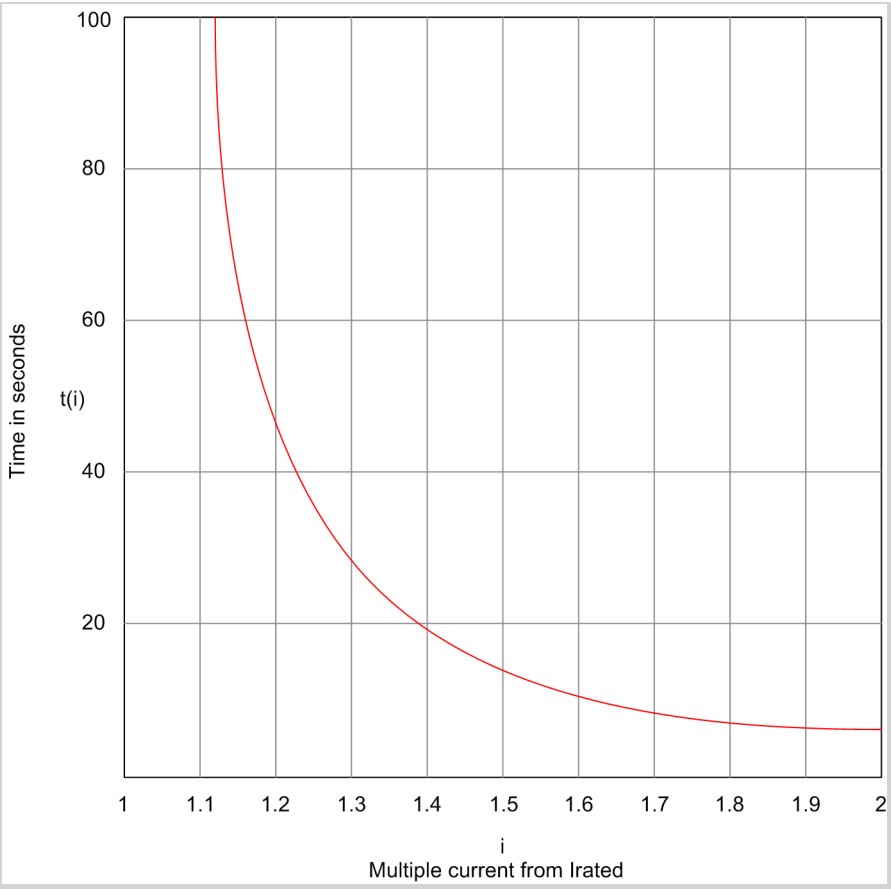
EXAMPLE

Protection of a current-limiting resistance

Rated current of the resistance: I_{rated} = 100 A

Values for the overload capability:

- 1.1 I_{rated} permanent (k-Factor = 1.1; k = 1.1)
- 1.5 I_{rated} for 20 s for charge by cold



The following time constant results from these assumed values:

$$\tau_{th} = t \times \left[\ln \frac{\left(\frac{I}{k \times I_{rated,obj}}\right)^2}{\left(\frac{I}{k \times I_{rated,obj}}\right)^2 - 1} \right]^{-1} = 20\ s \times \left[\ln \frac{\left(\frac{1.5}{1.1}\right)^2}{\left(\frac{1.5}{1.1}\right)^2 - 1} \right]^{-1} = 20\ s \times \left[\ln \frac{1.86}{0.86} \right]^{-1} \approx 26\ s$$

[fo_time_constance, 1, en_US]

For **Thermal time constant**, set 26 s.

The following time-dependent characteristic results from the data. In case of a current increase to 1.5 I_{rated}, the tripping occurs in 20 s.

Parameter: Imax thermal

- Recommended setting value **(_:107) Imax thermal** = ***2.5 A*** for I_{rated} = 1 A

The **Imax thermal** parameter allows you to set the threshold current for the **Behav. at I> Imax therm.** parameter. The selected current threshold of 2.5 $I_{rated, obj}$ is a practicable value.

Parameter: Temperature rise at Irated

- Default setting **(_:109) Temperature rise at Irated** = ***70 K***

NOTE

For an application as a 1-phase overload protection, the ambient temperature measured via the temperature sensor is not taken into account. Therefore, the setting has no influence. You can keep the default setting. If you take into account the temperature, note the following descriptions.

Set the overtemperature as the value that is the result if the equipment is continuously operated with the rated current and at an ambient temperature of 40 °C. Here, the rated current refers to the protected object. You can find the temperature value in the Technical data of the equipment or you can measure the value. If you use a temperature sensor when measuring at the rated current, deduct the actual ambient temperature or the coolant temperature from the measured value.

When selecting the setting value, you can also use the specified temperature class for orientation. Usually, you will find the overtemperature expressed in Kelvin (K), which can be accepted as is. If the absolute temperature is given, the ambient temperature must be deducted. As a rule, this is 40 °C.

The overtemperature (***ϑmax***) at maximum permissible current and the **Temperature rise at Irated** (***ϑrated,obj.***) can be converted by using the following formula:

$$k^2 = \left(\frac{\Delta\vartheta_{max}}{\Delta\vartheta_{rated\ ,obj.}} \right)$$

[fo_ueb_for_Irated, 3, en_US]

EXAMPLE:

Temperature class **B** for continuous operation: permissible overtemperature = 80 K
From this, a temperature for I_{rated} of 120 °C (80 K + 40 °C) can be derived when using a measuring element for the measurement.
Temperature class **F** as thermal limiting value: permissible overtemperature = 105 K.
From this, a maximum temperature of 145 °C (105 K + 40 °C) derives.
From these values, the magnitude of the K factor can also be derived.

$$k^2 = \frac{\Delta\vartheta_{max\ ,Obj.}}{\Delta\vartheta_{rated\ ,Obj.}} = \frac{105\ K}{80\ K} = 1.31 \qquad \rightarrow\ k = 1.146$$

[fo_bsp_kfaktor, 3, en_US]

If selecting a setting value of 1.1 for the **K-factor**, your selection can be considered as conservative.

Parameter: Storage of thermal replica

- Recommended setting value **(_:113) Storage of thermal replica** = ***no***

If a continuous auxiliary voltage of the bay units is ensured, the default setting can be retained.

Parameter: Behav. at I> Imax therm.

- Recommended setting value **(_:114) Behav. at I> Imax therm.** = ***current limiting***

The **Behav. at I> Imax therm.** parameter is used to select the process by which the function reacts to short-circuit currents. To prevent premature tripping of the overload protection at low time constants, high preloading and high short-circuit currents, the thermal replica can be modified.
The default setting has been selected compatible with SIPROTEC 4 devices. If you wish to take further temperature rise into consideration, the **current limiting** procedure is recommended.

Parameter Value	Description
current limiting	The input current is limited to the value set in the **Imax thermal** parameter. If the measured current exceeds the set current value, the limited current value is supplied to the thermal replica. An advisable current threshold is approx. 2 to 2.5 $I_{rated, obj}$.
freeze therm. rep.	If the input current exceeds the **Imax thermal** parameter, the thermal replica will be frozen for the time the parameter is exceeded. This parameter value is provided to enable compatibility with older products!

Parameter: Temperature sensor

- Default setting **(_:44) Temperature sensor** = ***none***

Use the **Temperature sensor** parameter to determine which temperature sensor to use to detect the ambient temperature.
A temperature sensor is used to measure the ambient temperature of the protected object and to feed it to the device via an RTD unit (RTD = Resistance Temperature Detector) or via an IO111 module. The function **Thermal overload protection** receives the measured temperature value via the functions **RTD unit Ether.**, **RTD unit Serial**, or **Temperature module IO111** from the function group **Analog units**.

Parameter: Default temperature

- Recommended setting value **(_:118) Default temperature** = ***40 °C***

Under the following conditions, the **Default temperature** will be set as ambient temperature:

- A temperature sensor for measuring the ambient temperature is not connected.
- The temperature measurement is interrupted and the measured temperature value is less than the **Default temperature**.

Siemens recommends using the default setting.

Parameter: Minimal temperature

- Default setting **(_:117) Minimal temperature** = ***-20 °C***

If the measured ambient temperature drops below the preset value, the set value will be assumed as the ambient temperature. If the overload protection works with a prespecified outside temperature, and this temperature drops below the value set in the **Minimal temperature** parameter, the **Minimal temperature** can also be used.

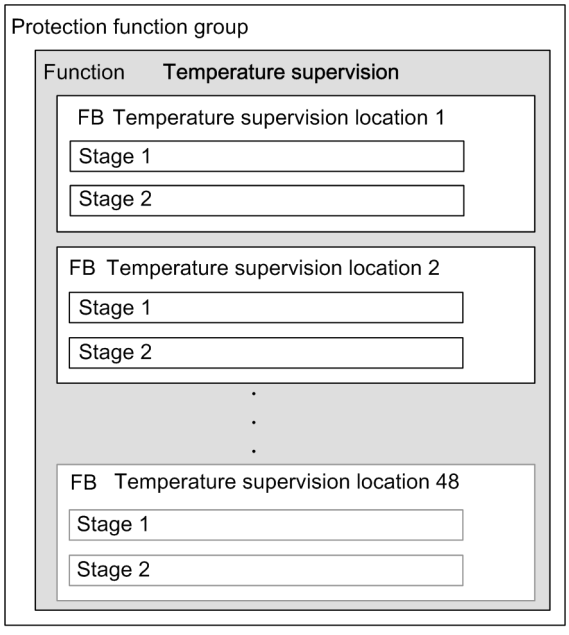
6.60 Temperature Supervision

6.60.1 Overview of Functions

The **Temperature supervision** function checks the thermal state of:

- Motors
- Generators
- Transformers



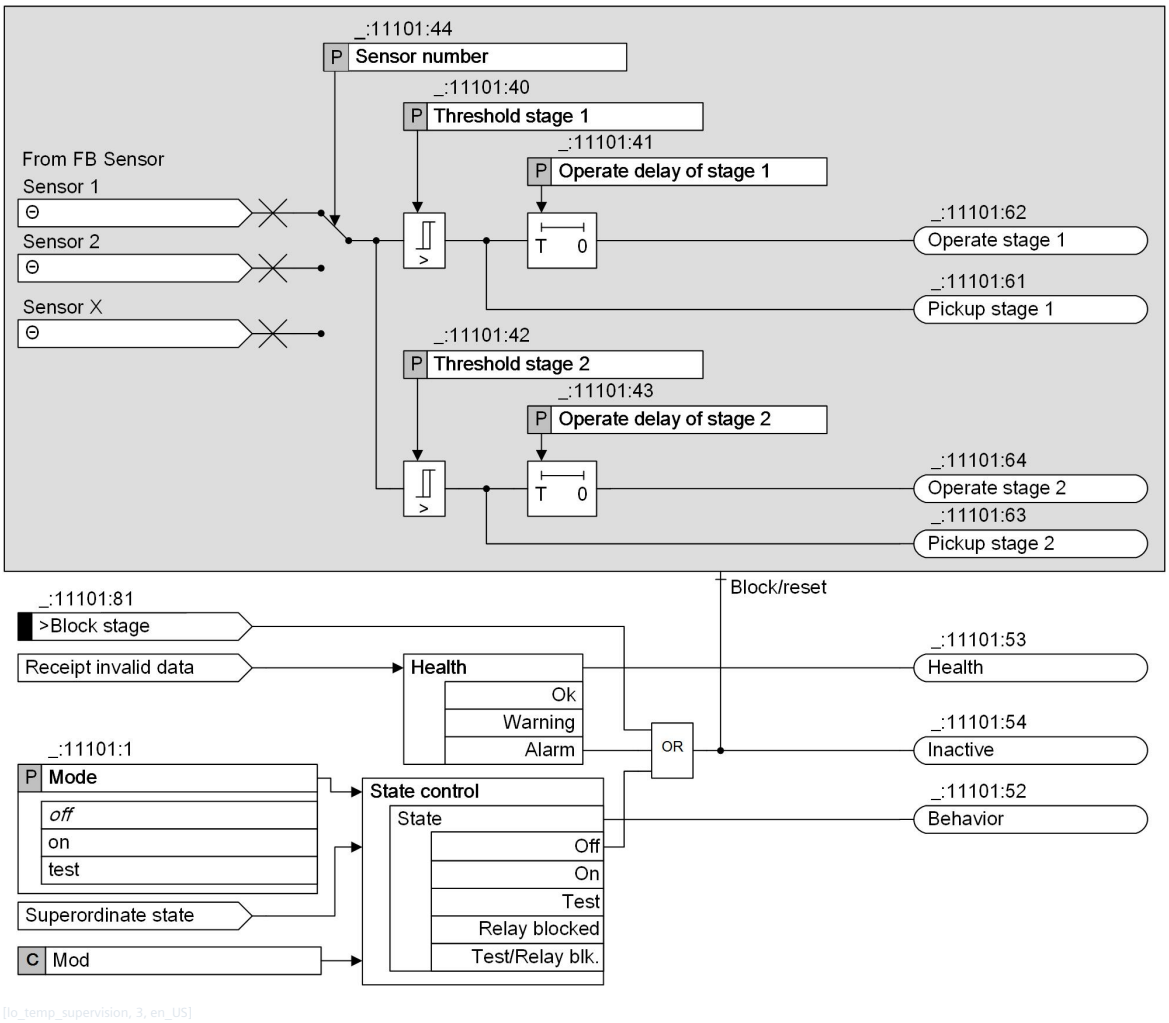
In rotating machines, it also checks bearing temperatures for a limit violation.

The temperatures are measured at various locations of the protected object using temperature sensors (RTD = Resistance Temperature Detector) and are sent to the device via one or more RTD units.

The **Temperature supervision** function receives its measured temperature values via the **RTD unit Ether.** or **RTD unit serial** functions from the **Analog units** function group.

6.60.2 Structure of the Function

The Temperature supervision function can work in all protection function groups. A maximum of 48 temperature supervision locations can operate simultaneously in the **Temperature supervision function** function. Each temperature supervision location has 2 threshold stages.



[dw_str_tmp, 1, en_US]

Figure 6-630 Structure/Embedding of the Function

6.60.3 Function Description

Logic

[lo_temp_supervision, 3, en_US]

Figure 6-631 Logic Diagram for a Temperature Supervision Location

The **Temperature supervision location** function block (**Location** FB) receives a measured temperature value in °C or °F as an input variable delivered from the temperature sensor function blocks of the **Analog units** function group. The **Sensor number** parameter is used to select the temperature sensor.

2 threshold value decisions can be performed for each measuring point. If the measured temperature value is greater than or equal to the set threshold values, the stages generate a pickup indication independent of one another and, after a set tripping time delay, an operate indication.

The indications from the supervision locations remain available for further processing.

NOTE

The pickup of the stages does not result in fault logging. The operate indications of the stages do not go into the trip logic of the device.

6.60.4 Application and Setting Notes

If you use an external RTD unit, connect the RTD unit via an interface (Ethernet or serial) to the SIPROTEC 5 device. Observe the setting notes for configuration of the interfaces in chapter *Analog Transformer Function Group Type* under *5.11.7.3 Communication with an RTD Unit*.

Parameter: `Sensor location`

- Default setting **`(_:11101:46) Sensor location`** = ***`Other`***

You inform the device of the sensor installation location using the **`Sensor location`** parameter. ***`Oil`***, ***`Ambient`***, ***`Turn`***, ***`Bearing`*** and ***`Other`*** are available for selection. The selection is not evaluated in the device, it only serves an informational purpose in the medium in which the temperature measurement takes place.

Parameter: `Sensor number`

- Default setting **`(_:11101:44) sensor number`** = ***`no function block selected`***

With the **`sensor number`** parameter, you assign a specific sensor whose temperature is to be monitored to the **Location** function block. You perform the assignment in DIGSI using a list box that contains all connected RTD units and their sensors.

Parameter: `Threshold stage 1`

- Default setting **`(_:11101:40) Threshold stage 1`** = ***`100 °C`***

With the **`Threshold stage 1`** parameter you establish the temperature value whose exceedance causes a pickup of the 1st tripping stage.

Parameter: `Operate delay of stage 1`

- Default setting **`(_:11101:41) Operate delay of stage 1`** = ***`5 s`***

With the **`Operate delay of stage 1`** parameter you establish the time the operate indication of the 1st tripping stage should be delayed after the pickup. This time delay depends on the specific application. If you set the time delay to ∞ the operate indication is blocked.

Parameter: `Threshold stage 2`

- Default setting **`(_:11101:42) Threshold stage 2`** = ***`120 °C`***

With the **`Threshold stage 2`** parameter you establish the temperature value whose exceedance causes a pickup of the 2nd tripping stage.

Parameter: `Operate delay of stage 2`

- Default setting **`(_:11101:43) Operate delay of stage 2`** = ***`0 s`***

With the **`Operate delay of stage 2`** parameter you establish the time the operate indication of the 2nd tripping stage should be delayed after the pickup. This time delay depends on the specific application. If you set the time delay to ∞ the operate indication is blocked.

Temperature Unit

Temperature Unit To change the display and evaluation of measured temperature values from °C to °F, adapt the DIGSI user default settings accordingly (see *5.11.7.5 Temperature Sensor*).

6.61 Hotspot Calculation

6.61.1 Overview of Functions

The **Hot-spot calculation** function (ANSI 49H) protects the transformer against thermal destruction at increased operating currents and monitors the thermal state of the turns.

The main use of this function is monitoring the temperature of the turns in the transformer. Continuously monitoring the temperature at special points, the **hot spots**, is very important. An increased turn temperature can have serious effects on the transformer.

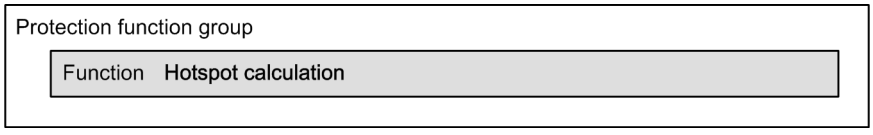
The most frequent consequential damage of this is:

- Reduction of the service life
- Formation of gas bubbles that can result in insulation breakdown
- Destruction of the winding insulation

The hot-spot calculation considers the IEC 60076-7 and IEEE C57.91 2011 standards and calculates 3 relevant variables for the protection function:

- Hot-spot temperature
- Relative aging
- Load margin until warning and alarm indication

The following information about the protected object is necessary to calculate the hot-spot temperature:



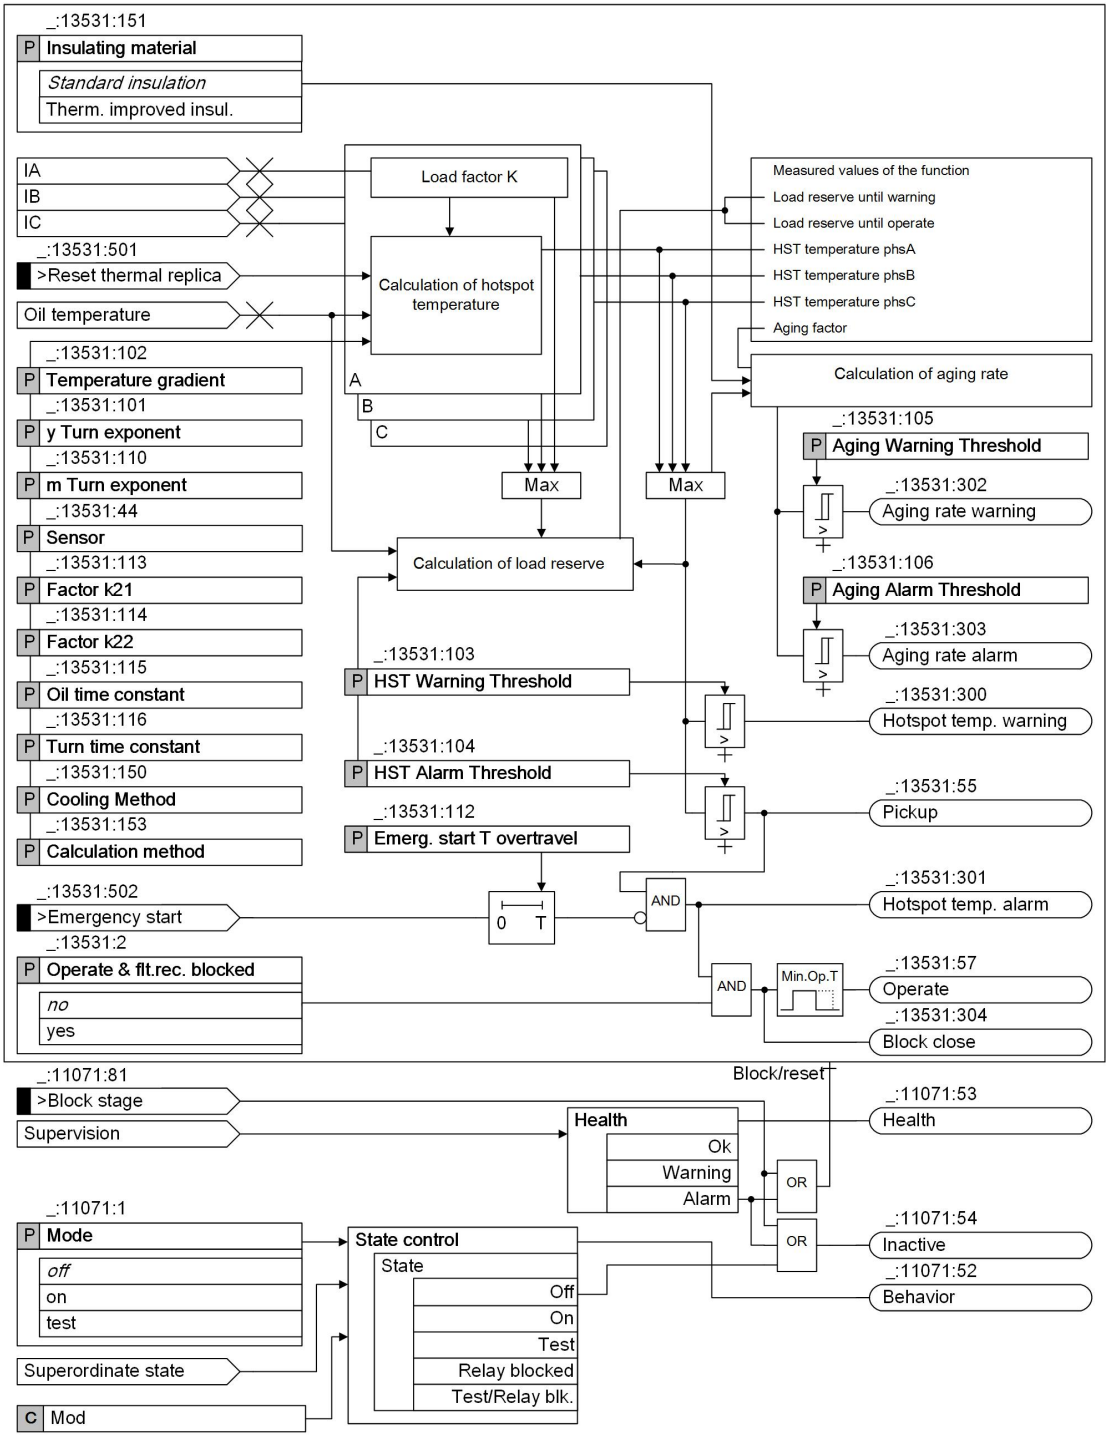
- Cooling methods
- Power factor
- Coolant temperature (top-oil temperature in the protected object)
- Transformer size
- Oil and turn time constants
- Factors as per IEC 60076-7 or IEEE C57.91 2011

The top-oil temperature is measured using temperature measuring points. In this case, up to 12 temperature measuring points can be transmitted to the protection device via one temperature coupling. One of these measuring points can be selected for calculating of the hot-spot temperature in the oil.

6.61.2 Structure of the Function

The **Hot-spot calculation** function can be used in every protection function group that has a 3-phase current input. During the engineering phase, you can incorporate the function into the project using drag & drop from the DISGI 5 function library.

The **Hot-spot calculation** function is continuous.



[dwhotspt-260213-01.tif, 1, en_US]

Figure 6-632 Structure/Embedding of the Function

6.61.3 Function Description

Logic of the Function

[lo_hotspt, 3, en_US]

Figure 6-633 Logic Diagram of the Hotspot Calculation Function

The hotspot temperature of a transformer winding can be calculated according to IEC 60076-7 or IEEE C57.91 2011. The following 3 variables, relevant for the protection function, are calculated:

- Temperature at the hotspot in the protected object
- Relative aging
- Load margin until warning and alarm indication

Measurement of the top-oil temperature on the transformer is required for this function. Specify a measuring point for the temperature measuring equipment that is relevant for calculating the hotspot temperature.

Cooling Versions

Calculating the hotspot is dependent on the cooling method. Air cooling is always available and is differentiated into 2 convection types:

- **AN** (**A**ir **N**atural): Artificial convection
- **AF** (**A**ir **F**orced): Forced-air convection (ventilation)

If a liquid coolant is also available, there are the following cooling versions:

- **ON** (**O**il **N**atural = convective oil flow): The coolant (oil) moves in the tank due to the temperature differences that occur. The cooling effect coming from natural convection is not very pronounced.
- **OF** (**O**il **F**orced = forced oil flow): The coolant (oil) moves in the tank because of an oil pump. The cooling effect is, for this reason, greater than for **ON**.
- **OD** (**O**il **D**irected = directed oil flow): The coolant (oil) follows a directional route in the tank because of an oil pump. As a result, the oil flow can be increased at points that are particularly temperature critical. The cooling effect is particularly good for this reason, the temperature gradient is smallest.

Calculating the Hotspot Temperature According to IEC 60076-7

The hotspot of the protected object is an important state value. The hottest point of the transformer occurs on the insulation of the topmost inner turn and it is relevant for the service life. The coolant temperature in the transformer increases from the bottom to the top. The cooling method influences the magnitude of the temperature gradient.

The hotspot temperature is composed of 3 components:

- Temperature at the hottest point in the coolant (coupled in by way of temperature measurement)
- Component coming from the temperature increase of the turn caused by the transformer load. It specifies the temperature gradient from the hotspot of the winding to the top-oil temperature.
- Component of the temperature rise of the turn due to a sudden change in the transformer load

To calculate the temperature at the hotspot, the protection device needs the following information:

- Data from the appropriate measuring point
- Data on the current in the winding
- Settings of the characteristic properties of the cooling system

An indication and/or tripping is generated if an adjustable threshold (temperature alarm) is exceeded.

To calculate the hotspot inside the transformer, the sum is formed from the top-oil temperature and the temperature difference between the hotspot and the top-oil:

$\Theta_h(t) = \Theta_o(t) + \Delta\Theta_h(t)$

with

$\Theta_h(t)$	Temperature of the hotspot in °C
$\Theta_o(t)$	Top-coolant temperature (oil temperature) in °C
$\Delta\Theta_h(t)$	Temperature difference between the hotspot of the winding and the oil in °C

The following 2 factors determine the temperature ratio between the hotspot and the oil temperature:

- Change in the oil viscosity (flow behavior of the oil)
- Change in the ohmic turn resistance (load-dependent)

$\Delta\Theta_h\,(t) = \Delta\Theta_{h1}\,(t) - \Delta\Theta_{h2}\,(t)$

$\Delta\Theta_{h1}\,(t) = \Delta\Theta_{h1}(t\text{-}1) + d\Delta\Theta_{h1}(t)$

$\Delta\Theta_{h2}\,(t) = \Delta\Theta_{h2}(t\text{-}1) + d\Delta\Theta_{h2}(t)$

with

$\Delta\Theta_{h1}\,(t)$	Temperature difference due to the turn resistance
$\Delta\Theta_{h2}\,(t)$	Temperature difference due to the oil viscosity

The following 2 equations are used for the calculation:

$$d\Delta\Theta_{h1}(t) = \frac{dt}{k_{22}\tau_w} \cdot (k_{21} \cdot K^Y \cdot H_{gr} - \Delta\Theta_{h1}(t - \Delta t))$$

[fohsalt8-300513-01.tif, 1, en_US]

$$d\Delta\Theta_{h2}(t) = \frac{dt}{(1/k_{22})\tau_o} \cdot \left[(k_{21} - 1) \cdot K^Y \cdot H_{gr} - \Delta\Theta_{h2}(t - \Delta t)\right]$$

[fohsalt9-300513-01.tif, 1, en_US]

with

H_{gr}	Insulation temperature gradient
K	Load ratio I/I_N (measured)
y	Turn exponent
k_{21}, k_{22}	Constant of the thermal model
τ_o	Oil time constant
τ_w	Turn time constant
t	Current calculation time point
Δt	Calculation Interval

During this, the load ratio K is determined from the measured current of the side and the rated object current. The rated current of the appropriate function group is used as the rated object current.

Calculating the Hotspot Temperature According to IEEE C57.91 2011

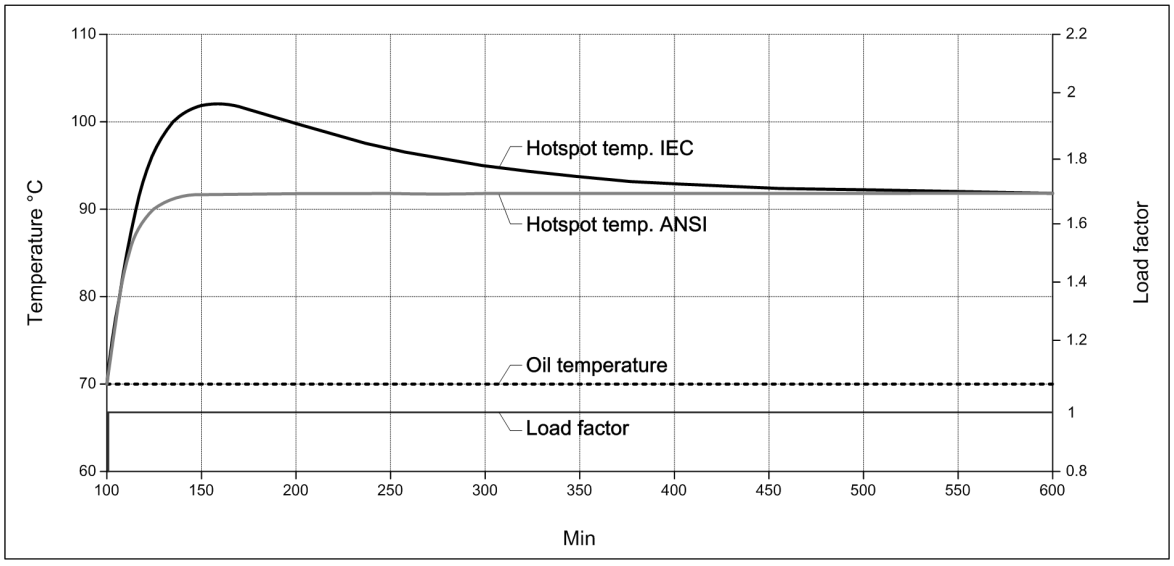
To calculate the hotspot inside the transformer, the sum is formed from the top-oil temperature and the temperature difference between the hotspot and the top-oil. The equation corresponds to the IEC standard:

$\Theta_h\,(t) = \Theta_o\,(t) + \Delta\Theta_h\,(t)$

with

$\Theta_h\,(t)$	Temperature of the hotspot in °C
$\Theta_o\,(t)$	Top-coolant temperature (oil temperature) in °C
$\Delta\Theta_h\,(t)$	Temperature difference between the hotspot of the winding and the oil in °C

$$\Delta\Theta_h(t) = (\Delta\Theta_h(t - \Delta t)) + \frac{\Delta t}{\tau_w}(\Delta\Theta_{H,U}(t) - \Delta\Theta_h(t - \Delta t))$$



[fohsalt7-060313-01.tif, 1, en_US]

$\Delta\Theta_{H,V}(t) = K^{2m} \cdot H_{gr}$

with

$\Delta\Theta_{H,V}(t)$	Load-dependent hotspot temperature increase via the top-oil temperature
K	Load ratio I/I_N (measured)
m	Turn exponent
H_{gr}	Temperature gradient from the turn hotspot to the oil temperature at rated load
τ_w	Turn time constant
t	Current calculation time point
Δt	Calculation Interval

The following graphic shows an example for the behavior of the hotspot temperature during a load jam of $0 \cdot I/I_N$ to $1 \cdot I/I_N$ and a steady oil temperature of 70 °C. All required settings correspond to the default values. The results of the calculation methods according to IEC 60076-7 and IEEE C57.91 2011 are compared.

[dwhslsfk-170613-01.tif, 1, en_US]

Figure 6-634 Example of a Hotspot Calculation

Calculation of the Relative Aging

The service life of cellulose insulation refers to a temperature of 98 °C in the immediate environment of the insulation. Experience has shown that an increase of 6 K cuts the service life in half. This yields the following equation for a relative aging V at a temperature different from 98 °C:

$$V = \frac{\text{Aging at } \Theta_h}{\text{Aging at } 98\,^\circ\text{C}} = 2^{(\Theta_h - 98\,^\circ\text{C})/6}$$

[fohsalt1-260213-01.tif, 1, en_US]

with

V	Relative aging
Θ_h	Temperature of the hotspot in °C

The mean relative aging rate L results from forming the average over an observed time lapse from T1 to T2. The time period between T1 and T2 is 1 min.

$$L = \frac{1}{T_2 - T_1} \cdot \int_{T_1}^{T_2} V dt$$

[fohsalt2-260213-01.tif, 1, en_US]

with

L	Mean relative aging
T2 - T1	60 s

At a steady rated load, L = 1 corresponds to a hotspot temperature of 98 °C; at values over 1, accelerated aging occurs, for example, at L = 2 only half the service life is reached with respect to normal load conditions.

The relative aging is defined according to IEC only in the range from 80 °C to 140 °C. This is the defined operating range of the aging calculation. Temperatures below 80 °C do not extend calculated aging. Values exceeding 140 °C do not result in a reduction in the calculated aging.

The calculation of relative aging described refers only to the winding insulation and is, for this reason, not applicable for other failure causes.

Results

The hotspot temperature is calculated for the associated function group of the protected object. The currents of this function group and the measured coolant temperature at a selected temperature measuring point are used for this. The rated object current of the appropriate function group is used as the rated current.

Hotspot Thresholds

There are 2 indication thresholds for the hotspot temperature: A warning threshold **HST Warning Threshold** and an alarm threshold **HST Alarm Threshold**. There is also one adjustable threshold each for warning **Aging Warning Threshold** and alarm **Aging Alarm Threshold** for the mean aging rate.

Emergency Start

If the transformer must be operated beyond the maximum permissible hotspot temperature for operational reasons, the trip command can be blocked or a closure made possible by way of a binary input (*>Emergency start*).

After the binary input signal *>Emergency start* drops out, it may be necessary for the blocking to stay in effect because the hotspot temperature determined is still above the trip threshold. For this reason, the protection function is equipped with an adjustable seal-in time (**Emerg. start T overtravel**) that starts when the binary input signal drops and continues to suppress the trip command. Tripping by the hotspot calculation is only possible again after this time has elapsed.

This binary input acts only on the alarm indication and the trip command, has no effect on fault logging and does not reset the thermal image.

Blocking the Function

In the event of blocking, the picked up function will be reset. The function can be blocked externally or internally by the binary input signal *>Block stage*. All indications drop out with this.

Blocking Closure

The signal *Block close* can be used to prevent closure of the protected object at a high thermal load. The signal is set if the tripping temperature is exceeded, and cancelled if the temperature falls below the dropout threshold.

Functional Measured Values

Measured Value	Description
(_:13531:307) Tmp.A	Hotspot temperature for phase A in °C or °F (depending on the setting)
(_:13531:308) Tmp.B	Hotspot temperature for phase B in °C or °F (depending on the setting)
(_:13531:309) Tmp.C	Hotspot temperature for phase C in °C or °F (depending on the setting)
(_:13531:310) TmpMa	Hotspot temperature for the 3 phases in °C or °F (depending on the setting)
(_:13531:311) AgRate	Relative aging rate
(_:13531:305) RsWarn	Load margin until warning indication in percent
(_:13531:306) RsAlm	Load margin until alarm indication in percent

You can read the current status at any time on the device under the functional measured value.

You can find the functional measured values for the **Hotspot calculation** under the following menu item of the device:

- Main menu → Measurements → Function → Functional Measured Values → Hotspot calculation

6.61.4 Application and Setting Notes

Parameter: Sensor

- Default setting **(_:13531:44) sensor** = ***No function block selected***

With the **Sensor** parameter, you specify which connected temperature measuring point is used for hotspot calculation. The sensor for measuring the top-oil temperature must be connected to this temperature measuring point. If no temperature measuring equipment is connected, the **Consistency failure** parameter is displayed.

Parameter: Cooling Method

- Default setting **(_:13531:150) Cooling Method** = ***ONAN Oil nat.&Air nat.***

With the **Cooling Method** parameter, you specify the cooling method. You will find the definitions under the margin title **Cooling versions** in the function description of the hotspot calculation.

Parameter: Emerg. start T overtravel

- Default setting **(_:13531:112) Emerg. start T overtravel** = ***300 s***

With the **Emerg. start T overtravel** parameter, you set the time for which blocking of the tripping has to remain active after the outgoing input signal **>Emergency start**. With an outgoing input signal, the load on the protected object is removed. The **Emerg. start T overtravel** is set so that the hotspot temperature can drop below the dropout threshold in this time.

Parameter: HST Warning Threshold

- Default setting **(_:13531:103) HST Warning Threshold** = ***98 °C***

With the **HST Warning Threshold** parameter, you set a temperature at which a warning is output when this temperature is exceeded.

Parameter: HST Alarm Threshold

- Default setting **(_:13531:104) HST Alarm Threshold** = ***108 °C***

With the **HST Alarm Threshold** parameter, you set a temperature at which an alarm is output when this temperature is exceeded.

Parameter: Insulating material

- Default setting **Insulating material** = ***Standard insulation***

With the parameter **Insulating material**, you set the available insulating material for the transformer windings. Potential setting options are ***Standard insulation*** or thermally improved insulation (***Therm. improved insul.***). The max. hotspot temperature required for continuous load depends on the thermal resistance of the insulating materials used. The thermal resistance is 98° for thermally non-stabilized paper and 110° for thermally stabilized paper. Relative aging depends on the hotspot temperature of the transformer windings. This is how the type of insulating material is incorporated into the aging rate calculation.

Parameter: Aging Warning Threshold

- Default setting **(_:13531:105) Aging Warning Threshold** = ***1.000***

With the **Aging Warning Threshold** parameter, you set the threshold value at which a warning indication of the calculated relative aging is output.

Parameter: Aging Alarm Threshold

- Default setting **(_:13531:106) Aging Alarm Threshold** = ***2.000***

With the **Aging Alarm Threshold** parameter, you set the threshold value at which an alarm indication of the calculated relative aging is output.

Parameter: Turn time constant

- Default setting **(_:13531:116) Turn time constant** = ***10 min***

With the **Turn time constant** parameter, you account for the heat transfer from an electrical conductor (turn) to the outside of the insulation. This takes a few minutes. If no appropriate specifications are available, those found in IEC 60076-7 or IEEE C57.91 2011 may be used. You can find an excerpt from the tables of these standards with the relevant data in this case in *Table 6-22*.

Parameter: Calculation method

- Default setting **(_:13531:153) Calculation method** = ***IEC 60076-7***

With the **Calculation method** parameter, you specify the standard used for calculating the hotspot temperature. Depending on the selection, the required setting values are either displayed or hidden.

IEC 60076-7

The following settings apply only for the calculation method according to the IEC 60076-7 standard.

Parameter: y Turn exponent

- Default setting **(_:13531:101) y Turn exponent** = ***1.6***

To calculate the hotspot temperature, the device requires the **y Turn exponent**. If no specifications are available, those found in IEC 60076-7 may be used. You can find an excerpt from the tables of these standards with the relevant data in this case in *Table 6-22*.

Parameter: Temperature gradient

- Default setting **(_:13531:102) Temperature gradient** = ***22***

To calculate the hotspot temperature, the device requires the **Temperature gradient** (H_{gr}). This temperature gradient specifies the temperature difference between the hot spot of the winding and the top-oil temperature at rated load.

The setting is unitless. The temperature gradient is specified in °C (SI unit). If the value is only known for °F, convert it according to the following equation:

°C = K · 5/9

°C	Value in °C
K	Temperature gradient in °F

If no specifications are available, those found in IEC 60076-7 may be used. You can find an excerpt from the tables of this standard with the relevant data in this case in *Table 6-22*.

Parameter: Factor k21

- Default setting **(_:13531:113) Factor k21** = ***2.0***

Parameter: Factor k22

- Default setting **(_:13531:114) Factor k22** = ***2.0***

The parameters **Factor k21** and **Factor k22** are model constants that account for the turn configuration of the transformer with regard to oil flow. If no specifications for the transformer in question are available, those found in IEC 60076-7 may be used. You can find an excerpt from the tables of this standard with the relevant data in this case in *Table 6-22*.

Parameter: Oil time constant

- Default setting **(_:13531:115) Oil time constant** = ***210 min***

The **Oil time constant** parameters account for oil flow and flow rate. The time constant depends on the winding type and the cooling method. If no specifications are available, those found in IEC 60076-7 may be used. You can find an excerpt from the tables of this standard with the relevant data in this case in *Table 6-22*.

IEEE C57.91 2011

The following settings apply only for the calculation method according to the IEEE C57.91 2011 standard.

Parameter: m Turn exponent

- Default setting **(_:13531:110) m Turn exponent** = ***0.8***

To calculate the hotspot temperature, the device requires the **m Turn exponent**. If no specifications are available, those found in IEEE C57.91 2011 may be used. You can find an excerpt from the tables of this standard with the relevant data in this case in *Table 6-22*.

Parameter: Temperature gradient

- Default setting **(_:13531:130) Temperature gradient** = ***22***

To calculate the hotspot temperature, the device requires the **Temperature gradient** (H_{gr}). This temperature gradient specifies the temperature difference between the hot spot of the winding and the top-oil temperature at rated load.

The setting is unitless. The temperature gradient is specified in °C (SI unit). If the value is only known for °F, convert it according to the following equation:

°C = K · 5/9

°C	Value in °C
K	Temperature gradient in °F

If no specifications are available, those found in IEEE C57.91 2011 may be used. You can find an excerpt from the tables of this standard with the relevant data in this case in *Table 6-22*.

Thermal Data of Transformers

If no specifications for the transformer in question are available, those found in the IEC 60076-7 or IEEE C57.91 2011 standards may be used. You can find an excerpt from the tables of these standards with the data relevant here in the table below.

Table 6-22 Thermal Data of Transformers

		Distribution Transformers	Medium-Size and Large Power Transformers						
Cooling methods		ONAN	ONAN[1)]	ONAN	ONAF[1)]	ONAF	OF[1)]	OF	OD
Turn exponent (IEC)	y	1.6	1.3	1.3	1.3	1.3	1.3	1.3	2.0
Turn exponent (ANSI)	m	0.8	0.65	0.65	0.65	0.65	0.65	0.65	1.0
Constant	k_{21}	1.0	3.0	2.0	3.0	2.0	1.45	1.3	1.0
Constant	k_{22}	2.0	2.0	2.0	2.0	2.0	1.0	1.0	1.0
Oil time constant	τ_o [min]	180	210	210	150	150	90	90	90

		Distribution Transformers	Medium-Size and Large Power Transformers

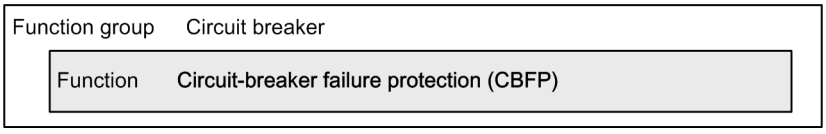
6.62 Circuit-Breaker Failure Protection



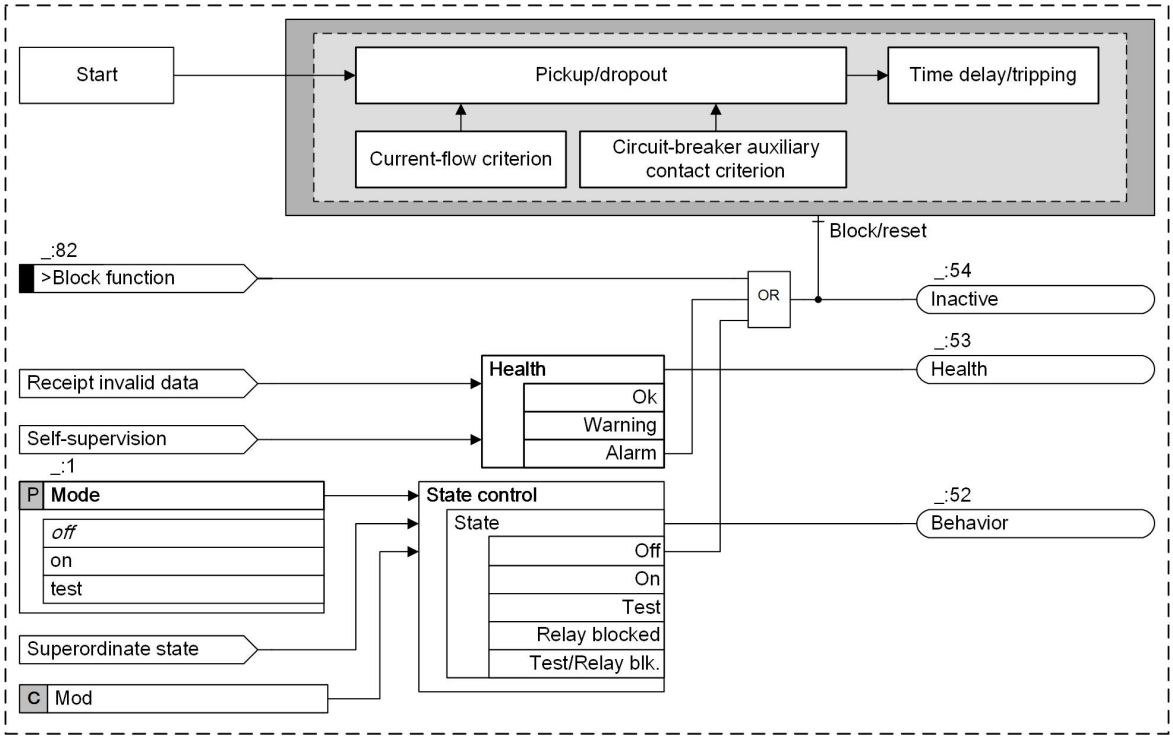
6.62.1 Overview of Functions

The **Circuit-breaker failure protection** function (ANSI 50BF) monitors the tripping of the associated circuit-breaker (CB) and generates a backup trip signal if the circuit-breaker fails.

Starting with version V7.50, the previous function **CB failure** has been replaced with the new Circuit-breaker failure protection with an adaptive algorithm **Adaptive CB failure protection**. In this way, you achieve a faster, more reliable detection of the opening of the circuit breaker in the event of complex signal histories. The 2 functions are identical, with the exception of a slightly increased processor load, in terms of setting options, logic and indications. Siemens recommends using the adaptive circuit-breaker failure protection and avoiding mixing the protection types in one device. You can find additional information on the processor load in DIGSI for each device under **Device information** in the **Resource consumption** tab.

6.62.2 Structure of the Function

The function **Circuit-breaker failure protection** (CBFP) can be used in the **Circuit-breaker** function group.



[dw_strbfp, 1, en_US]

Figure 6-635 Structure/Embedding of the Function

Figure 6-636 shows the functionalities and the function control of the function.

The start is initiated by the device-internal protection function or by an external protection. Along with the start, the current-flow criterion or the circuit-breaker auxiliary contact criterion is used to check whether the circuit breaker is closed. If the circuit breaker is closed, the function picks up and starts the time delay. During the time delay, the system continuously checks whether the circuit breaker has opened. If this is the case, the function drops out. If the circuit breaker is not opened, the function trips upon expiration of the time delay.

The following description elaborates on the detailed functionality of the individual function blocks.

[lo_svs_bfp, 3, en_US]

Figure 6-636 Function Logic Overview

6.62.3 Function Description

The circuit-breaker failure protection function is started by device-internal protection functions and/or externally (via a binary input or an interface, such as GOOSE). *Figure 6-637* and *Figure 6-638* show the functionality.

Internal Start

By default, each device-internal protection stage that must control the local circuit breaker starts the circuit-breaker failure protection. The function is started by the tripping of the protection stage. In the default setting, the starting signal **`Internal start`** (see *Figure 6-637*) is held when the pickup signal has a falling edge or the protection function has tripped. The Circuit-breaker failure protection function can in this case only drop out if the circuit breaker is detected to be open. This is detected using the current flow or circuit-breaker auxiliary contact criterion. If necessary, the Circuit-breaker failure protection function can also drop out when the pickup signal has a falling edge or the protection function trips (internal starting signal is not held).

You can use routing to determine whether individual protection stages or protection functions are used as a starting source or whether the start is only supposed to be external.

The internal starting sources are routed in the protection function groups via the entry **Circuit-breaker interaction** (for this, see*2.1 Embedding of Functions in the Device*. *Figure 2-6*.

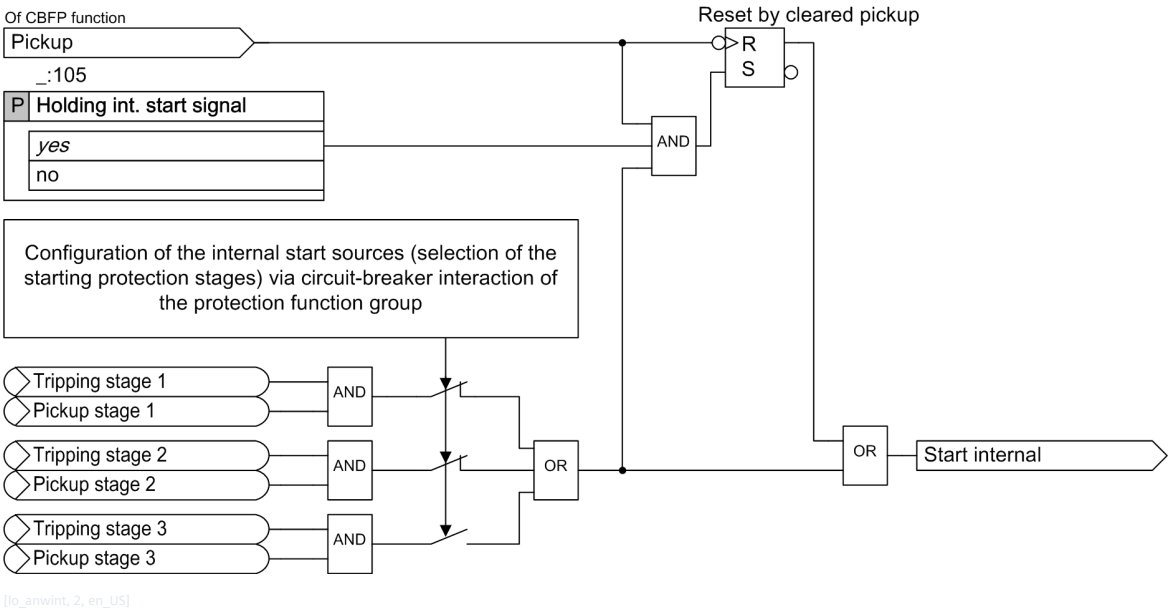


Figure 6-637 Internal Start of the Circuit-Breaker Failure Protection Function

External Start

The parameter **Start via binary input** is used to set whether the external start is initiated by a 1-channel or 2-channel signal. The required routing of the input signals is compared with the setting. If a routing is missing, an error message is generated. The Health signal changes to the state *warning*.

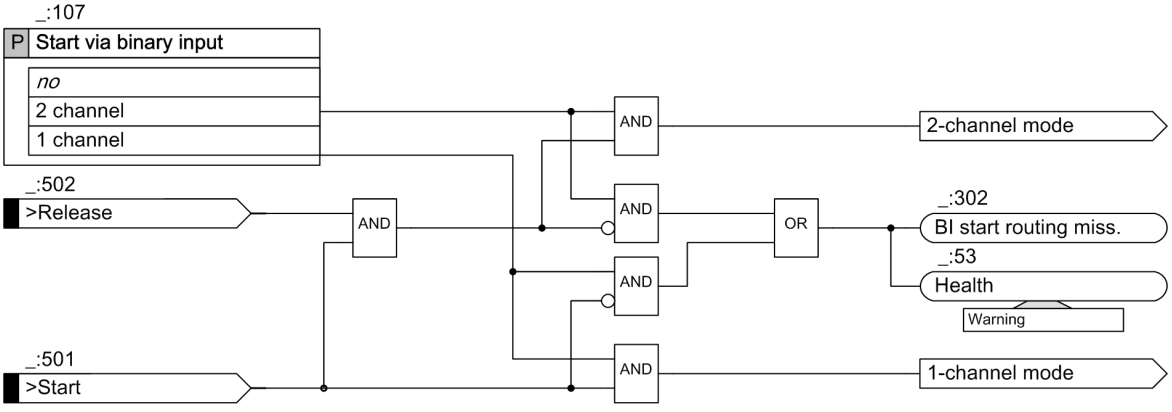

Figure 6-638 Configuration of the External Start of the Circuit-Breaker Failure Protection Function

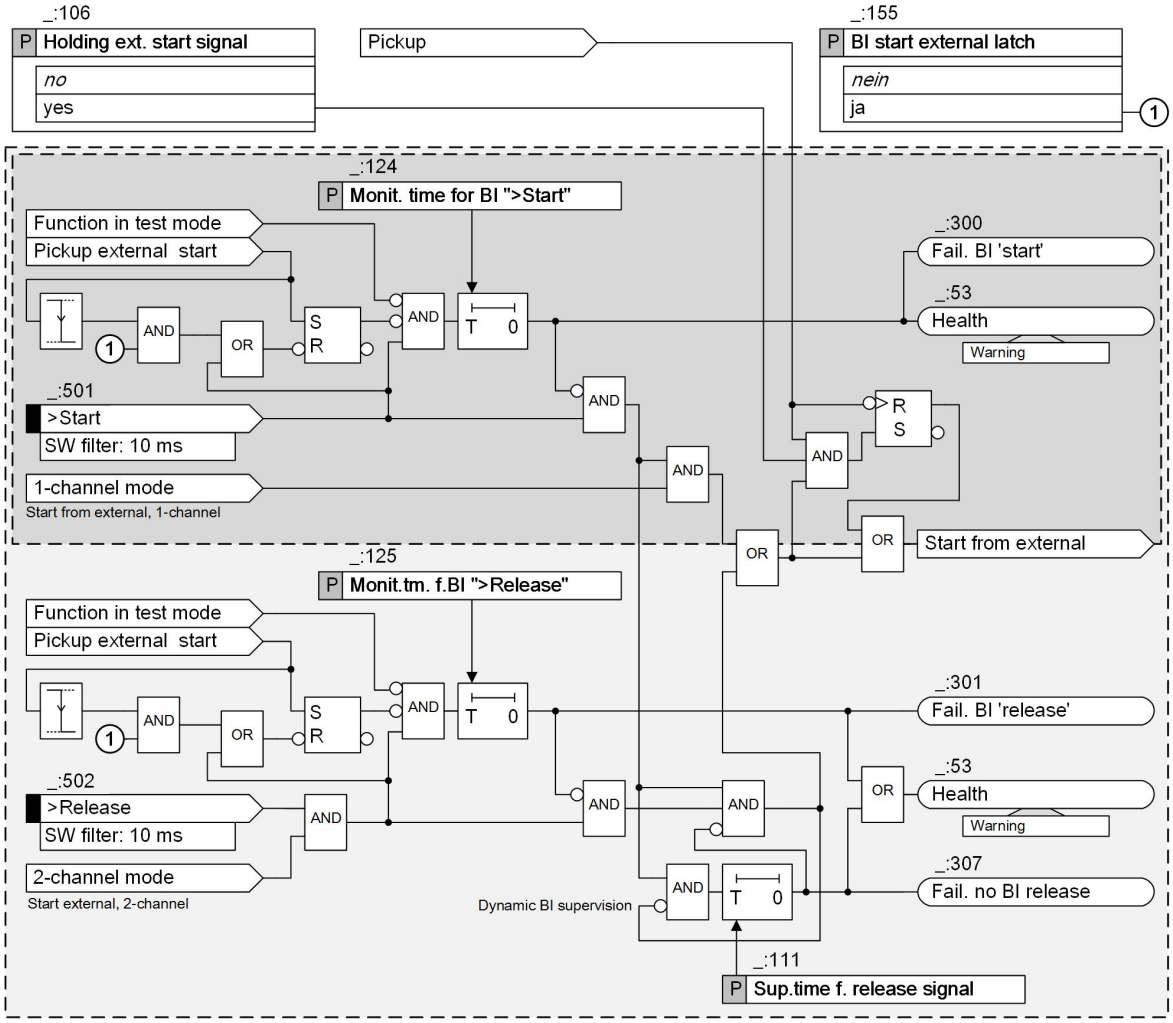
In 1-channel operation, the start is initiated with the binary input signal **>Start** only.

In 2-channel operation, the binary input signal **>Release** must also be activated to initiate the start. In the default setting, the starting signal **External start** drops out immediately when the input signals have a falling edge (see *Figure 6-639*). If necessary, the starting signal can be held. In this case the start remains active when the binary input signals have a falling edge.

The input signals are monitored to avoid an unwanted pickup of the function.



If either of the signals **>Start** or **>Release** is active for more than the set supervision time of the corresponding signal without the function being picked up, an error in the binary input circuit is assumed. The corresponding signal is blocked to exclude an external pickup of the function. An indication to this effect is output, and the Health signal changes to the state *warning*. The blocking is reset as soon as the binary input signal drops out.

Supervision is disabled in the following cases:

- On pickup of the Circuit-breaker failure protection function (only in the case of an external start). This prevents an unwanted pickup of the supervision if the external protection that starts the Circuit-breaker failure protection function uses a lockout functionality. When the starting signal drops out, supervision is enabled again.
- As long as the function or the device is in **test mode**. This allows to check the function without the supervision blocking the function.

If the signal **>Start** is active and no release signal is present after elapse of a settable supervision time for the starting signal, the pickup is blocked and an indication to this effect is output. The Health signal changes to the state Warning. The blocking is reset with the dropout of the starting signal.

The binary input signals only take effect if the binary inputs are activated for at least 10 ms (SW filter, see *Figure 6-639*).

[lo_ext, 3, en_US]

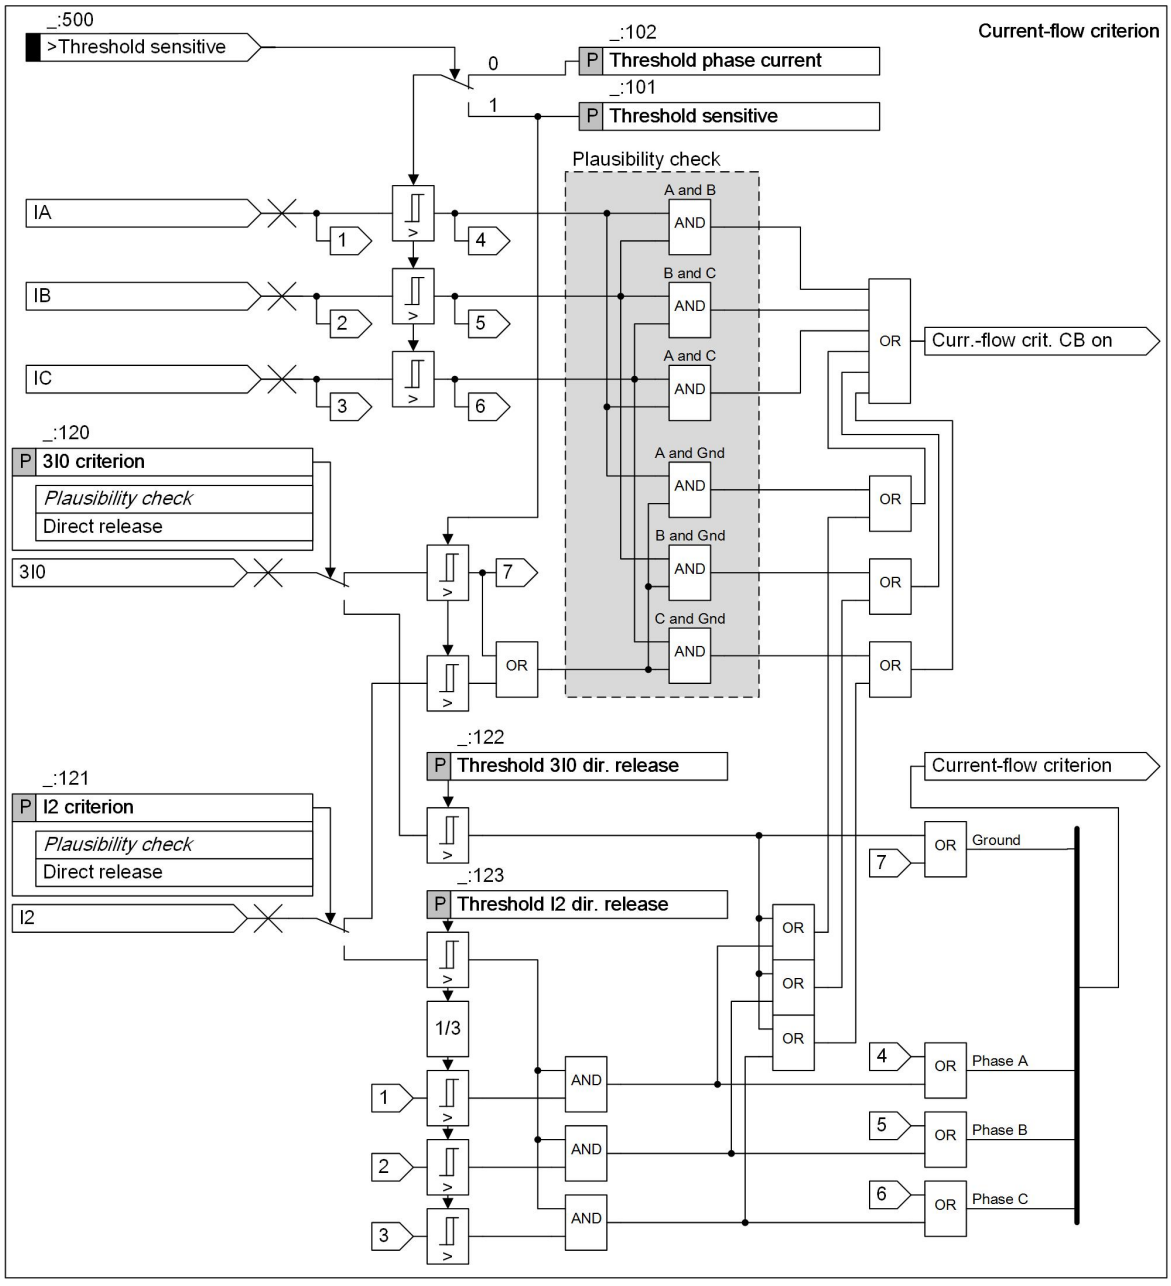
Figure 6-639 External Start of the Circuit-Breaker Failure Protection Function, Logic

Current-Flow Criterion

The current-flow criterion is the primary criterion for determining the circuit-breaker switch position. A circuit-breaker pole is supposed to be closed, and the current-flow criterion fulfilled, as soon as one of the phase currents exceeds the phase-current threshold value, and at the same time a plausibility current exceeds the associated threshold value. The plausibility current can be either a 2nd phase current (to compare with the threshold value for phase currents) or the zero-sequence or negative-sequence current (to compare with

the sensitive threshold value). The additional evaluation of the plausibility current increases the safety of a criterion.

If you are using the transformer connection type **3-phase, 2prim.trans.**, the ground current is neither measured nor calculated. The plausibility check via the ground current is therefore not possible. The setting ***Direct release*** via the ground current does not lead to a pickup of the circuit-breaker failure protection.



In the case of ground faults, the sensitive threshold value can be dynamically applied to the phase currents as well. The current-flow criterion is in this case fulfilled when the currents exceed the sensitive threshold value. The phase-current threshold value is then ineffective. The binary signal **>Threshold sensitive** is used for the switchover.

If you set the parameter **3I0 criterion** to ***Direct release***, you block the plausibility check of the zero-sequence current. In this way a pickup can only be achieved by way of this current. The **Threshold 3I0 dir. release** parameter is used to set the threshold value to be exceeded.

If you set the parameter **I2 criterion** to ***Direct release***, you also switch off the plausibility check of the negative-sequence current. The **Threshold I2 dir. release** parameter is used to set the threshold value to be exceeded.

If you set the parameter **I2 criterion** to ***Direct release***, a plausibility check is performed via the phase currents with 1/3 * **Threshold I2 dir. release**.

The measuring algorithm is optimized for fast dropout when the value drops below the threshold value.

[lo_current1, 4, en_US]

Figure 6-640 Current-Flow Criterion

Circuit-Breaker Auxiliary Contact Criterion

Settings allow you to specify whether the circuit-breaker auxiliary contacts are permitted for determining the circuit-breaker switch position.

The double-point indication **`3-pole position`** (from the function block **Circuit-breaker**) is used to determine whether all 3 poles of the circuit breaker are closed. If the double-point indication is not routed, the output is an error message. Furthermore, the Health signal changes to the state *`warning`*.

The detection of a static disturbed position (not an intermediate position) has the effect that the circuit-breaker auxiliary contact criterion is not used (the internal signal **`Aux.co.crit.: CB Clsd`** is disabled).

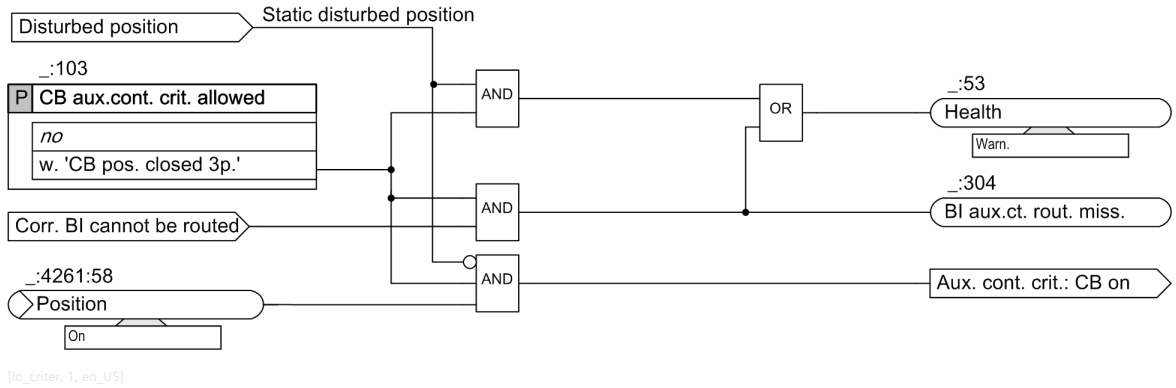


Figure 6-641 Circuit-Breaker Auxiliary Contact Criterion

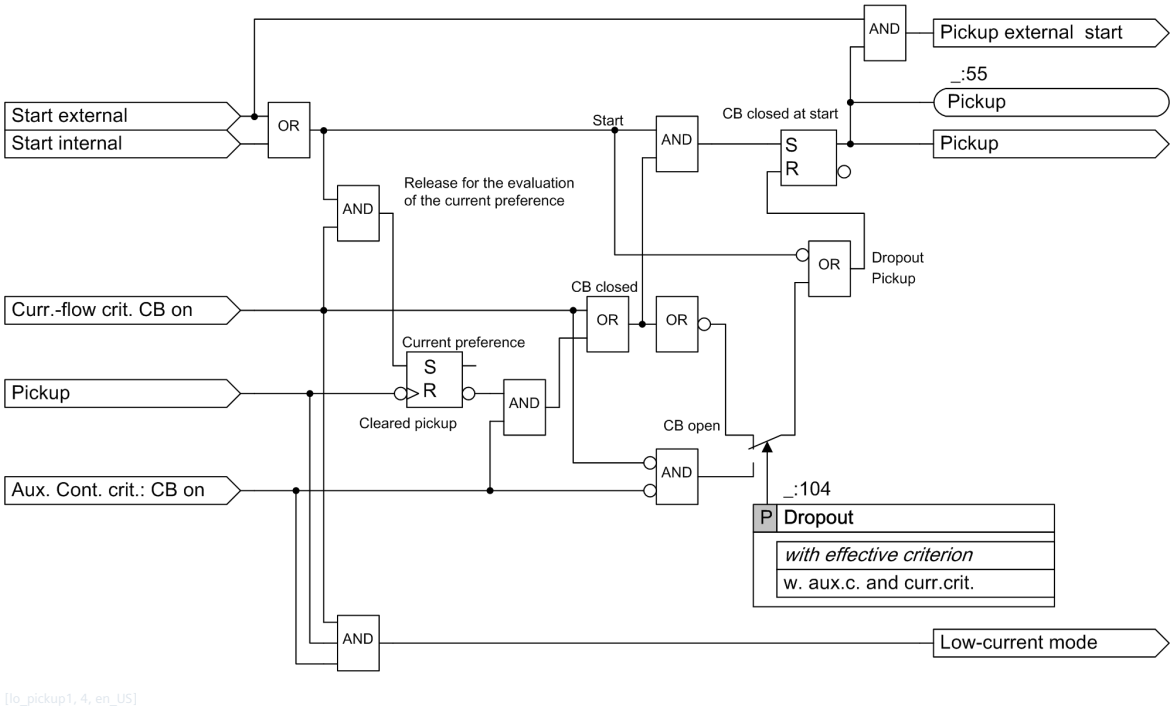
Pickup/Dropout

After the start, a check is performed whether the circuit breaker is closed. The current-flow criterion and the circuit-breaker auxiliary contact criterion are available for this purpose.

Even if the circuit-breaker auxiliary contact criterion is permitted, preference is given to the fulfilled current-flow criterion because the current-flow criterion is the most reliable criterion for detecting whether the circuit breaker is closed. This means that the circuit breaker is deemed to be closed if it is closed according to the current-flow criterion but at the same time open according to the circuit-breaker auxiliary contact criterion.



If no current is flowing at the start time, the function can only pick up on the basis of the circuit-breaker auxiliary contact criterion. For this purpose, the circuit-breaker auxiliary contacts must be permitted as criterion. When the current begins to flow after the start, the function switches over to the current-flow criterion.

If the circuit breaker is detected as closed and the starting condition is present, the function picks up.

The pickup starts a time delay (see Delay/Tripping). While the delay is running, the system checks continuously whether the circuit breaker has opened. In the default setting, the opening of the circuit breaker is checked on the basis of the currently valid criterion, which is normally the current-flow criterion because it is preferred. If until expiration of the time delay, no current flow above the set threshold values has been detected, the circuit-breaker auxiliary contact criterion becomes effective.

The function has also a setting in which dropout is only possible if both criteria in parallel detect the circuit breaker to be open (dropout with auxiliary contact and current-flow criterion).

In the default setting, the internal starting signal is held (see *Figure 6-637* and *Figure 6-639*). This means that dropout is controlled solely by the current or the circuit-breaker auxiliary contact criterion. If dropout is also to occur on the falling edge of the starting signal (that is, when the pickup signal has a falling edge or the protection function trips), holding of the start signal must be disabled.

[lo_pickup1, 4, en_US]

Figure 6-642 Pickup/Dropout of the Circuit-Breaker Failure Protection Function

Delay/Tripping

In a first step, tripping at the local circuit breaker can be repeated. Tripping is repeated after expiration of the settable delay T1. If the local CB was not yet tripped, for example, in the event of an external start of the circuit-breaker failure protection, the trip logic of the circuit breaker itself is activated when the time delay T1 elapses.

Time delay T2 (backup tripping) can commence in parallel either with the start of time T1 or after expiration of time T1.

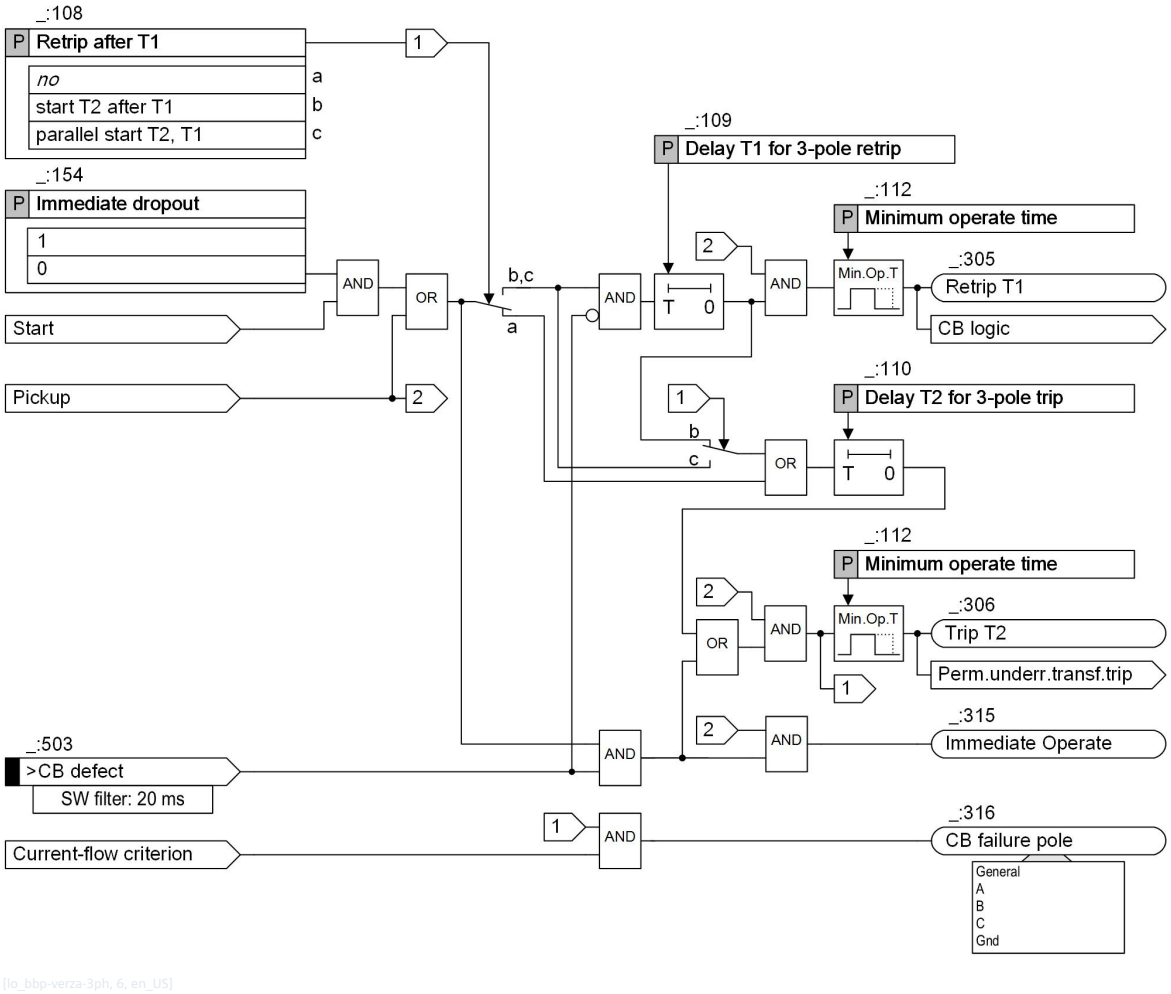
If time delay T2 expires without a dropout of the function, a circuit-breaker failure is assumed and the backup tripping signal **`Tripping T2`** is output. If there is a protection interface in the device, if needed a transfer-trip signal can be sent to the opposite end.

For detailed information, see *3.6 Protection Communication*.

If the **`>CB defect`** input signal is valid, any repetition of the trip signal is suppressed, and the backup tripping signal T2 is generated immediately (without delay). The binary input of the **`>CB defect`** input signal must be activated for at least 20 ms before the signal becomes valid.

With help of the *`CB failure pole`* indication, you can determine the phase currents that are above the threshold value at the tripping time T2.

The **`Minimum operate time`** parameter defines the minimum duration for tripping the function. In contrast to other protection functions, the parameter is set within its own function. As a result, the setting is independent of the identically named global parameter that is set in the **Device settings**.



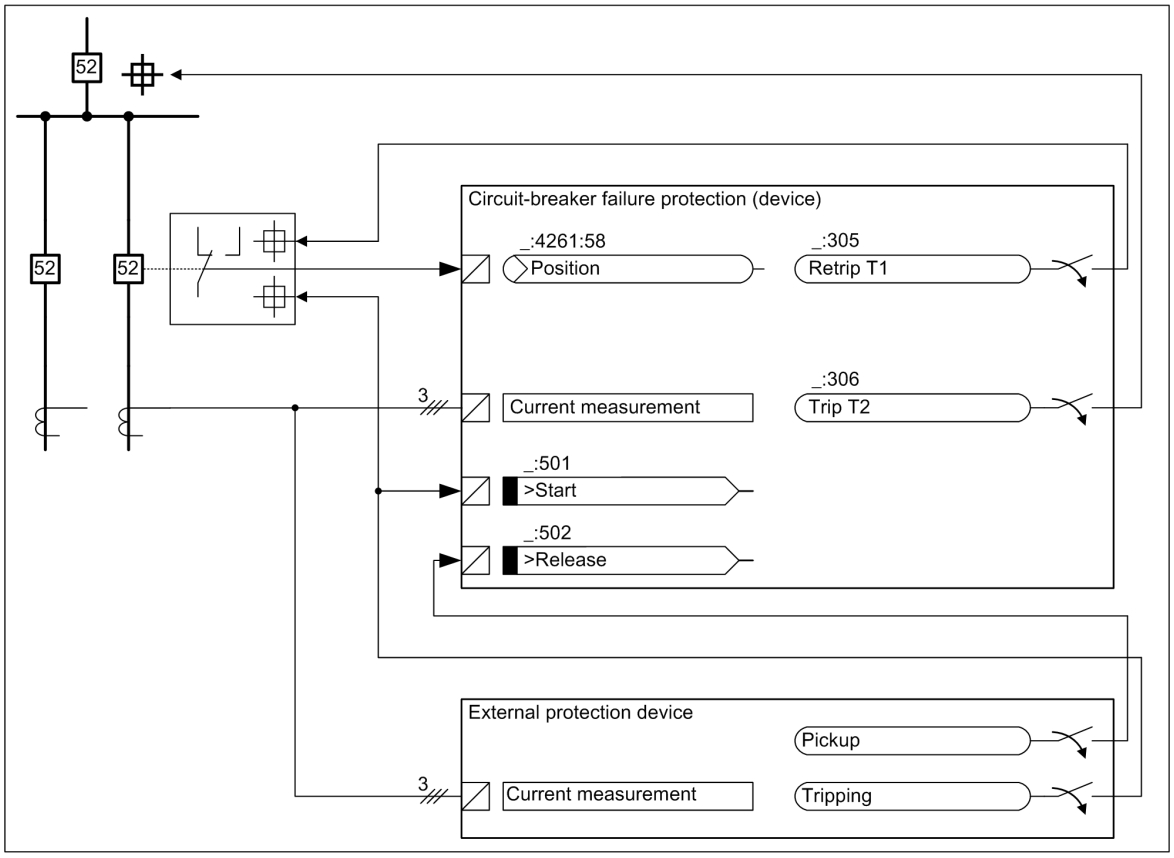


Figure 6-643 Delay/Tripping of the Circuit-Breaker Failure Protection Function

With the parameter **`Immediate dropout`**, you determine whether the circuit-breaker switch position is checked continuously or on expiration of the T1 and T2 time delays. If the circuit-breaker switch position is checked once the time delays have expired, the function picks up using Start.

6.62.4 Application and Setting Notes

Figure 6-644 gives an overview of the functions involved in an external start of the CBFP function. In the case of an internal start, there is no external protection device and the protection functionality is located in the CBFP device.

[lo_extpol, 2, en_US]

Figure 6-644 Circuit-Breaker Failure Protection with External Start, Tripping Repetition, and 3-Pole Tripping (T2)

Routing: Configuration of Internal Starting Sources (Internal Protection Function)

Configuration of the internal starting sources takes place in the protection function groups via the **Circuit-breaker interaction** entry (*2.1 Embedding of Functions in the Device*, *Figure 2-6*).

By default, the function can be started by any tripping of the internal protection functions that control the local circuit breaker. Depending on the specific application, it can be necessary to exclude certain device-internal protection functions from starting the CBFP. For instance, busbar disconnection following a local circuit-breaker failure may be undesirable in the case of load-shedding applications or ground faults in isolated/resonant-grounded systems.

Where a start exclusively from external sources is required, all internal protection functions must be routed so that they are excluded as a starting source.

Parameter: Start via binary input

- Default setting **(_:107) Start via binary input** = ***no***

Parameter Value	Description
no	If no external start is intended, the parameter is set to ***no***.
2 channel	2-channel start is used if there is a danger that the circuit-breaker failure protection causes a tripping due to a faulty activation of the start binary input. This is the case in the following situations: a) The CBFP pickup value (threshold value) is set to less than the load current. b) There can be operating conditions under which the current flow is higher than the pickup value. To avoid a possible overfunction, Siemens recommends using the 2-channel start.
1 channel	The 1-channel start must be used where only one control circuit of a binary input is available for starting the CBFP.

Input Signals: >Start, >Release

The start and release input signals have a filtering time of ***10 ms*** as default setting. If a transient control signal to the binary inputs is to be expected due to the design of the external binary-input control circuits and due to environmental conditions, the filtering time can be extended. This delays the start of the CBFP function.

Input Signals	Description
>Start	The start input signal is linked with the tripping of the external protection device (*Figure 6-644*).
>Release	The release input signal is normally linked with the pickup of the external protection device (*Figure 6-644*). Another common configuration is the parallel wiring of the external trip initiation to both binary inputs (start and release).

Parameter: Supervision time f. release signal

- Default setting **(_:111) Sup.time f. release signal** = ***0.06 s***

The setting depends on the external function which generates the release signal. If the pickup or tripping of the external protection is used as release signal, the default setting can be kept. If it is ensured that the release signal is always present before the start signal, the time can be set to 0.

Parameter: Holding internal start signal

- Recommended setting value **(_:105) Holding int. start signal** = ***yes***

Parameter Value	Description
yes	In the case of an internal start, the start signal is hold. The dropout of the CBFP depends exclusively on the determination of the circuit-breaker position. This setting must be selected if it is not ensured that all 3 poles of the CB have opened when the pickup signal of the protection function has a falling edge. Siemens recommends using this method as the standard method.
no	Holding of the start signal can be disabled if it is ensured by the application that the CB has reliably opened when the start signal has a falling edge, or if the CBFP is explicitly required to drop out when the start signal has a falling edge.

EXAMPLE

Holding Internal Start Signal (Setting Value: yes)

In the event of a 2-pole fault, only one contact of the CB opens. The fault current is thus reduced, and the starting phase short-circuit protection drops out.

Parameter: Holding external start signal

- Recommended setting value **(_:106) Holding ext. start signal** = ***no***

Parameter Value	Description
no	The CBFP drops out when the external start signal has a falling edge. This setting prevents the CBFP from generating a tripping signal when an unwanted pulse is received at the binary input and the current flow is high enough. Siemens recommends using this method as the standard method.
yes	You can hold the start signal if it is not ensured that the circuit breaker is open when the external start signal has a falling edge.

EXAMPLE

Holding External Start Signal (Setting Value: Yes)

The function is started from the opposite end via an auxiliary device for command transmission. This device generates only a signal pulse.

NOTE

Siemens would like to point out that, with a hold signal, the CBFP generates a trip signal each time a starting pulse is received and the current flow is high enough. Remember this particularly in the case of an external start.

Parameters: Threshold phase current/Threshold sensitive

- Recommended setting value **(_:102) Threshold phase current** = ***approx. 0.50*** $I_{sc, min}$
- Recommended setting value **(_:101) Threshold sensitive** = ***approx. 0.50*** $I_{sc,min}$

In order to ensure that the disconnection of the fault is promptly detected and the function can drop out quickly, Siemens recommends setting both thresholds to half the minimum short-circuit current ($I_{sc, min}$).

If – depending on the neutral-point treatment and/or load conditions – ground faults lead to relatively low fault currents, a sensitive setting of the parameter **Threshold sensitive** must be selected according to the rule (0.5 $I_{sc, min}$). There can also be values which are noticeably below the rated or load current.

Input Signal: >Threshold sensitive

In order to ensure that the function picks up reliably in all switch positions of the power system (examples: opposite end of line open, switching onto a ground fault), the setting of the parameter **Threshold sensitive** can be applied dynamically to all currents - including phase currents – in the presence of ground faults. For this purpose, the binary signal **>Threshold sensitive** must be activated. This can be done via a device-internal function for ground-fault detection (if provided in the device), for example, using **Overvoltage protection with zero-sequence voltage**. In this case, the pickup of the V0> function must be linked with the binary signal. Alternatively, the signal can be coupled from a separate device for sensitive ground-fault detection via a binary input.

Parameter: Circuit-breaker auxiliary-contact criterion allowed for protection

- Recommended setting value **(_:103) CB aux.cont. crit. allowed** = ***no***

Parameter Value	Description
no	If sufficient current flow is ensured under all conditions with the CB closed, Siemens recommends not to permit the auxiliary contacts as a further criterion for determining the CB position, because measurement based on the current flow is the most reliable criterion.
w. 'CB pos. closed 3p.'	The auxiliary contacts are permitted as a further criterion in applications (see the following examples) where the current is no reliable criterion for determining the circuit-breaker position.

Parameter: 3I0 criterion

- Recommended setting value (_:120) **3I0 criterion** = ***Plausibility check***

Parameter Value	Description
Plausibility check	The ground current is only used to check the plausibility of the phase currents. The value set under the parameter **Threshold sensitive** is used as the threshold for the ground current.
Direct release	The current-flow criterion can be fulfilled only by the ground current without the phase currents exceeding their set threshold value. The value set under the parameter **Threshold 3I0 dir. release** is used in this case as the threshold for the ground current.

If you have set the **Threshold phase current** to be larger than the maximum load current, overfunction because of a false start is impossible. To ensure **Circuit-breaker failure protection** for smaller ground faults even with this setting, you can select **3I0 criterion** to be ***Direct release*** and **Threshold 3I0 dir. release** to be appropriately smaller than **Threshold phase current**.

Parameter: I2 criterion

- Recommended setting value (_:121) **I2 criterion** = ***Plausibility check***

Parameter Value	Description
Plausibility check	The negative-sequence current is only used to check the plausibility of the phase currents. The value set under the parameter **Threshold sensitive** is used as the threshold for the negative-sequence current.
Direct release	If a phase current exceeds 1/3 of the **Threshold I2 dir. release**, the current-flow criterion can be fulfilled only by the negative-sequence current without the phase currents exceeding their set threshold value. The threshold for the negative-sequence current uses the value set in the **Threshold I2 dir. release** parameter in this case.

If you have set the **Threshold phase current** to be larger than the maximum load current, overfunction because of a false start is impossible. To have Circuit-breaker failure protection function for smaller unbalanced faults even with this setting, you can select **I2 criterion** to be ***Direct release*** and **Threshold 3I0 dir. release** to be appropriately smaller than **Threshold phase current**.

Parameter: Threshold 3I0 dir. release

Recommended setting value **(_:122) Threshold 3I0 dir. release** = ***approx. 0.5 Isc***$_{min}$

This parameter is effective only if the **3I0 criterion**parameter is set to ***Direct release***. Siemens recommends setting the threshold to half the minimum short-circuit current (Isc_{min}) to ensure that the disconnection of the fault is promptly detected and the function can drop out quickly.

Parameter: Threshold I2 dir. release

Recommended setting value **(_:123) Threshold I2 dir. release** = ***approx. 0.5 $I2_{min}$***

This parameter is effective only if the **I2 criterion**parameter is set to ***Direct release***. Siemens recommends setting the parameter to half the permissible negative-sequence current ($I2_{min}$) to achieve a fast fault clearing in the event of an undesired negative-sequence system component.

Parameters: Monit. time for BI ">Start"/Monit.tm. f.BI ">Release"

- Default setting **(_:124) Monit. time for BI ">Start"** = ***15 s***
- Default setting **(_:125) Monit.tm. f.BI ">Release"** = ***15 s***

With these parameters, you set the monitoring time of the binary inputs **>Start**/**>Release**. If the **Circuit-breaker failure protection** does not pick up during this monitoring time, a failure in the binary-input circuit is assumed. Siemens recommends retaining the default setting of 15 s.

EXAMPLES

Applications which Require you to Permit the Circuit-Breaker Auxiliary-Contact Criterion:

- Tripping of the high and low-voltage side CB on the transformer. If only one of the 2 CBs trips, there is no more current flow.
- Tripping of protection functions whose tripping decision is not based on a current measurement in combination with voltage or frequency protection functions
- Injection of the tripping signal from Buchholz protection

Parameter: Dropout

- Recommended setting value **(_:104) Dropout** = ***with effective criterion***

The parameter **Dropout** is available if the circuit-breaker auxiliary contact criterion is permitted (see parameter **CB aux.cont. crit. allowed**).

Parameter Value	Description
with effective criterion	Siemens recommends keeping the default setting, because it prefers the current as a reliable criterion for detection of an open CB and thus for dropout of the CBFP function.
w. aux.c. and curr.crit.	Select this setting for applications on transformers or generators (see the preceding examples) in which the current flow is such that the current is no longer a reliable criterion for detecting the opening of the CB.

Parameter: Retrip

- Default setting **(_:108) Retrip after T1** = ***no***

Parameter Value	Description
no	Where no redundant CB control is provided, a repetition of the trip signal to the local CB is not required.
start T2 after T1	Where a redundant CB control (2nd trip coil with 2 trip circuits) is provided, a repetition of the trip signal to the local CB makes sense. Siemens recommends the setting ***start T2 after T1*** because it provides a clear chronological separation of the processes for trip repeat and backup tripping. Remember here that the overall fault-clearance time in case of a failure of the local CB is the sum of T1 and T2.
parallel start T2, T1	As an alternative to the setting ***start T2 after T1***, the user can start T2 and T1 in parallel.

Parameter: Delay T1 for 3-pole retrip

- Default setting **(_:109) Delay T1 for 3-pole retrip** = ***0.05 s***

The parameter is visible only when retripping is set.

The setting depends on the user's philosophy.

The following settings make sense:

- If the minimum fault-clearing time has top priority, Siemens recommends setting the time to 0. This setting causes initiation of the retrip immediately upon the start. The drawback is that a defect of the 1st trip circuit is not detected.
- With a small time delay of, for instance, 50 ms, the defect of the 1st trip circuit can be detected based on the evaluation of the fault record.
- With a long time delay, which reliably ensures the dropout of the CBFP with the CB open, the rising edge indication of the trip repeat **Retrip T1** is a sure signal for a fault in the 1st trip circuit. The following example shows how this time is determined.

EXAMPLE

Determining the T1 Time that Reliably Ensures the Dropout of the CBFP with the CB Open:

Time of binary device output (when tripping is caused by device-internal protection)	5 ms
CB inherent time up to current interruption	2 periods (assumed rated frequency = 50 Hz)
Dropout time of CBFP function	1 period
Subtotal	65 ms
Security	Factor 2
Total (time T1)	130 ms

Parameter: Delay T2 for 3-pole trip

- Default setting **(_:110) Delay T2 for 3-pole trip** = ***0.13 s***

This setting has to ensure that after opening of the local CB the function drops out reliably and that backup tripping is avoided under all circumstances. The setting depends on the parameter **Retrip after T1**.

If T2 is started after T1, there is no need to consider the time T1 for the setting of T2.

EXAMPLE

Determining the T2 Time that Reliably Ensures the Dropout of the CBFP with the CB Open:

Time of binary device output (when tripping is caused by device-internal protection)	5 ms
CB inherent time up to current interruption	2 periods (assumed rated frequency = 50 Hz)
Dropout time of CBFP function	1 period
Subtotal	65 ms
Security	Factor 2
Total (time T2)	130 ms

If T1 and T2 are started in parallel, take into account the time T1 for the setting of T2.

EXAMPLE

Simultaneous Start of T2 and T1

Time for a reliable dropout after the local CB has opened	130 ms
Setting of T1	50 ms
Total (= T2)	180 ms

Parameter: Minimum operate time

- Default setting **(_:112) Minimum operate time** = **-**

The **Minimum operate time** parameter is used to set the minimum duration for tripping the function.

CAUTION

Too short setting times for the minimum tripping duration

If you set a time that is too short for tripping, there is a risk (dropout of the function without the current-flow criterion) that the device contacts will interrupt the control loop. If this happens, the device contacts will burn out.

✧ Set a minimum time period that is long enough to ensure that the circuit breaker reliably reaches the end position **Open** after a control operation.

Input Signal: >CB defect

The input signal **>CB defect** has a default filtering time of 20 ms. This filtering time prevents the input signal from becoming effective in the case of a transient activation of the physical binary input, which can be caused by the pressure change when the CB opens.

This time can be set to 0 if such a transient pickup of the physical binary input can be excluded due to the CB design.

Output Signal: Retrip T1

If only 1 control circuit is available for the local circuit breaker, the output signal does not necessarily have to be routed because the signal also controls the circuit-breaker trip logic.

If a 2nd control circuit is present, the **Retrip T1** output signal must be routed to the associated binary output.

Output Signal: Trip T2

For operational handling of the adjacent circuit breakers, the backup tripping (indication **Trip T2**) must be routed to a binary output; and if necessary, to an interface (intertripping to opposite end).

Parameter: CBFP interact. with dBBP

- Default setting (_:153) **CBFP interact. with dBBP** = ***No***

  If you use a merging unit as the bay unit of the distributed busbar protection, the **CBFP interact. with dBBP** parameter becomes visible after the successful central-unit update in the merging unit.

Parameter Value	Description
no	With this parameter, you specify that this function operates independently from the distributed busbar protection.
yes	With this parameter, the function will work with the distributed busbar protection.

Parameter: `Immediate dropout`

- Recommended setting (_:154) **`Immediate dropout`** = ☑

Parameter Value	Description
☑	The criteria are checked continuously and the circuit-breaker failure protection drops out immediately once the criteria have no longer been met. Siemens recommends keeping this setting.
☐	This setting is used to take alternating load cases into account in the event of a fault, for example when using a breaker-and-a-half layout. The time delays and function pickup are actuated separately using a starter. The criteria for determining a closed circuit breaker are only checked once the time delays have expired. Select the monitoring times for the binary inputs *>Start* and *>Release* in such a way that supervision for these inputs does not respond prior to achieving the current or circuit-breaker auxiliary-contact criterion.

Parameter: `BI start external latch`

- Default setting (_:155) **`BI start external latch`** = ☑

Parameter Value	Description
☑	In the case of buffered sources (for example lock-out mechanism after tripping) the start binary signal is latched externally after the protection trip. This means that the binary-input supervision remains inactive until the binary-input source has been reset. Supervision is only activated after this has taken place.
☐	In the case of sources that are not buffered for an external start, the expectation is that they will drop out once the circuit-breaker failure protection has picked up. If this is not the case, the binary input may fail. This is why this setting results in binary-input supervision being reactivated once the Circuit-breaker failure protection function drops out.

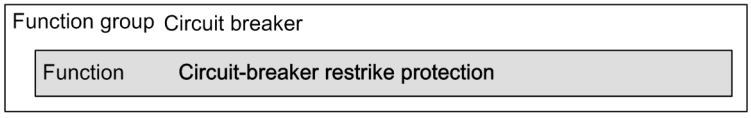
6.63 Circuit-Breaker Restrike Protection

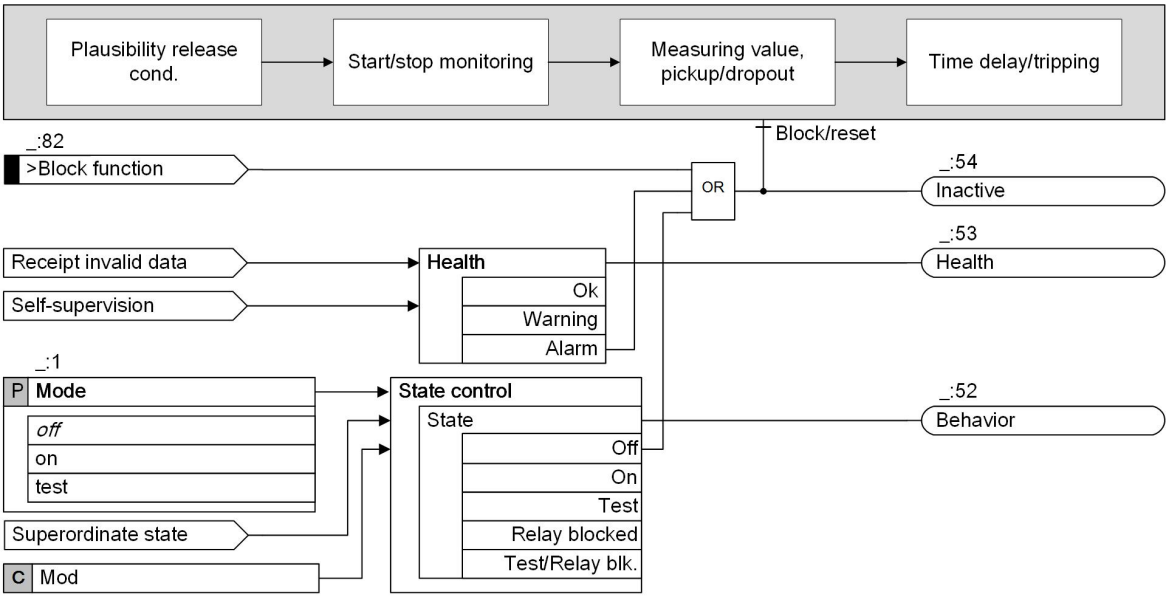


6.63.1 Overview of Function

The **Circuit-breaker restrike protection** function:

- Monitors the circuit breaker against restriking, for example, caused by an overvoltage over the circuit-breaker poles after switching off a capacitor bank
- Generates a backup operate signal in case of a circuit-breaker restriking

6.63.2 Structure of the Function



The **Circuit-breaker restrike protection** function is used in the **Circuit-breaker** function group. A maximum of 2 functions can operate simultaneously within the function group.

[lo_strrestrike, 2, en_US]

Figure 6-645 Structure/Embedding of the Function

The function logic is grouped into the parts shown in *Figure 6-646*. In the following chapter, these logic parts are described in detail.

[lo_respro, 2, en_US]

Figure 6-646 Logic Overview of the Function

6.63.3 Function Description

Plausibility Release

The function **Circuit-breaker restrike protection** issues a trip command to a superordinated circuit breaker, usually the infeed circuit breaker of a busbar. Overfunction of this protection can cause extreme problems for the whole application.

The logic of plausibility release strongly reduces the risk of a false start of the function by adding an extra release criteria for a function start.

Each criterion can be switched on or off individually.

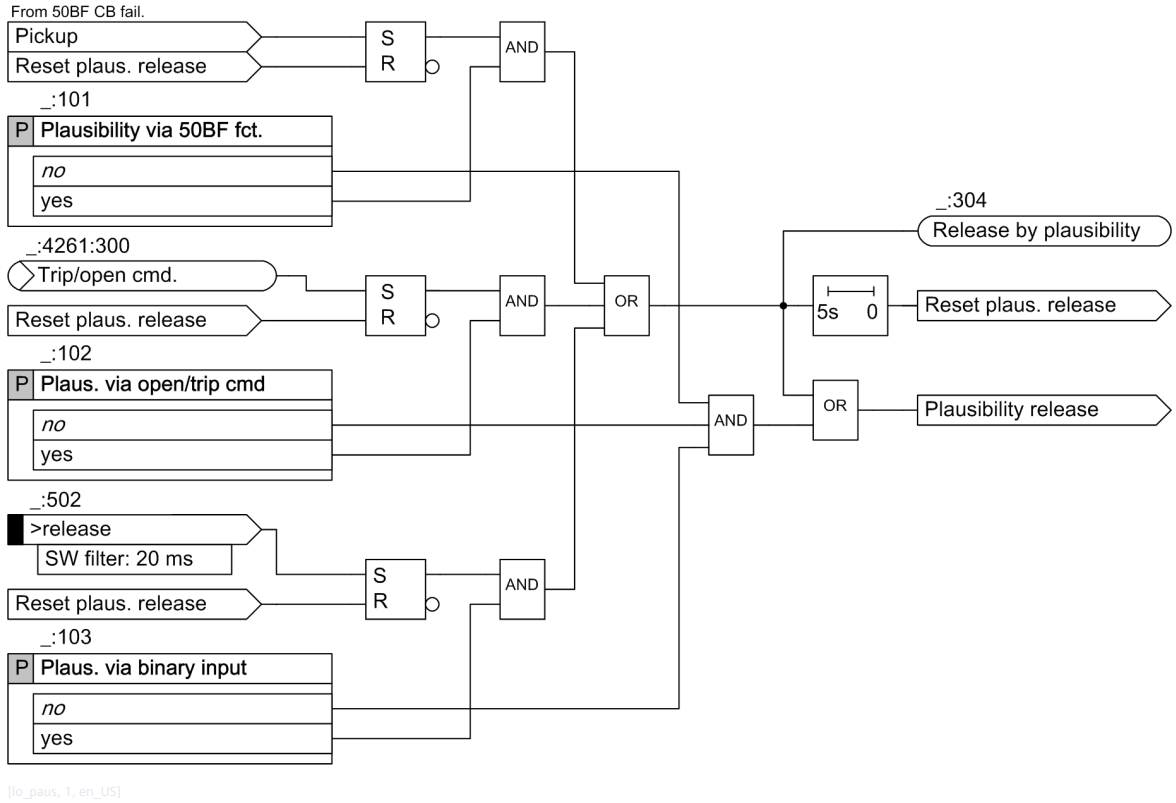


Figure 6-647 Logic Diagram for the Plausibility Release of the Circuit-Breaker Restrike Protection

The plausibility-release logic checks the following conditions:

- When the parameter **`Plausibility via 50BF fct.`** is set to ***yes***, the pickup signal of the **Circuit-breaker failure protection** is monitored. The plausibility release is given if the **Circuit-breaker failure protection** has picked up.
- When the parameter **`Plaus. via open/trip cmd`** is set to ***yes***, the trip/open command is monitored. The plausibility release is given if the trip/open command has been generated.
- When the parameter **`Plaus. via binary input`** is set to ***yes***, the *>release* signal is monitored. The plausibility release is given if the *>release* signal has been received.

If one of the conditions is fulfilled, the plausibility release is given for 5 s. The 5-s timer ensures that the release criterion and start condition relate to the same circuit-breaker opening/tripping process.

If all the 3 plausibility settings are set to ***no***, the start/stop-monitoring logic considers the release as fulfilled.

For safety reasons, the input signal *>release* has a preset software filtering time of 20 ms.

Start/Stop Monitoring

Via the start/stop monitoring logic, the monitoring duration of the current signal regarding restriking is determined.

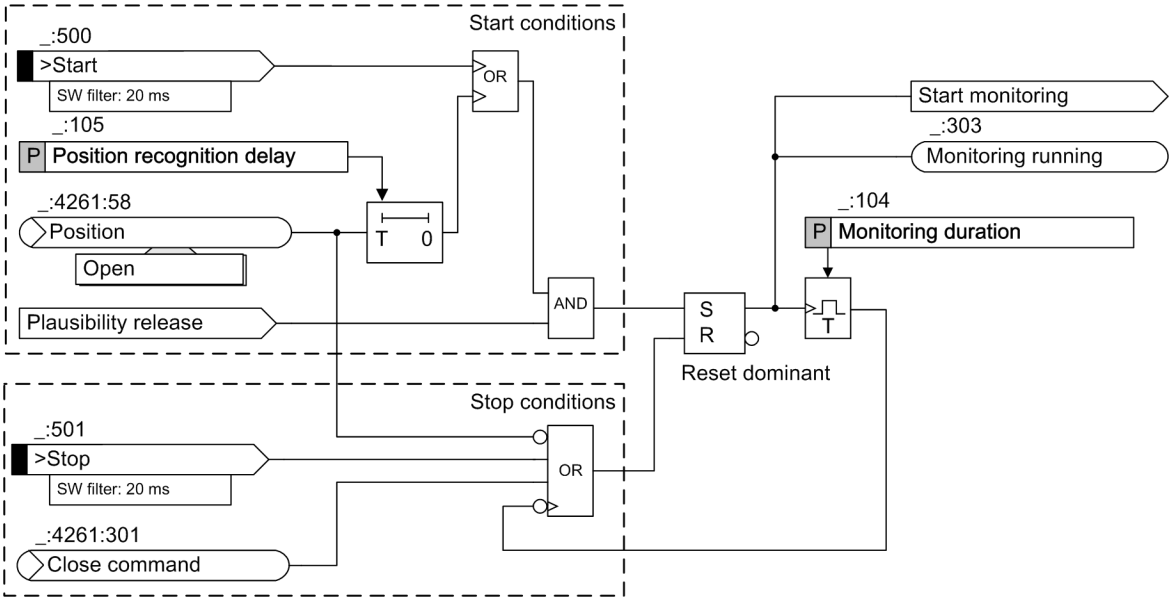

Figure 6-648 Logic Diagram for Start/Stop Monitoring of the Circuit-Breaker Restrike Protection

The monitoring is started if one of the following conditions is met:

- The circuit-breaker position is detected as **open** via the circuit-breaker auxiliary contacts during the time set with the parameter **`Position recognition delay`**.

  The **`Position recognition delay`** time is used for safety means to ensure that the circuit breaker is definitely open when the monitoring starts. This parameter allows to adapt this start criterion to all kinds of auxiliary-contact configurations.

- The binary input signal *`>Start`* is activated.

For safety reasons, the input signal has a preset software filtering time of 20 ms.

In addition to the active start criterion, the plausibility release (refer to the *Plausibility Release, Page 1708*) must be present to start the monitoring duration.

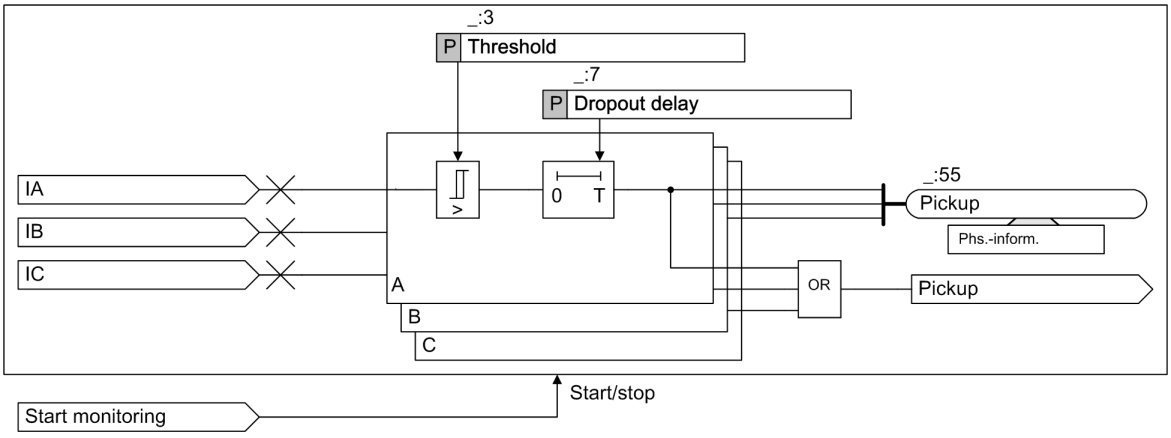
With the fulfilled start condition, the **`Monitoring duration`** timer is started. This timer defines how long the current signal is monitored regarding restriking. If the time expires, the monitoring is terminated.

The monitoring is also terminated immediately if one of the following conditions is met:

- The circuit-breaker position is detected no longer as **open**.
- A close command is given by the device.
- The binary input signal *`>Stop`* is activated.

  For safety reasons, the input signal has a preset software filtering time of 20 ms.

Measuring Value, Pickup/Dropout



During the **`Monitoring duration`**, the current signal is monitored phase-selectively regarding restriking.

As a measuring value, the fundamental component of the current is used.

- On one hand, current peaks are damped but still detected reliably by the fundamental-component value.
- On the other hand, a DC (Direct Current) component is suppressed. A DC component can occur after switching off the circuit breaker.

Thus, the fundamental-component value is a good choice for a reliable restrike detection.

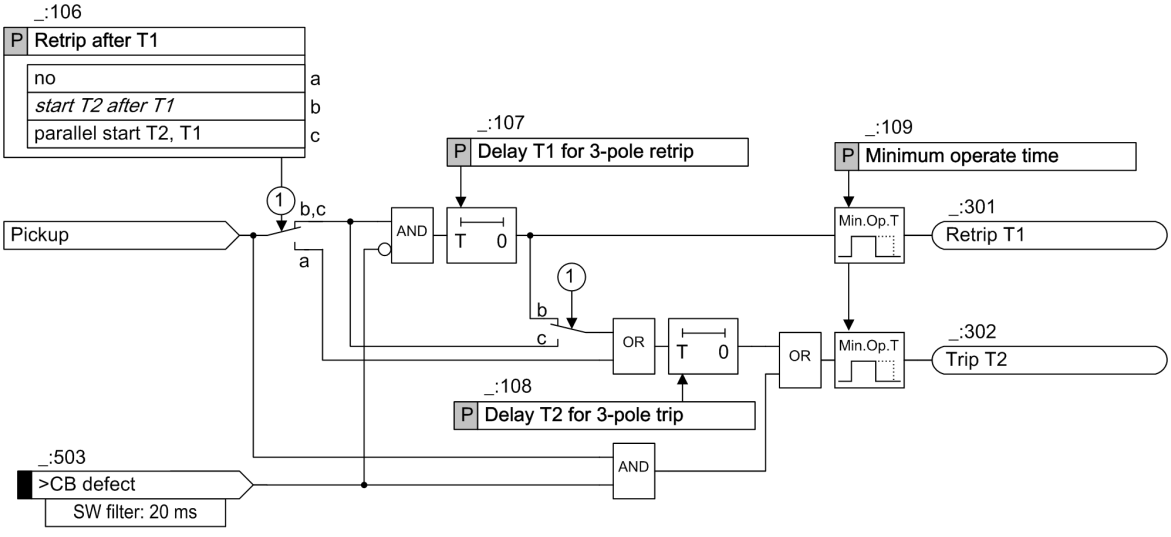
If any phase current exceeds the set current threshold value, the function picks up. The coming pickup indicates the first restrike current pulse. With the pickup, the operate delay timers are started, see also the following description *Delay/Tripping, Page 1711*.

[lo_pickdrop, 1, en_US]

Figure 6-649 Logic Diagram for Measuring Value, Pickup/Dropout of the Circuit-Breaker Restrike Protection

If restriking occurs, the current signal drops below the current threshold if the time between restrike pulses is long enough. In this case, the operate delay must not be reset. During the dropout delay, the pickup is extended to ensure that the operate delay timers are not reset. However, if the dropout delay time expires (no new current peak occurred), the function drops out and the operate delay timers are reset.

Delay/Tripping



In the first step, tripping of the local circuit breaker can be repeated. Tripping is repeated after expiration of the settable delay T1. The retrip on the local circuit breaker is as a safety mechanism as well. In the event of a wrong start and pickup, only the local circuit breaker is opened instead of the superordinated circuit breaker.

Time delay T2 (backup tripping) can start in parallel either with the start of time T1 or after expiration of time T1.

If time delay T2 expires, circuit-breaker restriking takes place and the backup-tripping signal *Trip T2* is generated.

If the *>CB defect* input signal is valid, any repetition of the trip signal is suppressed and the backup-tripping signal *Trip T2* is generated immediately (without delay). For safety reasons, a default software filter time of 20 ms is preset (configurable in DIGSI) for the binary input signal *>CB defect*.

The **Minimum operate time** parameter defines the minimum duration for the trip command of the function. In contrast to other protection functions, the parameter is set within its own function. As a result, the setting is independent of the identically named comprehensive parameter that is set in the **Device settings**.

[lo_del_trip, 2, en_US]

Figure 6-650 Logic Diagram for Delay/Tripping of the Circuit-Breaker Restrike Protection

6.63.4 Application and Setting Notes

Parameter: Switch On or Off Additional Plausibility Release Criteria

- Default setting **(_:101) Plausibility via 50BF fct.** = ***no***
- Default setting **(_:102) Plaus. via open/trip cmd** = ***no***
- Default setting **(_:103) Plaus. via binary input** = ***no***

When using the plausibility release, the start condition and the release condition instead of only the start condition must be present to start the current monitoring regarding restriking. Since the current threshold value is set below the operating current, a false start would directly cause tripping. Thus, the plausibility release strongly reduces the risk that a falsely given start criterion leads to a wrong tripping of the superordinated circuit breaker.

3 different release criteria are available. You can use one or more than one or none of them. The selection depends on the application.

NOTE

When using release criteria, it must be ensured that the criteria are given under all the conditions where the **Circuit-breaker restrike protection** shall be started. If you choose no release criteria, the release is permanently given.

- **Open/trip command by the device**

Use this criterion in case that all control or trip commands are given by the protection device.

NOTE

Opening the circuit breaker manually without using the device will not release the start of the **Circuit-breaker restrike protection**.

- **Pickup of the Circuit-breaker failure protection**

Use this criterion if the **Circuit-breaker restrike protection** should only be started in case that the **Circuit-breaker failure protection** was started (picked up) before.

NOTE

Opening the circuit breaker by control or manually will not trigger the **Circuit-breaker failure protection**. Consequently the **Circuit-breaker restrike protection** cannot be released either.

- **Binary input signal**

Use this option if neither of the above 2 release criteria fit the application and you want to define your own release criterion.

Input signals: *>Start, >release, >Stop*

Input Signals	Description
>Start	This input signal allows to start the monitoring, for example, via protocol commands from a master (by use of a CFC chart) or by other specific conditions.
>release	This input signal allows to define specific release conditions by use of a CFC chart. Also refer to *Parameter: Switch On or Off Additional Plausibility Release Criteria , Page 1712*.
>Stop	This input signal allows to stop the monitoring, for example, via protocol commands from a master (by use of a CFC chart) or by other specific conditions.

The input signals *>Start* , *>release* , and *>Stop* have a filtering time of *20 ms* as default setting. If a transient spurious signal to the binary inputs is expected due to the design of the external binary-input control circuits and environmental conditions, the filtering time can be extended.

Parameter: Position recognition delay

- Default setting **(_:105) Position recognition delay** = *0.02 s*

With the parameter **Position recognition delay**, you define how long the circuit breaker must be detected as **open** (via the circuit-breaker auxiliary contacts) before the monitoring time is started. This definition is a safety feature to ensure that the monitoring is not started too early. For example, in case that due to a non-standard auxiliary-contacts configuration, the circuit-breaker is already detected as **open** while current flow is still present.

The setting depends on the circuit-breaker auxiliary-contacts configuration. If it can be ensured that the auxiliary contacts announce the circuit breaker as **open** after the current flow is interrupted, the time can be set to zero.

Parameter: Monitoring duration

- Default setting **(_:104) Monitoring duration** = *200.00 s*

With the parameter **Monitoring duration** , you define how long the current signal is monitored regarding restriking after the circuit breaker has been opened.

With ongoing discharging of the capacitor bank, the probability of restriking is decreasing. There is no need to set the monitoring time longer than the discharging time. Siemens recommends setting the monitoring time in the range of 0.5 * discharging time to 1 * discharging time.

Parameter: Threshold

- Default setting **(_:3) Threshold** = *0.250 A*

After opening of the circuit breaker, the phase currents are compared with the threshold value. If no restriking takes place, the current is zero. Consequently the threshold for detecting restriking can be set much smaller than the operating current. A typical value is 25 % of the operating current.

With a threshold below the operating current, a falsely-given start directly cause tripping. For minimizing this risk, Siemens recommends applying a release criterion additionally. Refer to *Parameter: Switch On or Off Additional Plausibility Release Criteria , Page 1712*.

Parameter: Dropout delay

- Default setting **(_:7) Dropout delay** = *0.05 s*

The parameter **Dropout delay** ensures that a short dropping below the current threshold does not cause the operate delay timers to be reset.

Since restriking is normally a periodical effect, the dropout delay can be set to a rather small time. Siemens recommends applying the default value of 50 ms.

Input signal: *>CB defect*

The input signal *>CB defect* has a preset filtering time of 20 ms. This filtering time prevents the input signal from becoming effective in the case of a transient activation of the physical binary input, which can be caused by the pressure change when the circuit breaker opens.

This time can be set to 0 if such a transient response of the physical binary input can be excluded due to the circuit-breaker design.

Parameter: Retrip after T1

- Default setting **(_:106) Retrip after T1** = *start T2 after T1*

Parameter Value	Description
start T2 after T1	The retrip on the local circuit breaker is a safety mechanism to avoid false tripping of the superordinated circuit breaker. With generating a retrip, only the local circuit breaker is tripped in the event of a false start. Afterwards the **Circuit-breaker restrike protection** function drops out during the T2 delay time. Siemens recommends applying a retrip on the local circuit breaker. Siemens also recommends applying the parameter value ***start T2 after T1***. The parameter value provides a clear chronological separation of the processes for trip repeat and backup tripping. Remember that the overall fault-clearance time in case of circuit-breaker restriking is the sum of T1 and T2.
no	No retrip is given
parallel start T2, T1	As an alternative to the setting ***parallel start T2, T1*** the customer can start T2 and T1 in parallel.

Parameter: **Delay T1 for 3-pole retrip**

- Default setting (_:109) **Delay T1 for 3-pole retrip** = ***0.00 s***

The parameter is visible only when the parameter **Retrip after T1** is set to ***start T2 after T1*** or ***parallel start T2, T1*** .

The retrip on the local circuit breaker is as a safety mechanism to avoid false tripping of the superordinated circuit breaker. In the event of a false start, only the local circuit breaker is tripped by the retrip. Afterwards the **Circuit-breaker restrike protection** function will drop out during the T2 delay time.

Siemens recommends applying a retrip on the local circuit breaker. Since the retrip is a safety mechanism, it can be given without a delay time. Siemens recommends setting the delay time to 0 s.

Parameter: **Delay T2 for 3-pole trip**

- Default setting (_:110) **Delay T2 for 3-pole trip** = ***0.15 s***

This parameter defines the duration of restriking after the backup tripping is sent. The following should be considered:

- When using the retrip functionality, this delay time must ensure a safe function dropout after giving the retrip on the local circuit breaker.

Siemens recommends applying a delay time of 150 ms which is the default setting.

Parameter: **Minimum operate time**

- Default setting **(_:109) Minimum operate time** = ***0.15 s***

The **Minimum operate time** parameter is used to set the minimum duration for the trip command of the function.

CAUTION

Do not set a time that is too short.

If you set a time that is too short, there is a danger (dropout of the function without the current-flow criterion) that the device contacts interrupt the control circuit. If this happens, the device contacts burn out.

✧ Set a duration that is long enough to ensure that the circuit breaker reliably reaches its final position (**open**) after a control operation.

Output signal: *Retrip T1*

The output signal *Retrip T1* must be routed to a binary output.

If only one control circuit is available for the local circuit breaker, the output signal must be routed to the binary output to which the general circuit breaker trip command (command *Position*) is routed.

If a second control circuit is present, the *Retrip T1* output signal can be routed to the associated binary output.

Output signal: *Trip T2*

In order to trip the adjacent circuit breakers, the backup tripping (indication *Trip T2*) must be routed to a binary output and if necessary, to an interface (intertripping to the opposite end). Thus, the circuit breaker on the opposite end can be tripped without delay.

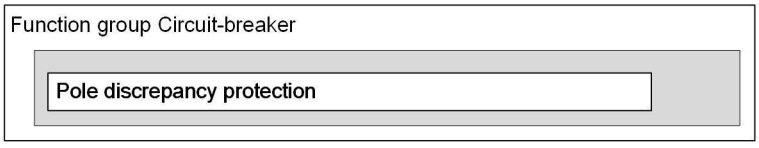
6.64 Pole Discrepancy Protection

6.64.1 Overview of Functions

Due to the high probability of 1-phase short circuits in power systems, 1-pole tripping and automatic reclosing is used mainly in transmission to ensure the reliable and stable operation of the system. However, this brings about new problems, that is, open-phase operation adds certain risks to the power system.



Therefore, a function that can reflect open-phase operation conditions of CBs must be installed to open those CBs in abnormal status. Siemens develops the function block **Pole discrepancy protection** for this purpose.

The function block **Pole discrepancy protection** has the task to detect discrepancies in the position of the 3 circuit-breaker poles. Under steady-state operating conditions, either all 3 poles of the circuit breaker must be closed, or all 3 poles must be open. Discrepancy is permitted only for a short time interval during a 1-pole automatic reclose cycle.

6.64.2 Structure of the Function

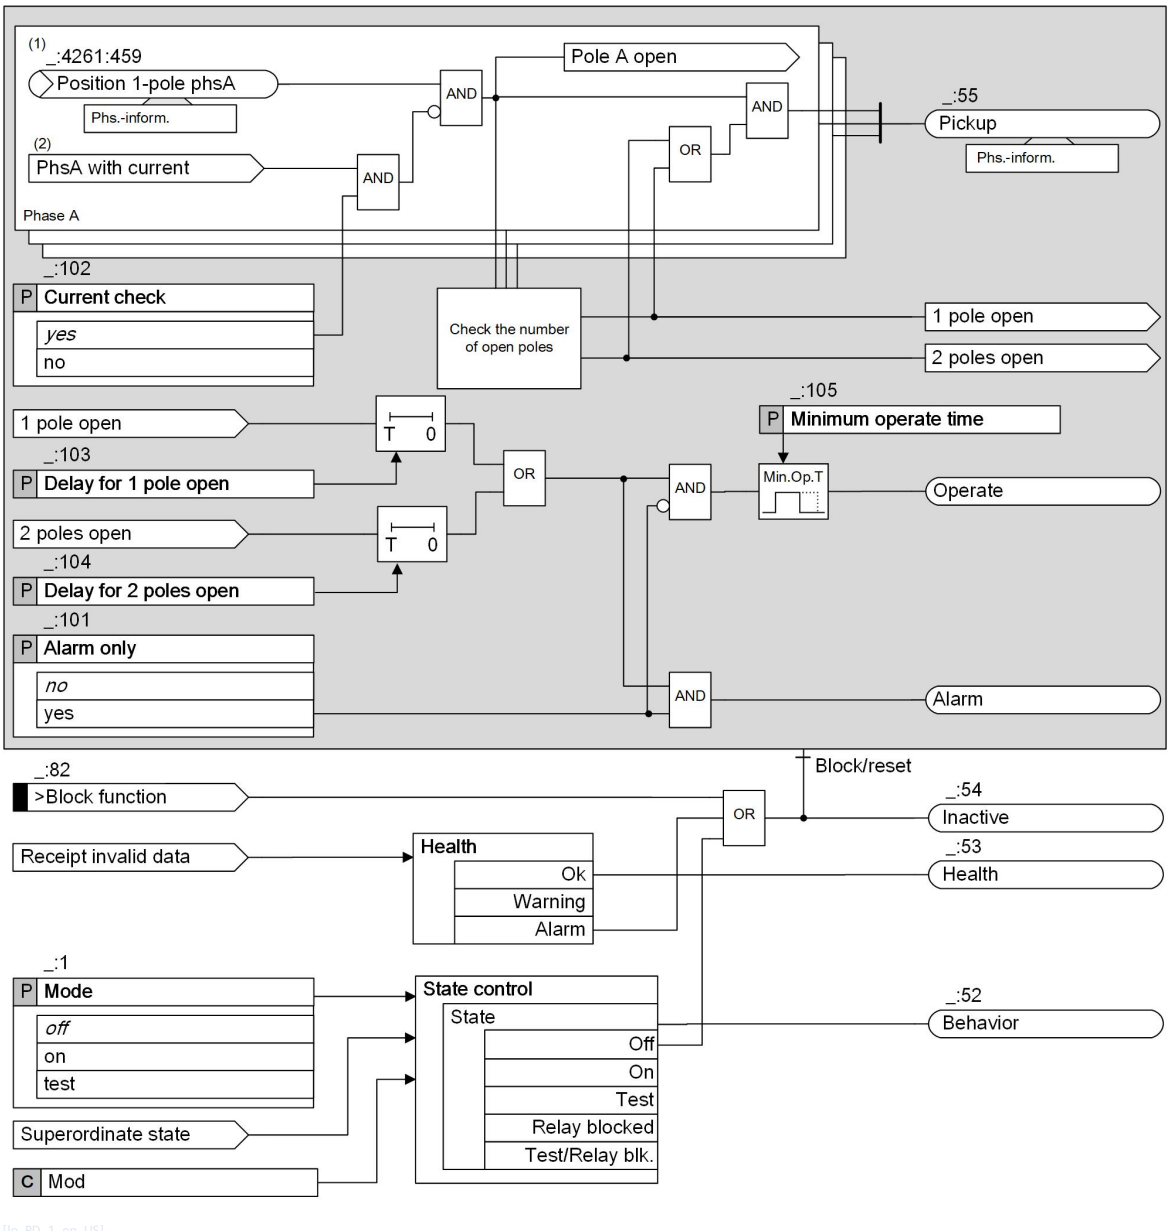
In DIGSI 5, you can find the function block **Pole discrepancy protection** under the directory **Global DIGSI 5 libraries** > **FG Circuit breaker**.

You can instantiate 1 function block **Pole discrepancy protection** in the function group .

[dw_structure_PD, 1, en_US]

Figure 6-651 Structure/Embedding of the Function Block

6.64.3 Description



Routing 1-Pole Positions

With the following CB signals routed, the function block **Pole discrepancy protection** can obtain positions of the phase-selective CB auxiliary contacts:

- Position 1-pole phsA
- Position 1-pole phsB
- Position 1-pole phsC

If any of the signals is not routed, *Health* of the function block **Pole discrepancy protection** is set to ***Alarm***.

Logic

[lo_PD, 1, en_US]

Figure 6-652 Logic Diagram of the Function Block Pole Discrepancy Protection

(1) From FB Circuit breaker

(2) From FB CB position recognition

Positions of the CB Poles

There a 2 ways to get the positions of the poles:

- With current check
  The function block **Circuit-breaker position recognition** calculates the positions of the CB poles from the evaluation of the CB auxiliary contacts and the current flow.
  If you want to take the current flow into consideration in the function block **Pole discrepancy protection**, you can set the parameter **Current check** to ***yes***. Then, the function block **Pole discrepancy protection** reuses the results of the function block **Circuit-breaker position recognition**.
  For more information, refer to *5.9.8 Circuit-Breaker Position Recognition for Protection-Related Auxiliary Functions*.
- Without current check
  If you set the parameter **Current check** to ***no***, then, the current flow is not considered and the function block **Pole discrepancy protection** gets the positions of the CB poles from the function block **Circuit breaker**.

Current-Flow Criterion

For each phase, the internal signal **PhaseX with current** comes from the function block **Circuit-breaker position recognition**. When the phase current exceeds the parameter **Current thresh. CB open**, the value of the corresponding signal **PhaseX with current** is ***true***.

Pickup

Whenever a pole discrepancy is detected, the function block **Pole discrepancy protection** issues the signal *Pickup*.

Tripping

If you want the function block **Pole discrepancy protection** to trip the circuit breaker, set the parameter **Alarm only** to ***no***. Then, when a 1-pole-open discrepancy or a 2-pole-open discrepancy is detected, the function block **Pole discrepancy protection** issues the signal *Operate*.
The signal *Operate* can block the function **Automatic reclosing**.

Fault Recording and Fault Logging

If you enable the function block **Pole discrepancy protection**, once the signal *Operate* is issued, the fault recording and fault logging are triggered.

Blocking of the Function Block

In the event of blocking, the function is reset. Blocking is possible externally or internally via the binary input signal *>Block function*.

6.64.4 Application and Setting Notes

Parameter: Alarm only

- Default setting **(_:101) Alarm only** = ***no***

With the parameter **Alarm only**, you can decide to trip the circuit breaker or not.
With the default value ***no***, after pickup, once the time delay expires, the signal *Operate* is issued.

Parameter: Current check

- Default setting **(_:102) Current check** = ***yes***

With the parameter **Current check**, you can decide to take the current flow into consideration or not. For more information, refer to *Positions of the CB Poles, Page 1719*.

Siemens recommends keeping the default setting to ensure precise positions.

Parameters: `Delay for 1 pole open`, `Delay for 2 poles open`

- Default setting **`(_:103) Delay for 1 pole open`** = ***`2.00 s`***
- Default setting **`(_:104) Delay for 2 poles open`** = ***`2.00 s`***

With these parameters, you can determine the minimum time delay for operating the function block **Pole discrepancy protection**.
If you enable the function **Automatic reclosing**, set these parameters larger than the parameter **`Dead time aft. 1-pole trip`**.

Parameter: `Minimum operate time`

- Default setting **`(_:105) Minimum operate time`** = ***`0.12 s`***

With the parameter **`Minimum operate time`**, you set the minimum duration for the trip command of the function block **Pole discrepancy protection**.

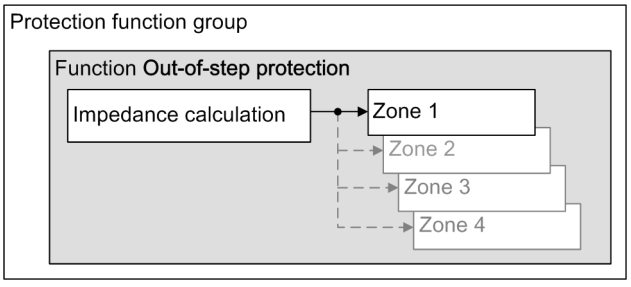
6.65 Out-of-Step Protection

6.65.1 Overview of Functions



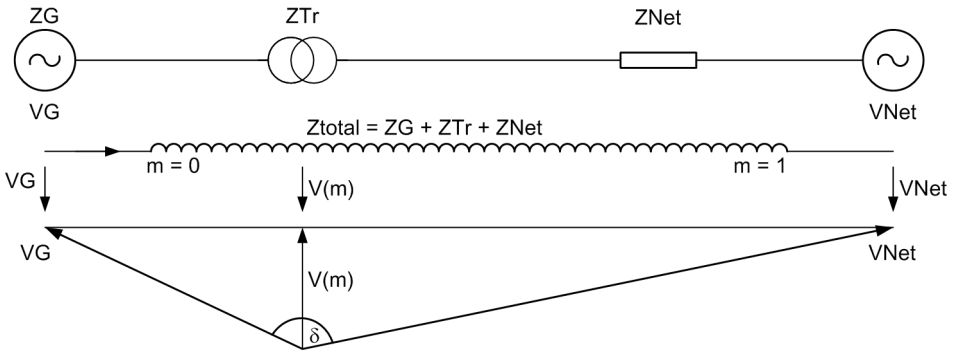
The **Out-of-step protection** function (ANSI 78)

- Detects an out-of-step condition (asynchronous operation) between machines connected and the power system and between power systems
- Protects generators from unacceptable electromechanical stresses
- Prevents damage and unacceptable aging of equipment
- Ensures the stability of the entire power system by disconnection
- Suitable for integration into more complex automatic operations for power system monitoring and disconnection
- Serves as a basic function for the protection of larger power plant units
- Used in the protection of power systems for selective disconnection in case of power swings

6.65.2 Structure of the Function

The **Out-of-step protection** function is preconfigured with one zone by the manufacturer. A maximum of 4 zones can be operated simultaneously in the function (see *Figure 6-653*). All zones are configured identically.

The **Out-of-step protection** function is contained in a function group with at least 3 voltage inputs and current inputs. The process monitor provides the function with status information regarding the protected object (open poles on the line in particular). The protected object can be a line or a power plant unit (generator with generator transformer).



[dwoosstr-190912-01.tif, 1, en_US]

Figure 6-653 Structure of the Function

6.65.3 Description of a Zone

Measuring Principle of the Out-Of-Step Protection

Out-of-step protection is based on measuring the impedance and analyzing the history of the impedance phasor. The simplified 2-machines model shown in the following figure is used for that purpose. The left side of the figure shows the generator with a driving voltage V_G. The impedances - generator impedance Z_G, transformer impedance Z_{Tr}, and system impedance Z_N – are located between the 2 sources. The power system with a voltage V_{Net} can be found as a backup machine on the right side.

[dwmodlpe-230211-01.tif, 1, en_US]

Figure 6-654 The 2-Machines Model to Explain a Power Swing

Measuring point m divides the total impedance into 2 impedances m· Z_{total} and (1-m)· Z_{total}. The following details apply to the impedance at a measuring point m:

$$\underline{Z}(m) = \frac{\underline{V}(m)}{\underline{I}(m)}$$

[foimpdnz-170309-01.tif, 1, en_US]

Current I does not depend on the measuring point m:

$$\underline{I}(m) = \underline{I} = \frac{\underline{V}_G - \underline{V}_{Net}}{\underline{Z}_{total}}$$

[fostroms-170309-01.tif, 1, en_US]

Voltage V at the measuring point m is calculated for:

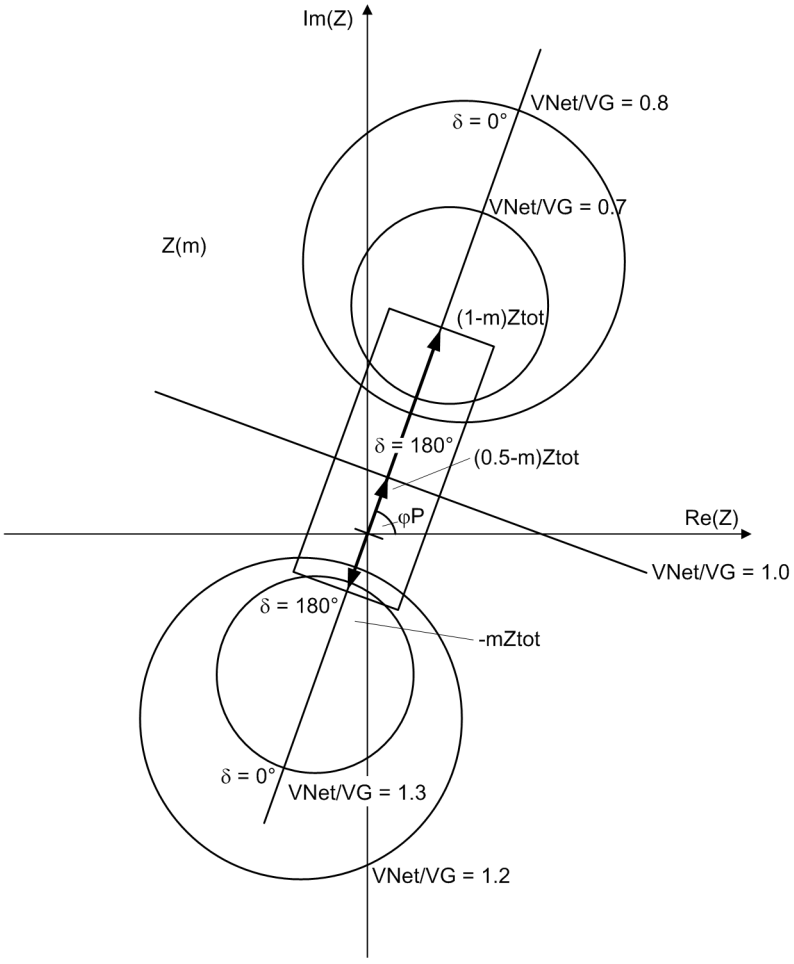
$$\underline{V}(m) = \underline{V}_G - (m \cdot \underline{Z}_{total} \cdot \underline{I})$$

[fospanng-170309-01.tif, 1, en_US]

In combination with

$$\underline{V}_G = V_G \cdot e^{j\delta_G} \qquad \underline{V}_{Net} = V_{Net} \cdot e^{j\delta_N} \qquad \delta = \delta_G - \delta_{Net}$$

[foumesor-170309-01.tif, 1, en_US]



the data results in the formula:

$$\underline{Z}(m) = \left[\frac{1}{1 - \frac{V_{Net}}{V_G} \cdot e^{-j\delta}} - m \right] \cdot \underline{Z}_{total}$$

[fozmesrt-170309-01.tif, 1, en_US]

Angle δ is the angle between the generator voltage and the power system voltage. In normal operation, this angle depends on the load profile and is relatively constant. In contrast, in the event of an out-of-step condition, the angle changes continuously and passes through all values between 0° and 360°. *Figure 6-655* shows the impedance process at the measuring point m according to the equation mentioned above. The point of origin corresponds to the point where the protection device is built in (measuring point of the voltage-transformer substitute). Assuming a constant ratio between V_{Net}/V_G and a variable angle δ, the locus diagram is a set of circles. The center and the radius are specified through the ratio V_{Net}/V_G. All centers of the circles are located on one axis specified by the direction of Z_{total}. The maximum and minimum impedance values are the result for the 2 extreme values δ = 0° and δ = 180°. If the measuring point coincides directly

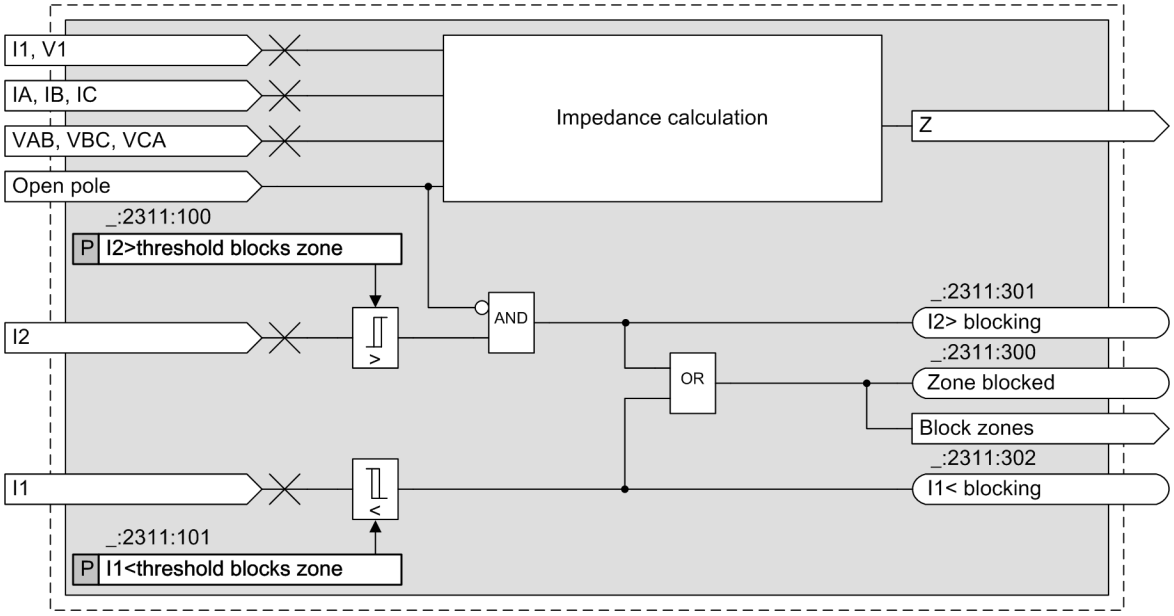
with the electrical center of the system, the measured voltage and thus the operating impedance result in 0 at an angle δ = 180°.

[dwzverla-230211-01.tif, 1, en_US]

Figure 6-655 Impedance Trajectories for Different Voltage Conditions

Impedance Method of Measurement

The fundamental components are determined from the phase-to-ground voltages and the phase currents and are the basis for calculating the phasors of the positive sequence system. The phasors of the positive-sequence system are the basis for calculating the impedance.



Special cases:

- If an unbalanced fault occurs during swinging, the zone (zones) is/are frozen.
- If an open circuit-breaker pole is detected, the loop resistance of a healthy loop is calculated temporarily.

Out-of-step detection works when the positive-sequence current flow is high enough. If the flow falls below the adjustable positive-sequence current threshold **`I1<threshold blocks zone`**, the zone (zones) is/are frozen.

Behavior in the Event of Unbalanced Faults

To avoid overfunctioning of the Out-of-step protection in the event of unbalanced faults (for example, short-circuits), the negative-sequence current is evaluated. If the negative-sequence current exceeds the pickup threshold **`I2>threshold blocks zone`**, the zones for the detection of an out-of-step condition are blocked. *Figure 6-656* shows the partial logic and the input variables for the impedance calculation.

[lo0imped-100611-01.tif, 2, en_US]

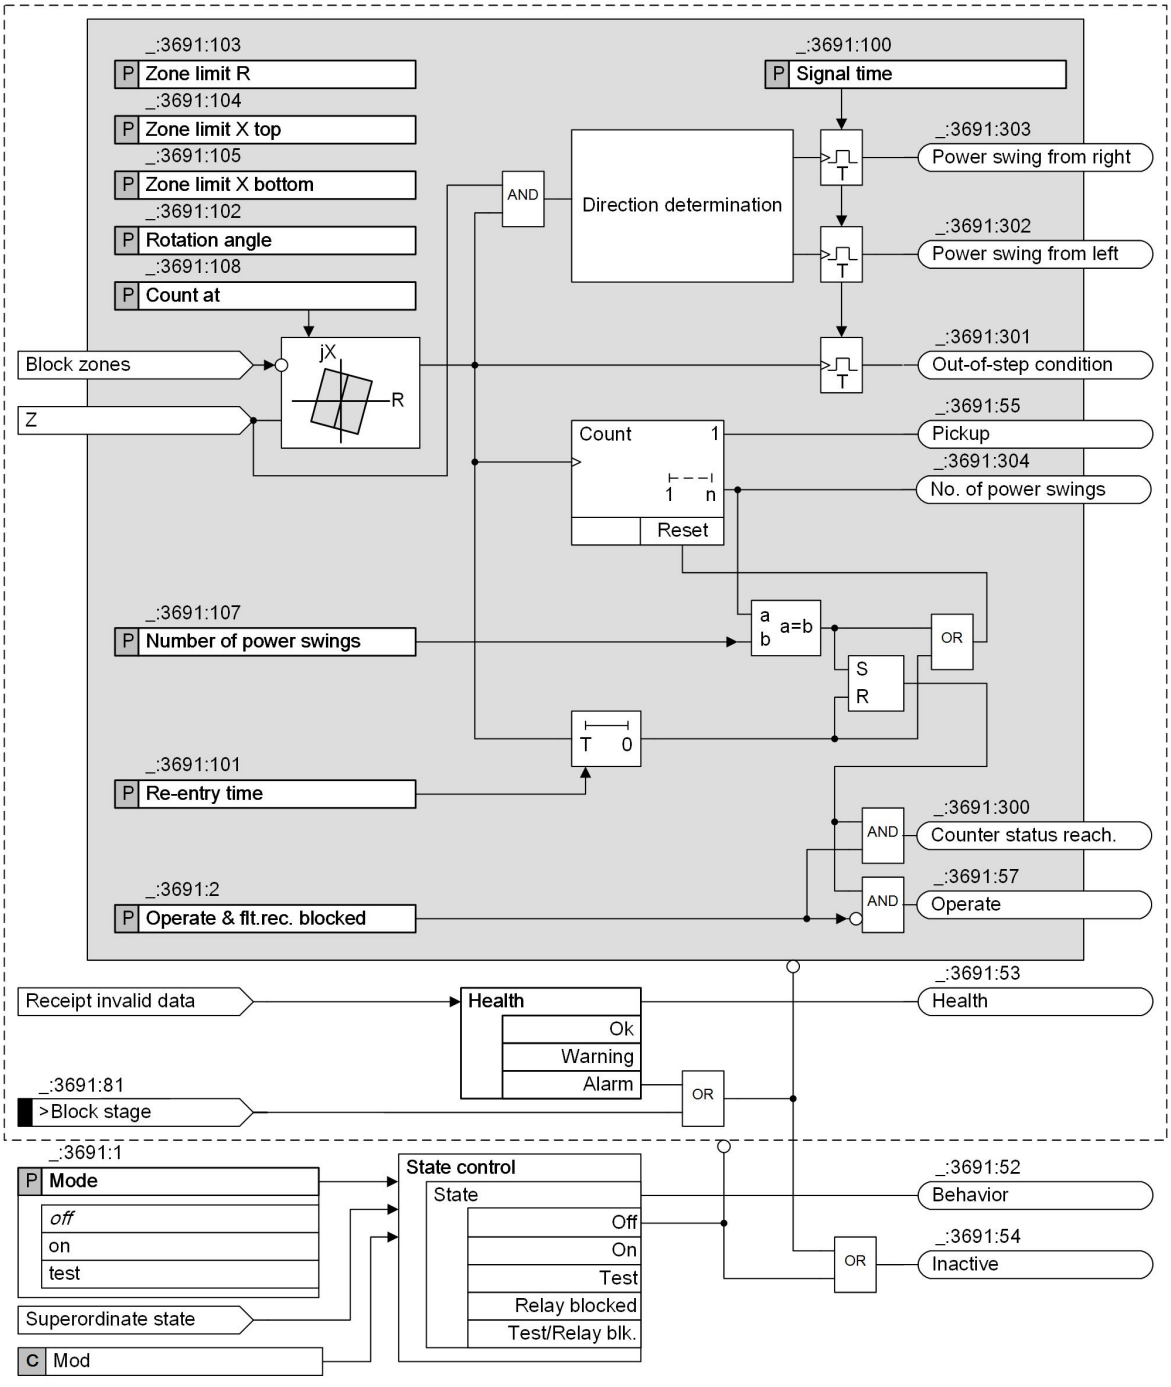


Figure 6-656 Impedance Measurement and Monitoring of the Positive and Negative Sequenced of the Currents

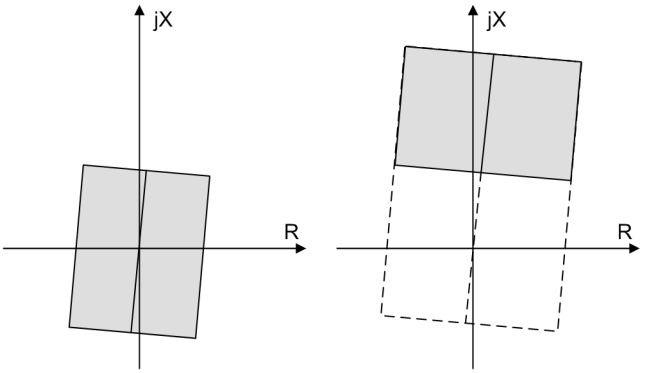
Identifying the Out-of-Step Condition/Central Logic

Figure 6-657 shows the central logic. Cycling of the positive-sequence impedance phasor through the set impedance zone is monitored and counted. The power swing counter is incremented depending on the setting of the parameter **(_:3691:108) Count at**. Each counter increment is signaled. The signal duration can be set via the **(_:3691:100) Signal time** parameter. The trip command is issued when the counter status (parameter **(_:3691:107) Number of power swings**) is reached after incrementing. Between each counter increment, the function checks whether another power swing occurs within a specified time (parameter **(_:3691:101) Re-entry time**). If this is not the case, the counter is reset. The central logic detects the direction of the power swing and issues an indication. In generator mode, for example, the impedance swings into the zone from the right.

NOTE

If the impedance phasor enters through the straight lines, which can be set using the parameters **Zone limit X top** or **Zone limit X bottom**, the power swing direction is not determined. Since the direction determination is coordinated with the setting parameter **Count at**, the above limitation applies only to the setting ***entry***, ***entry left*** and ***entry right***.



[lo_ost_zon, 2, en_US]

Figure 6-657 Logic Diagram of a Zone

Impedance Zone (Characteristic Curve)

An impedance phasor within the impedance zone is the essential criterion for the out-of-step condition. In order to implement different applications, resistance and reactance are freely settable. The resistance setting parameter **`Zone limit R`** works inversely to the imaginary axis. A lower and an upper setting value (**`Zone limit X bottom`** and **`Zone limit X top`**) can be selected for reactance. The zone can be shifted in any X direction. *Figure 6-658* shows 2 possible setting examples. To map the power system impedance (R, jX), the zone can also be rotated through an angle **`Rotation angle`**. If several zones are used in power system protection applications, they are typically interleaved.

[dwzonein-230211-01.tif, 1, en_US]

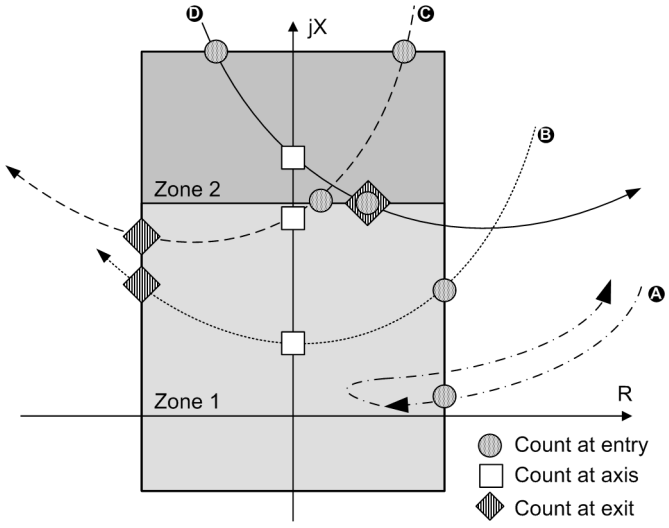
Figure 6-658 Zone Setting

Power-Swing Counter

Passing though the impedance zone is the criterion for incrementing the power swing counter. Use the setting parameter (**Count at**) to define when the counter is incremented. Depending on the application, there are different selection options available for this parameter. For machine protection applications, you only see 3 selection options without direction dependency.

entry	The counter is incremented upon entry into the zone.
entry left	The counter is incremented upon entry into the zone from the left.
entry right	The counter is incremented upon entry into the zone from the right.
axis	The counter is incremented upon crossing the middle ordinate of the zone.
axis from left	The counter is incremented upon crossing the middle ordinate of the zone from the left.
axis from right	The counter is incremented upon crossing the middle ordinate of the zone from the right.
exit	The counter is incremented upon exit of the zone.
exit left	The counter is incremented upon exiting the zone from the left.
exit right	The counter is incremented upon exiting the zone from the right.
	In all cases, the impedance phasor must first have crossed the entry line and the middle ordinate.

Figure 6-659 shows how counting is done for the different trajectories of the impedance phasor. 2 zones are shown as an example. Each zone has a counter of its own.



4 cases are shown:

Case A: The counter for zone 1 is incremented only if ***entry*** or ***entry right*** is set for zone 1.

Case B: The counter for zone 1 is incremented. The time at which the increment takes place depends on the settings (***entry***, ***entry right***, ***axis***, ***axis from right***, ***exit***, ***exit left***).

Case C: The counter for zone 2 is incremented only if ***entry*** or ***entry right*** is set for zone 2. The counter for zone 1 is incremented. The time at which the increment takes place depends on the settings (***entry***, ***entry right***, ***axis***, ***axis from right***, ***exit***, ***exit left***).

Case D: The counter for zone 1 is incremented only if ***entry*** or ***entry right*** is set for zone 1. The counter for zone 2 is incremented. The time at which the increment takes place depends on the settings (***entry***, ***entry left***, ***axis***, ***axis from left***, ***exit***, ***exit right***).

Figure 6-659 Incrementing the Power Swing Counter for Different Impedance Phasor Trajectories

6.65.4 Application and Setting Notes (System Protection)

The protection setting is exemplified by a power-system configuration. If a power swing occurs in the power system, the out-of-step protection must separate the power system into islands. Each system island must be able to establish a stable operating state. Although a certain amount of load shedding must be taken into account, the aim is to minimize power loss. *Figure 6-660* shows the power-system configuration used in the example.

[dwbspnet-210211-01.tif, 1, en_US]

Figure 6-660 Power-System Configuration

If an asynchronous swing condition occurs, the out-of-step protection function separates the 2 systems A and C from each other. To allow the subnetwork with power reserve to remain connected to the busbar (and the local load), either the lines A1 and A2 or the lines C1 and C2 must be disconnected from the busbar, depending on the direction of the impedance curve. This ensures that the infeeding side remains connected with the busbar and the local load.

Focus of the Example

In the example (*Figure 6-660*), the setting values for relay A are determined. All information and calculations in this section are therefore based on relay A. Out-of-step tripping by this relay is also passed to the circuit breakers for lines A1 and A2, since both lines must be disconnected if an out-of-step condition occurs. Similarly, relay C affects the circuit breakers for lines C1 and C2. Since the out-of-step impedance measurement in relay A is also affected by the power flows in line A2, 2 separate setting values are determined for relay A. The appropriate setting characteristic is enabled depending on the switch position of the line A2 circuit breaker (**ON** or **OFF**).

The parameters for the 2 zones (zone 1 and 2) are shown below with reference to the operating state of line A2 (active or open). In practice, the corresponding zone must be blocked or enabled using the binary input (GOOSE). Settings that are the same for both zones are not described separately.

Blocking the Zone

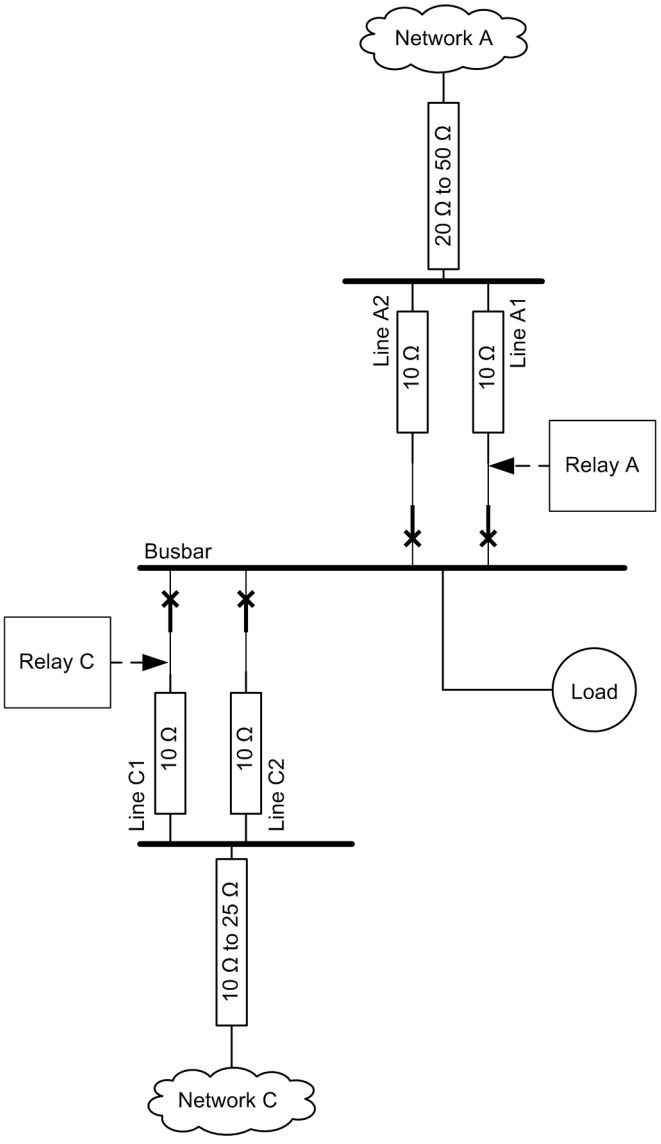
- Recommended setting value **(_:2311:100) I2>threshold blocks zone** = ***20*** **%**

Out-of-step tripping must be prevented in case of unbalanced faults and single open-pole conditions. To do so, the negative-sequence current threshold (parameter **I2>threshold blocks zone**) is set to ***20*** **%** (default setting).

If power-swing frequencies > 7 Hz are expected to occur, Siemens recommends increasing the setting value to 40 % to 45 %.

The setting value should not be set to be too sensitive in the case of a 1-pole AREC. Check the possible negative-sequence current on the line to be protected if a pole on the adjacent line is open following a 1-pole AREC. As a result, a negative-sequence current flows on the healthy line (parallel line).

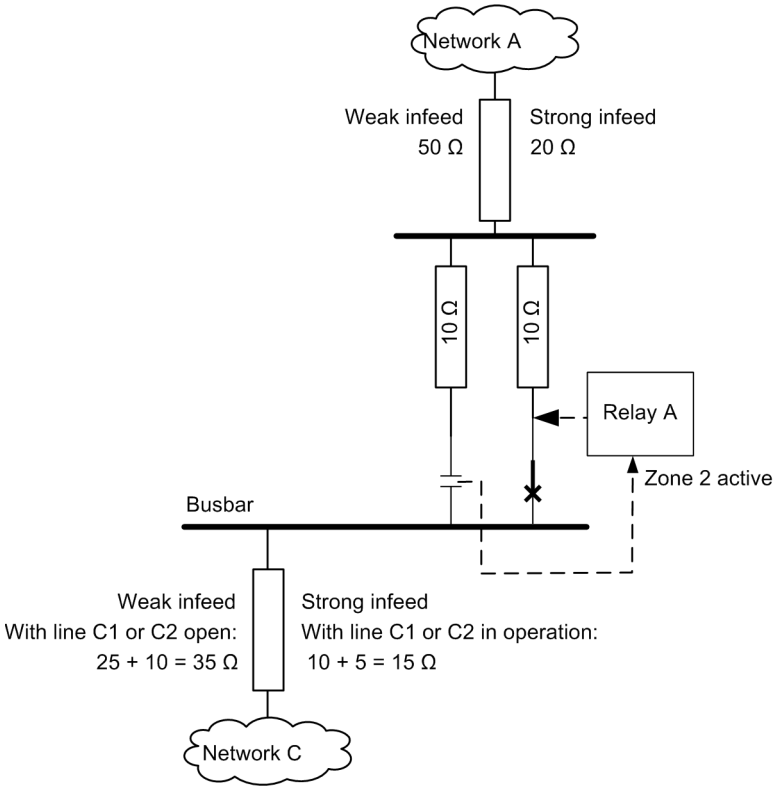
Zone Impedance Calculation



To set the zones, the **electrical center** of the power system, as seen from the relay, must be determined.

NOTE

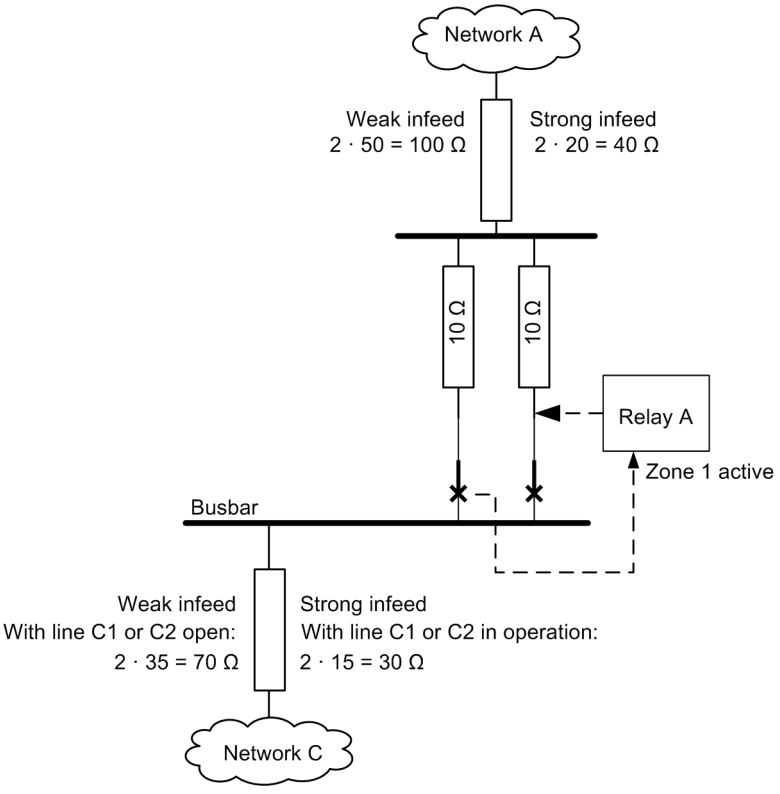
Note that the infeed conditions are not fixed to the sources and that the parallel line is not always available. Therefore, the electrical center of the power system is not located at a fixed point.



For setting the zone limit, you have to calculate the electrical center **active** and **open** using the maximum and minimum infeed and with parallel line. The source impedances of the infeeds and lines in *Figure 6-661* are specified for the purposes of the example. All impedance values are secondary values and are related to a secondary rated current of 1 A. Power system simulation tests are recommended in practice to determine the zone limits.

[dwvorimp-020211-01.tif, 1, en_US]

Figure 6-661 Source Impedances of Infeeds and Feeders



To determine the source impedances as seen from relay A, *Figure 6-661* is simplified as follows for the state = line A2 open (zone 2 active):

[dwvrimp2-020211-01.tif, 1, en_US]

Figure 6-662 Calculation of Source Impedances with Open Line A2 (Zone 2 Active)

The impedances of lines C1 and C2 and of infeed C are combined in *Figure 6-662*. Only one of the 2 lines is used for calculation in the case of a weak infeed (10 Ω); both are used in parallel for a strong infeed (5 Ω). Since the values for zone 2 are calculated with line A2 open here, simply add the impedance in the direction of power system A for strong infeed to the line impedance of 10 Ω and 25 Ω for weak infeed. The results for zone 2 are entered in *Table 6-24*.

[dwvorim1-020211-01.tif, 1, en_US]

Figure 6-663 Calculation of Source Impedances with Closed Line A2 (Zone 1 Active)

When line A2 is in operation, the current is split between lines A1 and A2. The impedance seen from Relay A is therefore doubled at the infeeds. *Figure 6-663* shows the relevant values for strong and weak infeed. The impedances for zone 1 are entered in *Table 6-24*. Zone 1 is effective when line A2 is active.

Table 6-24 Extreme Conditions: Extreme Conditions: Impedance, Seen from Relay A

Condition	Activated Zone in Relay A	Line A2	Impedance / $\Omega_{secondary}$ In the direction of source A	Impedance / $\Omega_{secondary}$ In the direction of source C
Strong source power system A Weak source power system C	Zone 1	Active	50 Ω	70 Ω
	Zone 2	Open	30 Ω	35 Ω
Weak source power system A Strong source power system C	Zone 1	Active	110 Ω	30 Ω
	Zone 2	Open	60 Ω	15 Ω

The condition in which both sides provide a weak or strong source is not relevant for the determination of the outermost ends of the electrical center.

If one end shows a maximum source impedance and the other a minimum one, you obtain the outermost end of the electrical center. Use the following equation for calculation (shown for relay A):

$$Z_{Center_A} = Z_{Source_A} - \frac{Z_{Source_A} + Z_{Source_B}}{2}$$

[foeztrum-170309-01.tif, 1, en_US]

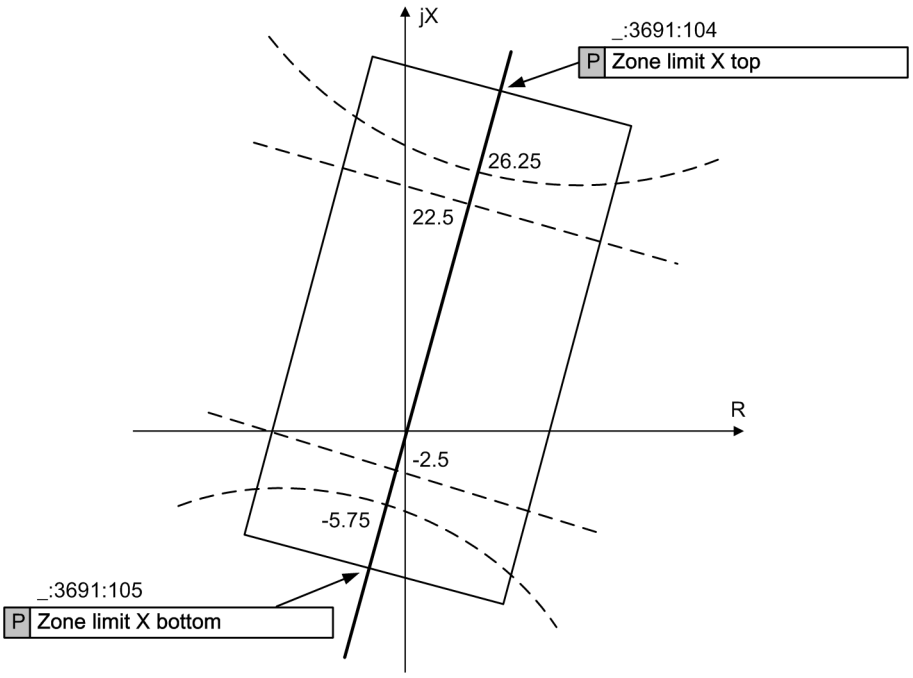
The results must be calculated separately for zone 2 and zone 1 according to the open or closed switch positions of infeed B. *Table 6-25* shows the electrical center, as seen from relay A.

Table 6-25 Calculation Results for the Electrical Center

Source Side A / $\Omega_{secondary}$	Source Side C / $\Omega_{secondary}$	Activated Zone in Relay A	Line A2	Electrical Center (Impedance, Seen from Relay A) / $\Omega_{secondary}$
50 Ω	70 Ω	Zone 1	Active	-10 Ω
30 Ω	35 Ω	Zone 2	Open	-2.5 Ω
110 Ω	30 Ω	Zone 1	Active	40 Ω
60 Ω	15 Ω	Zone 2	Open	22.5 Ω

If the 2 sources have different voltage levels, the power-swing impedance differs from the electrical center. This fact must be considered when determining the outermost ends of the electrical center:

$$Z_{deviation} = \frac{V_{max} - V_{min}}{V_{max} + V_{min}} \cdot Z_{total}$$



[fodvitio-170309-01.tif, 1, en_US]

Table 6-26 shows the results obtained for relay A.

Table 6-26 Impedance Deviation from Electrical Center

Z_{total} / $\Omega_{secondary}$	Activated Zone in Relay A	Line A2	Electrical Center (Seen from Relay A) / $\Omega_{secondary}$	Deviation with a Voltage Level Difference of 10 % / $\Omega_{secondary}$	Outer End of the Electrical Center / $\Omega_{secondary}$
50 + 70 Ω	Zone 1	Active	-10 Ω	-6 Ω	-16 Ω
30 + 35 Ω	Zone 2	Open	-2.5 Ω	-3.25 Ω	-5.75 Ω
110 + 30 Ω	Zone 1	Active	40 Ω	7 Ω	47 Ω
60 + 15 Ω	Zone 2	Open	22.5 Ω	3.75 Ω	26.25 Ω

Figure 6-664 shows the outer ends of the electrical center for relay A, zone 2 (line A2 is open), including the possible power-swing impedance locations.

[dwimpelo-070611-01.tif, 1, en_US]

Figure 6-664 Swing Impedance Locations and Outer Ends of the Electrical Center for Relay A (Line A2 is Open)

To ensure that the power swing zone in *Figure 6-664* covers the power swing trajectories, the upper and lower zone limits X are calculated as shown in the following formula. The calculated values reliably cover the determined outermost electrical centers in *Table 6-26*. The safety clearance is half the distance between the determined centers. Depending on the application, another formula can be used to satisfy the requirements placed on the geometry of the zone:

$$\text{Upper Zone Limit} = 26.25\ \Omega + \frac{26.25\ \Omega + 5.75\ \Omega}{2} = 42.25\ \Omega$$

$$\text{Lower Zone Limit} = -5.75\ \Omega - \frac{26.25\ \Omega + 5.75\ \Omega}{2} = -21.75\ \Omega$$

[foznengr-310111-01.tif, 1, en_US]

Table 6-27 shows the **zone limit X** setting for relay A based on this formula.

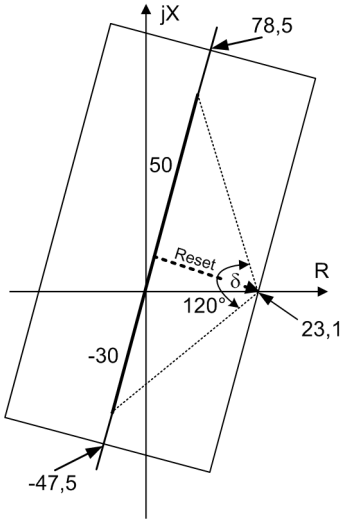
Table 6-27 jX Setting for the Zones

Activated Zone in Relay A	Line A2	Most Extreme Electrical Center, 1st Quadrant	Most Extreme Electrical Center, 3rd Quadrant	`Upper Zone Limit X`	`Lower Zone Limit X`
Zone 1	Active	47 Ω	-16 Ω	78.5 Ω	-47.5 Ω
Zone 2	Open	26.25 Ω	-5.75 Ω	42.25 Ω	-21.75 Ω

To determine the **`Zone limit R`**, the out-of-step tripping mode must be considered:

- If an out-of-step tripping on entry occurs, the R setting must equal the smallest value which occurs when the power swing reaches the transient stability limit angle.
- The R setting is less critical if the out-of-step condition trips when the axis of symmetry is exceeded. It can be set to the 0.9-fold minimum stable load impedance or to the 0.25-fold distance between the values of **Zone limit X**. Note that the circuit breaker is exposed to a very strong recovery voltage after switching.
- If an out-of-step tripping on exit occurs, the R setting depends on how long the trip command is to be present after the axis of symmetry has been exceeded (180°-condition). The calculation of the R setting can be based on the currently set swing locus angle.

In the example, tripping is to occur when the zone is entered. Therefore, you have to calculate the R setting using the transient stability limit angle δ. Based on the maximum transmission angle under stable operating conditions, the transient stability limit angle is calculated as follows:



Transient stability angle = 180 - maximum transmission angle.

A maximum transmission angle of 60° can be assumed in most cases. The result is a transient stability limit δ of 120°.

To ensure that the R setting is not too high, it must be determined on the basis of the minimum source impedances. The minimum source impedances (with closed/open line A2) or relay A are shown in *Table 6-28*.

Table 6-28 Calculated R Setting Values

Condition	Activated Zone in Relay A	Line A2	Impedance in the Direction of Source A	Impedance in the Direction of Source C	Zone Limit R Setting
Strong source A	Zone 1	Active	50 Ω	30 Ω	23.1 Ω
Strong source C	Zone 2	Open	30 Ω	15 Ω	13.0 Ω

[dwreinst-210211-01.tif, 1, en_US]

Figure 6-665 Calculation of the R Setting with Minimum Source Impedances (Line A2 Active, Zone 1)

$$R_{set.} = \frac{Z_{Source_A} + Z_{Source_C}}{2 \cdot \tan\left(\frac{\delta}{2}\right)}$$

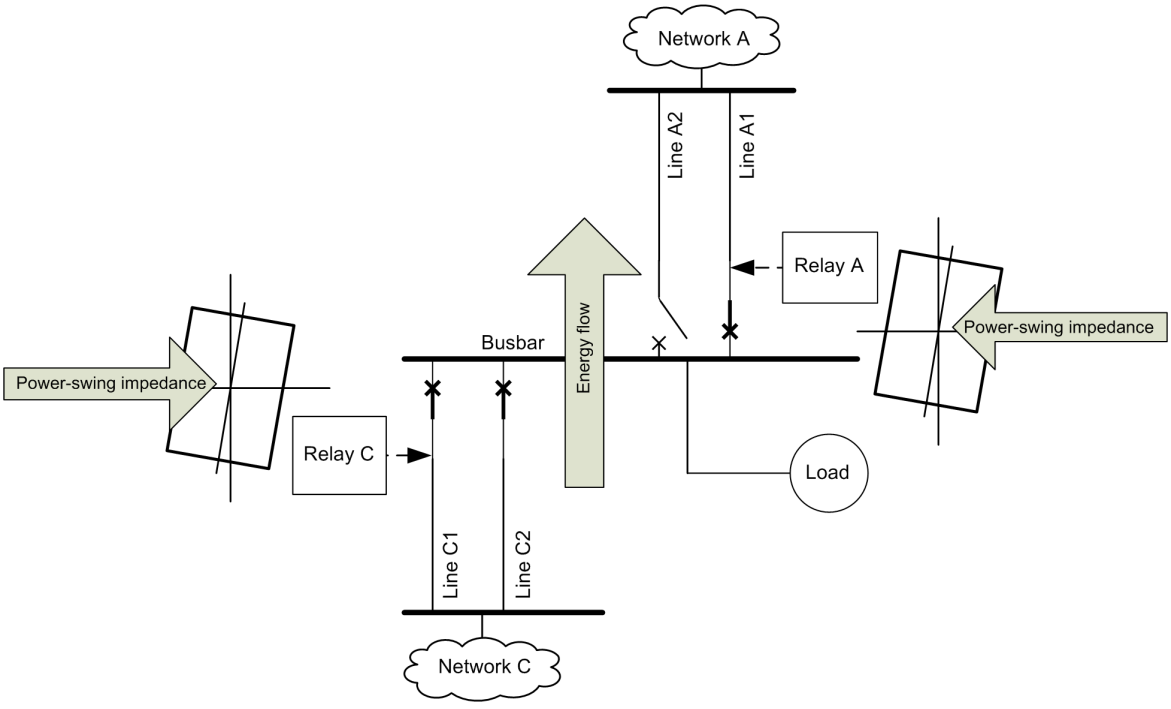
$$R_{set.} = \frac{50\,\Omega + 30\,\Omega}{2 \cdot \tan 60} = 23.1\,\Omega$$

[forfmel1-310111-01.tif, 1, en_US]

Determination of the Rotation Angle of the Characteristic

Not all impedances in the power system have the same angle. Set the rotation angle to the same value as the impedance angle of the total impedance between the 2 sources (sum of the impedances of power system A and C). This example uses the typical angle of 85° for transmission lines.

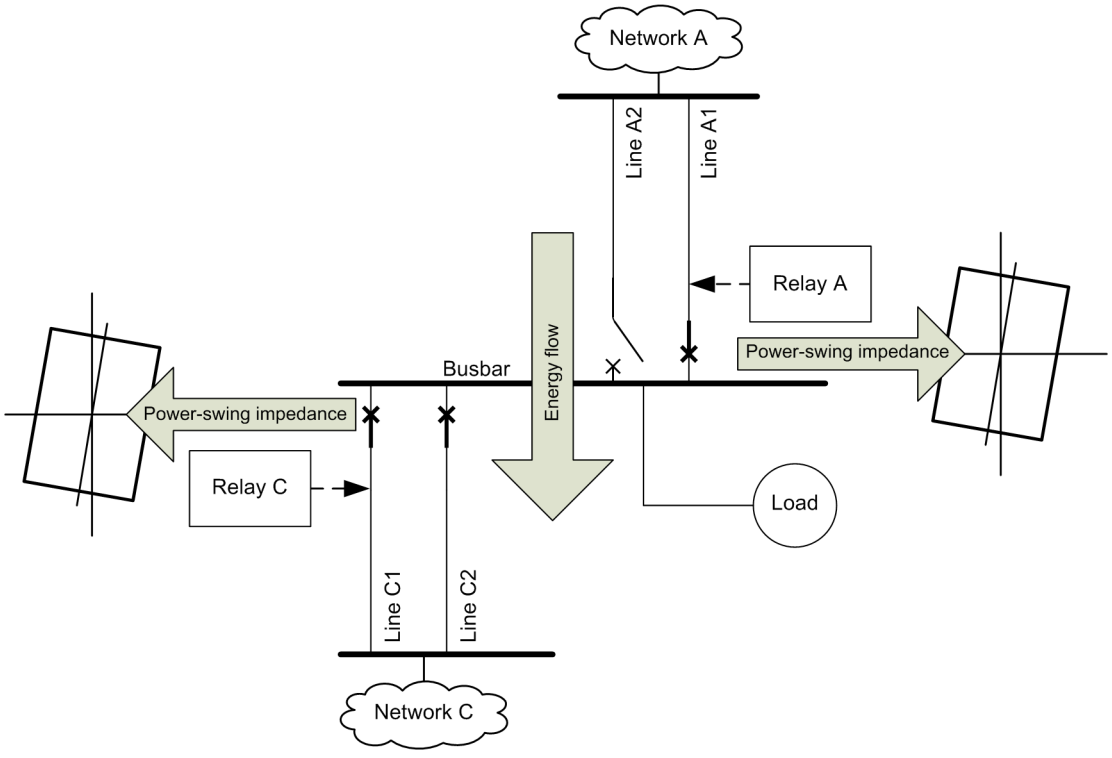
(_:3691:102) Rotation angle = ***85°***



Counting of Power Swings

In this application, power swing tripping is to take place immediately on entry. Therefore the number of power swings is set to 1:

(_:3691:107) Number of power swings = ***1***



Power swing tripping is to cause selective disconnection to keep the busbar connected to the infeeding power system. *Figure 6-666* and *Figure 6-667* show the swing impedance trajectory for relay C and A depending on the energy flow. Power swing tripping is to cause a selective disconnection of the power system that draws energy from the busbar. Therefore, power swing tripping takes places at entry from the right. In *Figure 6-666*, line A1 is disconnected from the busbar by relay A with swing tripping. Power system C remains connected to the busbar via lines C1 and C2 and feeds the load connected there.

(_:3691:108) Count at = ***entry right***

[dwenergc-020211-01.tif, 1, en_US]

Figure 6-666 Direction of the Swing Impedance Locus with Energy Transfer from Power System C to Power System A

[dwenerga-020211-01.tif, 1, en_US]

Figure 6-667 Direction of the Swing Impedance Locus with Energy Transfer from Power System A to Power System C

In *Figure 6-667*, the energy flows in the opposite direction. Out-of-step tripping must take place at lines C1 and C2. In this case, power system A remains connected to the local load of the busbar.

Setting the Time Function Elements

- Recommended setting value **(_:3691:101) Re-entry time** = ***20 s***

Use the **Re-entry time** parameter to define the resetting condition for the counter. If the counter was incremented and if there is no new swing cycle during the re-entry time, the swing counter is set back to 0. Assuming slow power swings of approx. 0.2 Hz (corresponds to a duration of 5 s), the setting value of 20 s offers sufficient safety.

- Recommended setting value **(_:3691:100) Signal time** = ***0.05 s***

Use the **Signal time** parameter to define how long a binary indication (incrementing or swing direction), is present, for instance at a contact. The time depends on the speed of subsequent evaluation units. A value between 50 ms and 100 ms is sufficient for fast further processing.

6.65.5 Settings

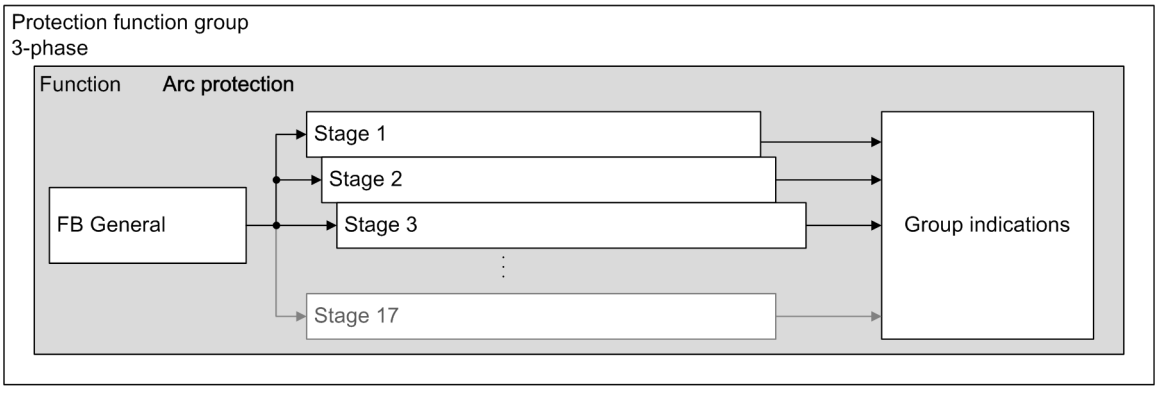
6.66 Arc Protection

6.66.1 Overview of Function

The function **Arc protection**:



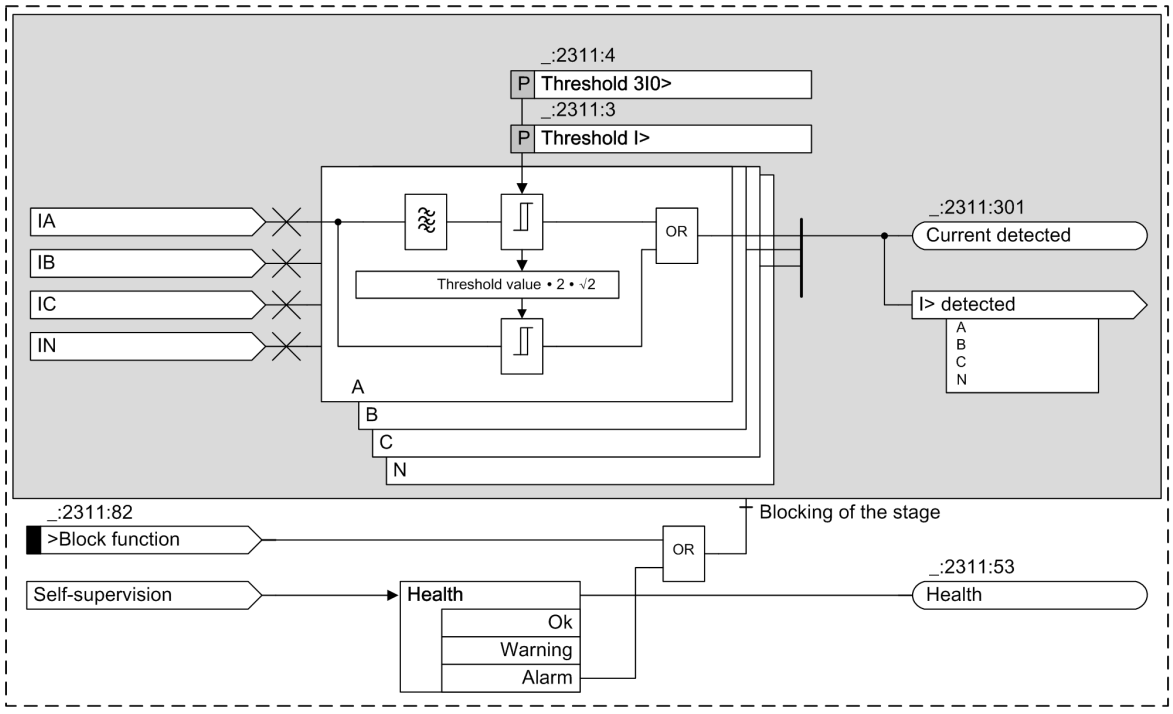
- Detects arcs in air-insulated switchgear parts without delay and in a fail-safe way
- Limits system damage through instantaneous high-speed tripping
- Protect systems from thermal overload
- Increases safety of personnel
- Trips in a 3-pole way
- Is suitable for use in all voltage levels

6.66.2 Structure of the Function

The **Arc protection** function can be added to function groups that provide current measured values.
The **Arc protection** function consists of the following blocks.

- General
- 3 stages
- Output logic 3-phase

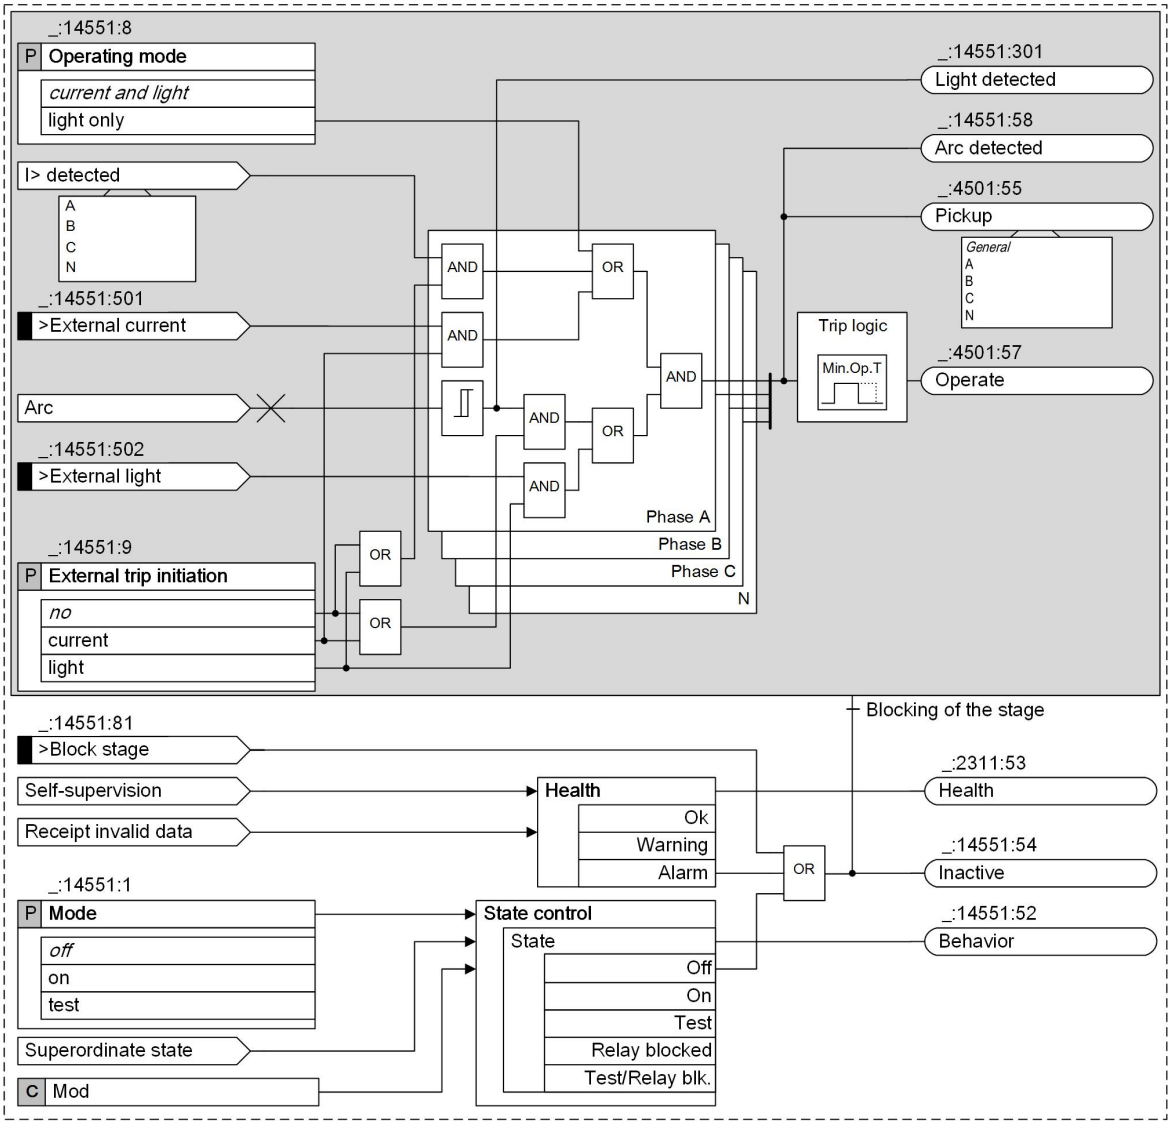
The **Arc protection** function is preconfigured with 3 stages. A maximum of 17 tripping stages can be operated simultaneously in the function. The tripping stages have an identical structure.
The following figure shows the basic structure of the **Arc protection** function.



{dw_structure_arcprot, 2, en_US}

Figure 6-668 Structure/Embedding of the Arc Protection Function

6.66.3 Function Description



General Logic of the Function Block

[lo_fb0_arcprot, 3, en_US]

Figure 6-669 General Logic Diagram of the Function Block

Logic of the Stage

[lo_stage_arcprotection, 2, en_US]

Figure 6-670 Logic Diagram of the Stage

The **Arc protection** function uses a locally connected optical arc sensor or an external trip initiation by other devices in order to detect arcs.

NOTE

Install the arc sensors inside the switchgear in such a way that they are not hidden behind other system components!

Shadowing of the arc sensors must be avoided!

NOTE

Once an optical sensor has detected an arc, you must replace the affected optical sensor!

Within the **Arc protection** function, you can use a fast current-flow criterion as an additional release criterion. The parameters for the current-flow criterion can be found in the **General** block. For each stage, you can select individually whether the current-flow criterion must be evaluated as well.

Method of Measurement, Current-Flow Criterion

The current-flow criterion works with 2 different methods of measurement:

- Measurement of the fundamental component:
  This method of measurement processes the sampled current values and filters out the fundamental component numerically. A direct-current component is thus eliminated. The RMS value of the fundamental component is compared with the set threshold value.
- Evaluation of the unfiltered measurand:
  If the current exceeds the threshold value set by the current ≥ 2 ·√2 · threshold value, the stage uses additional unfiltered measurands. Thus, very short operate times are possible.

NOTE

If using the current-flow criterion in addition to the light, prevent a potential overfunction caused by the suddenly occurring light signal.

If you use the current-flow criterion, arcs are typically detected in 4 ms!

Self Monitoring

The **Arc protection** function uses a self-monitoring circuit. This circuit monitors the optical arc sensors and the fiber-optic cables. The arc-protection module uses the fiber-optic cable to send a cyclic test signal (light) to the arc sensors. If the channel is operating properly, the test signal is sent back to the arc protection module. If the test signal is not returned to the arc protection module, the indication *channel # Sensor failure* is generated.

If the self-monitoring function detects a fault, the indication *Health* is set to *Alarm* and the stage/function is blocked.

6.66.4 Application and Setting Notes – General Settings

Go to **General** under the function **Arc protection** and set the following parameters. The setting values apply to all stages.

Parameter: Sensor supervision

- Default setting **(_:2311:2) Sensor supervision** = ***yes***

With the parameter **Sensor supervision**, you set whether you want to monitor the arc sensors or not.

Parameter: Threshold I>

- Default setting **(_:2311:3) Threshold I>** = ***2.000 A***

With the parameter **Threshold I>**, you define the trigger threshold of the phase currents. The **Threshold I>** is relevant for the current-flow criterion of the function **Arc protection**.

Set the **Threshold I>** of the function **Arc protection** in such a manner that the RMS value of the inrush current does not exceed the **Threshold I>** when activating the local circuit breaker.

For more information about how to calculate the setting value, refer to *6.23.4.2 Application and Setting Notes*.

Parameter: Threshold 3I0>

- Default setting **(_:2311:4) Threshold 3I0>** = ***1.000 A***

With the parameter **Threshold 3I0>**, you determine the tripping threshold for the zero-sequence current. The **Threshold 3I0>** is relevant for the current-flow criterion of the function **Arc protection**.

Set the **Threshold 3I0>** of the function **Arc protection** in such a manner that the RMS value of the inrush current does not exceed the **Threshold 3I0>** when activating the local circuit breaker.

For more information about how to calculate the setting value, refer to *6.24.4.2 Application and Setting Notes*

NOTE

If you set the parameter **CT connection** = ***3-phase, 2 primary CT*** for the **3-phase current measuring point**, the parameter **Threshold 3I0>** has no effect.

If you set the parameter **CT connection** = ***3-phase + IN*** for the **3-phase current measuring point**, the function works with the measured current IN.

If you set the parameter **CT connection** = ***3-phase + IN-separate*** for the **3-phase current measuring point**, the function works with the calculated current 3I0.

6.66.5 Application and Setting Notes for the Stage

Parameter: External trip initiation

- Default setting **(_:14551:9) External trip initiation** = ***no***

With the **External trip initiation** parameter, you set whether an external input signal is used to trigger the stage.

Parameter Value	Description
no	The stage does not operate with an external input signal.
current	The stage operates with an external input signal. If the stage operates with an external input signal, the binary input signal *>External current* must be routed in the DIGSI 5 information routing. In this setting option, the binary input signal *>External current* is only visible in the DIGSI 5 information routing
light	The stage operates with an external input signal. If the stage operates with an external input signal, the binary input signal *>External light* must be routed in the DIGSI 5 information routing. In this setting option, the binary input signal *>External light* is only visible in the DIGSI 5 information routing **Note**: When working with the ***light*** external trip initiation, do not select a channel. If an additional channel is selected with this setting value, the DIGSI 5 will signal an inconsistency.

Parameter: Operating mode

- Default setting **(_:14551:8) Operating mode** = ***current and light***

With the **Operating mode** parameter, you define the basic functionality of the stage.

Parameter Value	Description
current and light	The stage operates with the input variables current and light. The current-flow criterion ensures that the light signal originates from an arc. Siemens recommends using this setting value.
light only	This stage operates only with the input signal 'light' and is triggered even if current is not measured. This operating mode can cause a overfunction if light is detected suddenly. Use this setting value only if the effect caused by external light signals is impossible.

Parameter: Sensor

- Default setting **(_:14551:11) Sensor** = ***point sensor***

With the **Sensor** parameter, you set which sensor type is connected to the device.

Parameter Value	Description
point sensor	A point sensor is connected to the device.
line sensor	A line sensor is connected to the device.
custom	If you select this setting option, the parameter **Threshold light** is visible. Siemens recommends the default setting values ***point sensor*** or ***line sensor***. This allows arcs to be detected reliably regardless of diffused light.

Parameter: Threshold light

- Default setting **(_:14551:7) Threshold light** = ***-20.00 dB***

With the **Threshold light** parameter, you set the light sensitivity. If you set **Threshold light** to a smaller value, the sensitivity increases. If you set **Threshold light** to a higher value, the sensitivity decreases. If the sensors even pick up in case of a switching arc of the circuit breaker, set the **Threshold light** parameter to a higher value.

Siemens recommends the default settings for point or line sensors.

Set the parameter **Threshold light** manually only if you have special default settings for light sensitivity.

Parameter: Channel

- Default setting **(_:14551:10) Channel** = ***No channel is selected***

With the **Channel**parameter, you select which sensor channel the stage uses.

If the **Arc protection** function has several stages, a different channel must be selected for each stage.

For parameter **Channel**, the selection texts are identical to the name of the arc-protection module and its channels.

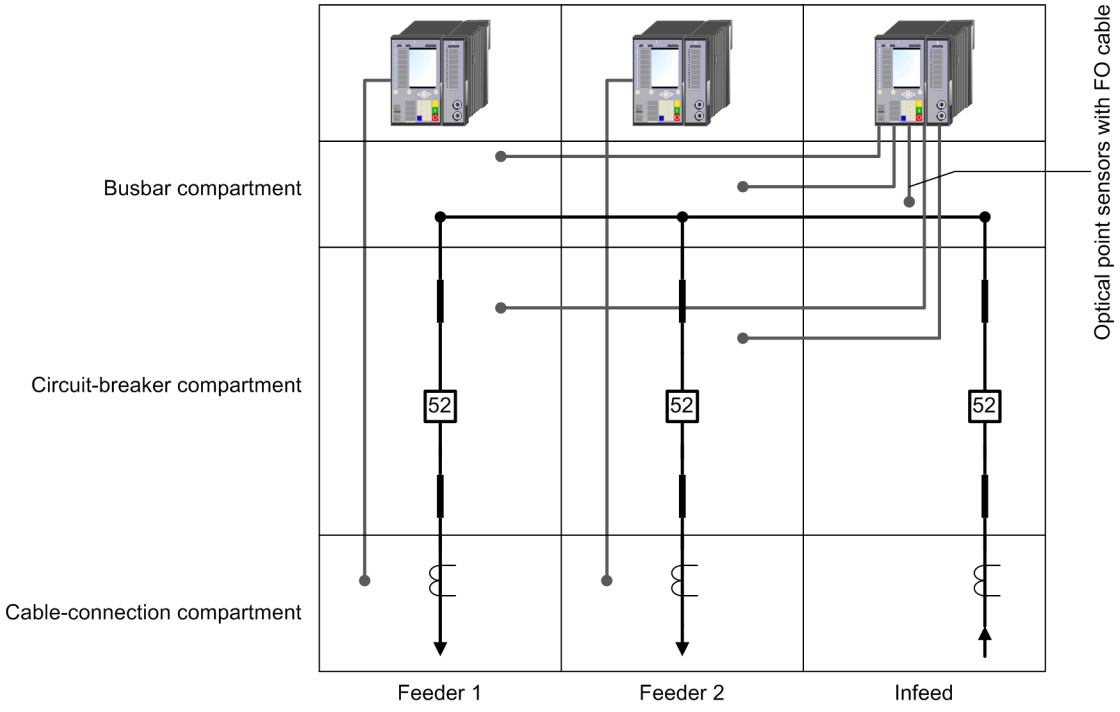
6.66.8 Application Example for Arc Protection with Point Sensors in Operating Mode: Light Only

6.66.8.1 Description



Overview

The example describes the **Arc protection** function in a medium-voltage switchgear with one infeed and 2 feeders. The **Arc protection** function operates with the **Operating mode** = ***light only***.

The following items are considered in the example below:

- Positioning the optical point sensors in the switchgear
- Connecting the optical point sensors to the protection devices in the feeders and the infeed
- Number of necessary stages of the functions in the protection devices of the feeders and the infeed
- Setting notes about the selected parameters in the stages of the function

The following figure shows the arrangement and the connection of the optical point sensors:

[dw_arcprot-light-only, 2, en_US]

Figure 6-671 Layout and Connection of the Optical Point Sensors (Operating Mode = Light only)

For this example, the following is assumed:

- The circuit breaker of the infeed must be switched off. This ensures that the arcs in the busbar compartments of the infeed and the feeders or in the circuit-breaker compartment of the feeders are off.

  Install the optical point sensors in the busbar compartments (BB compartment) of the infeed and feeders. Install additional optical point sensors in the circuit-breaker compartment (CB compartment) of the feeders. Connect all optical point sensors to the protection device of the infeed.
- The optical point sensors in the cable-connection compartment of the feeders detect arcs in this compartment. Install one optical point sensor in the cable-connection compartment of the feeders and connect it to the protection device of the feeder. This allows for the selective clearing of arcs inside the cable-connection compartment.

  Due to the pressure waves that occur during the formation of an arc, partitions can deform and cause undesirable light influences in adjacent compartments. This can result in a non-selective tripping.
- If there is an arc in the circuit-breaker compartment and in the cable-connection compartment of the infeed, the superordinate protection device must switch off.

NOTE

If the **Arc protection** function operates in **`Operating mode`** = ***`light only`***, the effects of external light can result in non-selective tripping.

NOTE

It must be considered that the number of arc protection modules connected to the device depends on the hardware configuration of the device.

When using modular devices, a maximum of 15 sensors can be connected. If using non-modular devices, a maximum of 6 sensors (3 sensors per module) can be connected.

6.66.8.2 Application and Setting Notes

General Notes

- Connect one optical point sensor from the cable-connection compartment in feeder 1 to the protection device in feeder 1. Arcs in the cable-connection compartment are cleared selectively by the circuit breaker in feeder 1.
- Connect one optical point sensor from the cable-connection compartment in feeder 2 to the protection device in feeder 2. Arcs in the cable-connection are cleared selectively by the circuit breaker in feeder 2.
- Connect optical point sensors from all busbar compartments and all circuit-breaker compartments of feeders 1 and 2 to the protection device in the infeed. Arcs in these compartments are detected and cleared by the device in the infeed.

Setting Notes for the Protection Device in Feeder 1

The **Arc protection** function operates with **one** stage.
Set the parameters of the stage as follows:

- Parameter: **Operating mode** = ***light only***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Channel** = ***Arc mod. 1 channel 1***

The parameters in block **General** are not relevant since the **Operating mode** = ***light only***.

Setting Notes for the Protection Device in Feeder 2

The **Arc protection** function operates with **one** stage.
Set the parameters of the stage as follows:

- Parameter: **Operating mode** = ***light only***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Channel** = ***Arc mod. 1 channel 1***

The parameters in block **General** are not relevant since the **Operating mode** = ***light only***.

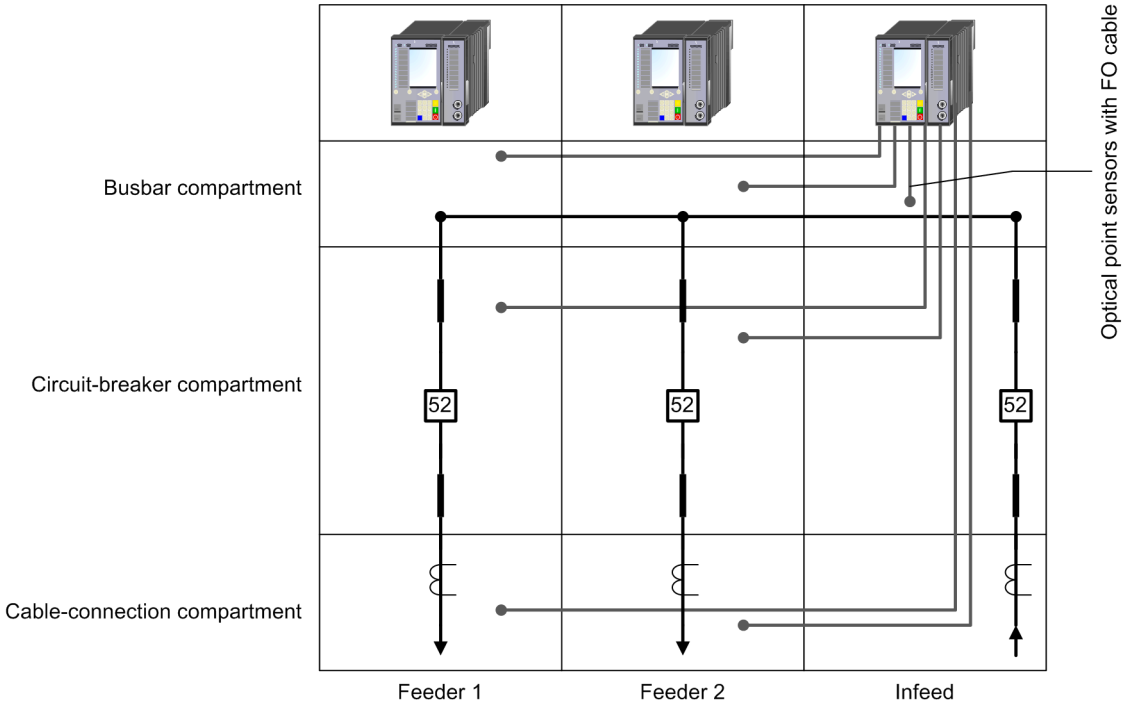
Setting Notes for the Protection Device in the Infeed

The **Arc protection** function operates with **5** stages.
Set the parameters of the stages as follows:

- Parameter: **Operating mode** = ***light only*** (applies to all stages)
- Parameter: **Sensor** = ***point sensor*** (applies to all stages)
- Parameter: **External trip initiation** = ***no*** (applies to all stages)
- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (Stage 1) → Busbar compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (Stage 2) → Circuit-breaker compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 1 channel 3*** (Stage 3) → Busbar compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 2 channel 1*** (Stage 4) → Circuit-breaker compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 2 channel 2*** (Stage 5) → Busbar compartment supervision in the infeed

The parameters in block **General** are not relevant since the **Operating mode** = ***light only***.

6.66.9 Application Example for Arc Protection with Point Sensors in Operating Mode: Light and Current



6.66.9.1 Description

Overview

The example describes the **Arc protection** function in a medium-voltage switchgear with one infeed and 2 feeders. The **Arc protection** function operates with the **Operating mode** = ***current and light***. In the example, all arcs are detected by the protection device in the infeed.

The following items are considered in the example:

- Positioning the optical point sensors in the switchgear
- Connecting the optical point sensors to the protection devices in the feeders and the infeed
- Number of necessary stages of the functions in the protection devices of the feeders and the infeed
- Setting notes about selected parameters in the stages of the function

[dw_light-and-current, 2, en_US]

Figure 6-672 Layout and Connection of the Optical Point Sensors (Operating Mode = Current and Light)

For this example, the following is assumed:

- The current-flow criterion offers additional security to prevent unwanted tripping caused by sudden light influences.

  Depending on the arc location in the cable-connection compartment of the feeder, it is not always possible to measure the current. If an arc is detected in the cable-connection compartment of the feeder, the current will therefore be evaluated in the infeed.
- Install the optical point sensors in the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of the feeders as well as the busbar compartment of the infeed. Connect the optical point sensors to the protection device in the infeed.

- The protection device in the infeed clears all arcs in the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of feeder 1 and 2. Furthermore, the protection device clears arcs in the busbar compartment of the infeed.
- If the optical point sensors in the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of the feeders, or in the busbar compartment of the infeed detect an arc, the protection device in the infeed evaluates the current as well.
- If an arc occurs in the circuit-breaker compartment and in the cable-connection compartment of the infeed, the superordinate protection device must trip.

NOTE

If the **Arc protection** function operates with the **`Operating mode`** = ***`current and light`***, the additional current-flow criterion prevents unwanted tripping caused by external light influences.

NOTE

This application example requires the connection of several optical point sensors to a single protection device. It must be considered that the number of arc-protection modules that are connected to the device depends on the hardware configuration of the device.

When using modular devices, a maximum of 15 sensors can be connected. If you use non-modular devices, a maximum of 6 sensors (3 sensors per module) can be connected.

6.66.9.2 Application and Setting Notes

General Notes

- Connect the optical point sensors from the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of feeders 1 and 2 to the protection device in the infeed. Arcs in the busbar compartment, the circuit-breaker compartment and the cable-connection compartment of feeders 1 and 2 are detected and cleared by the device in the infeed.
- Connect an optical point sensor from the busbar compartment in the infeed to the protection device in the infeed. Arcs in the busbar compartment of the infeed are cleared selectively by the circuit breaker in the infeed.

Setting Notes for the Protection Device in the Infeed

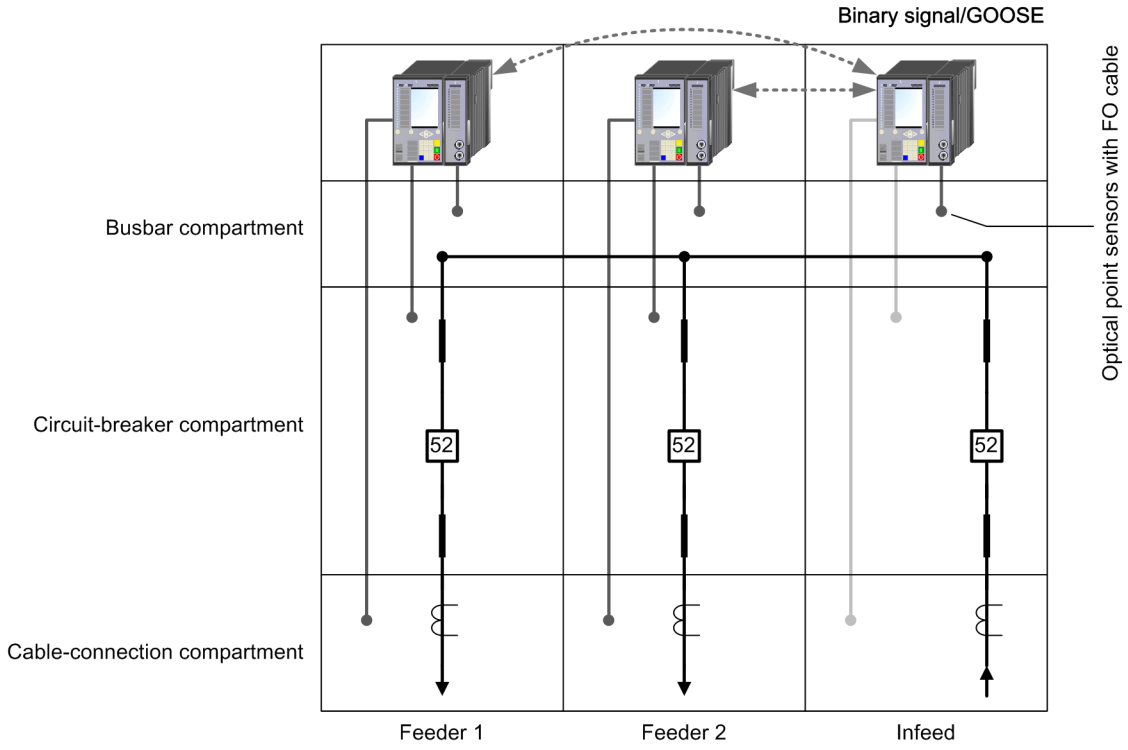
The **Arc protection** function operates with **7** stages.

Set the parameters of the stages as follows:

- Parameter: **`Operating mode`** = ***`current and light`*** (applies to all stages)
- Parameter: **`Sensor`** = ***`point sensor`*** (applies to all stages)
- Parameter: **`External trip initiation`** = ***`no`*** (applies to all stages)

- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (Stage 1) → Busbar compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (Stage 2) → Circuit-breaker compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 1 channel 3*** (Stage 3) → Cable-connection compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 2 channel 1*** (Stage 4) → Busbar compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 2 channel 2*** (Stage 5) → Circuit-breaker compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 2 channel 3*** (Stage 6) → Cable-connection compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 3 channel 1*** (Stage 7) → Busbar compartment supervision in the infeed

You can find more information about the settings of the parameters **Threshold I>** and **Threshold 3I0>** in chapter *6.66.4 Application and Setting Notes – General Settings*.



6.66.10 Application Example for Arc Protection with Point Sensors via External Trip Initiation

6.66.10.1 Description

Overview

The example describes the **Arc protection** function in a medium-voltage switchgear with one infeed and 2 feeders. The stages of the **Arc protection** function are triggered by **External trip initiation**.
The following items are considered in the example below:

- Positioning the optical point sensors in the switchgear
- Connecting the optical point sensors to the protection devices in the feeders and the infeed
- Number of necessary stages of the functions in the protection devices of the feeders and the infeed
- Setting notes about the selected parameters in the stages of the function

[dw_arcprot-extern-input, 3, en_US]

Figure 6-673 Arc Protection with External Trip Initiation

For this example, the following is assumed:

- Install the optical point sensors in the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of the feeder and the infeed. Connect the optical point sensors to the respective protection device in the feeder and infeed.
- If the optical point sensors detect an arc in the busbar compartment or the circuit-breaker compartment of the feeders, the *Light detected* indication is sent via binary inputs/outputs, a protection interface, or IEC 61850 GOOSE to the protection device in the infeed. Then, the protection device in the infeed evaluates the current as well. If the measured current exceeds the thresholds **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed switches off the malfunction.

  You can find detailed information in chapter *6.66.10.2 Application and Setting Notes*
- Arcs in the cable-connection compartment of the feeders can also be switched off selectively by the protection device of the affected feeder. To do this, the *Current detected* pickup indication from the infeed unit must be sent to the appropriate protection device in the feeder.
- If an arc occurs in the circuit-breaker compartment and in the cable-connection compartment of the infeed, the superordinate protection device trips.

NOTE

If the **Arc protection** function operates via the **External trip initiation**, only 3 optical point sensors are required per feeder protection device in order to detect the arcs (only one arc-protection module).

The number of GOOSE messages is not limited. Therefore, the number of feeders is not limited, and the protection of complex systems is feasible.

6.66.10.2 Application and Setting Notes

General Notes:

- Install the optical point sensors in the busbar compartment, the circuit-breaker compartment, and the cable-connection compartment of the feeders and the infeed to the respective protection devices.
- Arcs in the busbar compartment and the circuit-breaker compartment of the feeders must be switched off by the protection device in the infeed. To do this, the protection devices in the feeder device must send the indication *Light detected* to the infeed device. Use the binary inputs/outputs, a protection interface, or IEC 61850 GOOSE.
  The protection device in the infeed evaluates the current. If the measured current exceeds the **Threshold I>** and/or **Threshold 3I0>** threshold values, the protection device in the infeed switches off faults on the busbar and the circuit-breaker compartment of the feeders.
  Connect the signals over 4 stages, using the external trip initiation or a CFC chart.
- Arcs in the cable-connection compartment of the feeders are switched off locally. The protection device in the infeed evaluates the current. If the measured current exceeds the threshold values **Threshold I>** and/or **Threshold 3I0>**, the *Current detected* indication is sent to the protection devices in the feeders. If, at the same time, an optical sensor in a cable-connection compartment detects light, the protection device trips in the corresponding feeder.

Setting Notes for the Protection Device in Feeder 1

The **Arc protection** function operates with **3** stages.

Stage 1 and 2 (supervision of busbar compartment and circuit-breaker compartment):

Set the parameters of the stages as follows:

- Parameter: **Operating mode** = ***light only***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Operate & flt.rec. blocked** = ***yes***
- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (stage 1) → busbar-compartment supervision in feeder 1
  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (stage 2) → circuit-breaker compartment supervision in feeder 1

Stage 3 (supervision of cable-connection compartment):

Set the parameters of the stage as follows:

- Parameter: **Operating mode** = ***current and light***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***current***
  The protection device in the infeed evaluates the current. If the measured current exceeds the threshold values **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed returns the indication *Current detected* to the protection device in the feeder.
  Only if the indication in the feeder device *Current detected* is connected with the signal *>Externa l current* an external trip initiation for this stage is effective.
- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Channel** = ***Arc mod. 1 channel 3***

Setting Notes for the Protection Device in Feeder 2

The **Arc protection** function operates with **3** stages.

Stage 1 and 2 (supervision of busbar compartment and circuit-breaker compartment):

Set the parameters of the stages as follows:

- Parameter: **Operating mode** = ***light only***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Operate & flt.rec. blocked** = ***yes***
- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (stage 1) → busbar-compartment supervision in feeder 2
  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (stage 2) → circuit-breaker compartment supervision in feeder 2

Stage 3 (supervision of cable-connection compartment):
Set the parameters of the stage as follows:

- Parameter: **Operating mode** = ***current and light***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***current***
  The protection device in the infeed evaluates the current. If the measured current exceeds the threshold values **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed returns the indication *Current detected* to the protection device in the feeder.
  Only if the indication in the feeder device *Current detected* is connected with the signal *>External current* an external trip initiation for this stage is effective.
- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Channel** = ***Arc mod. 1 channel 3***

Setting Notes for the Protection Device in the Infeed

The **Arc protection** function operates with **7** stages.
Stage 1 (busbar-compartment supervision):

- Parameter: **Operate & flt.rec. blocked** = ***no***
  If an arc is detected in the busbar compartment of the infeed and the thresholds **Threshold I>** and/or **Threshold 3I0>** are exceeded, an operate indication is generated immediately.
- Parameter: **Channel** = ***Arc mod. 1 channel 1***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***

Stage 2 (circuit-breaker compartment supervision):

- Parameter: **Operate & flt.rec. blocked** = ***yes***
  If an arc is detected in the circuit-breaker compartment of the infeed (light-gray point sensors in *Figure 6-673*), a pickup indication is generated immediately. The arc is switched off by a superordinate protection device.
- Parameter: **Channel** = ***Arc mod. 1 channel 2***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***

Stage 3 (cable-connection compartment supervision):

- Parameter: **Operate & flt.rec. blocked** = ***yes***

  If an arc is detected in the cable-connection compartment of the infeed (light-gray point sensors in *Figure 6-673*), a pickup indication is generated immediately. The arc is switched off by a superordinate protection device.

  Depending where the arc is generated in the cable-connection compartment of the infeed, it is not always possible to measure the current. If an arc is detected in the cable-connection compartment of the infeed, the current must be evaluated by the superordinate protection device.

- Parameter: **Channel** = ***Arc mod. 1 channel 3***
- Parameter: **Operating mode** = ***light only***
- Parameter: **Sensor** = ***point sensor***
- Parameter: **External trip initiation** = ***no***

Stage 4 to 7 (External trip initiation):

- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **External trip initiation** = ***light***

  If an arc is detected in the busbar compartment or the circuit-breaker compartment of the feeder, the feeder device sends the *Light detected* indication to the infeed device. Only if the indication in the infeed device *Light detected* is connected with the signal *>External light*, an external trip initiation via these stages is effective.

  The protection device in the infeed evaluates the current. If the measured current exceeds the **Threshold I>** and/or **Threshold 3I0>** threshold values, the protection device in the infeed switches off the arc.

6.66.10.3 Application and Setting Notes for Variant 2 (with Feedback to Feeder Protection Devices)

General Notes:

- Connect the optical sensors in the busbar compartment, the CB compartment, and the cable-connection compartment of the feeder 1 and 2 and the infeed to the respective protection devices.
- Arcs in the busbar compartment and in the CB compartment of the feeders must be cleared by the protection device in the infeed. To do this, the protection devices in the feeder must send the indication *Arc detected* to the infeed device. Use the binary inputs/outputs, a protection interface, or IEC 61850 GOOSE.
- Arcs in the cable-connection compartment of the feeder are cleared selectively. Here, the message *Arc detected* is sent as well via binary inputs/outputs, a protection interface, or IEC 61850 GOOSE to the protection device in the infeed.

  The protection device in the infeed evaluates the current. If the measured current exceeds the threshold values **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed sends the pickup indication of the stage back to the protection device in the affected feeder. The protection device in the affected feeder clears the arc selectively.

  Due to the pressure wave that occurs during an arc, partitions may deform and cause undesirable light influences in adjacent compartments. This may result in a non-selective trip.

NOTE

The **External trip initiation** function must be instantiated in the protection devices of the feeders.

Setting Information for the Protection Device in Feeder 1

The **Arc protection** function operates with **4** stages.

Stage 1 to 3:

- Parameter: **Operating mode** = ***light only***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Operate & flt.rec. blocked** = ***yes***
- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (Stage 1) → Monitoring busbar compartment in feeder 1

  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (Stage 2) → Monitoring CB compartment in feeder 1

  Parameter: **Channel** = ***Arc mod. 1 channel 3*** (Stage 3) → Monitoring cable-connection compartment in feeder 1

Stage 4 (External trip initiation):

- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Operating mode** = ***light only***
- Parameter: **External trip initiation** = ***yes***

  If an arc is detected in the cable-connection compartment of the feeder, the indication *Arc detected* is sent to the protection device in the infeed.

  The protection device in the infeed evaluates the current. If the measured current exceeds the thresholds **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed picks up. The pickup indication from the protection device in the infeed is injected via this stage into the feeder protection device. This makes a selective tripping in the feeder possible.

Setting Information for the Protection Device in Feeder 2

The **Arc protection** function operates with **4** stages.

Stage 1 to 3:

- Parameter: **Operating mode** = ***light only***
- Parameter: **External trip initiation** = ***no***
- Parameter: **Operate & flt.rec. blocked** = ***yes***
- Parameter: **Channel** = ***Arc mod. 1 channel 1*** (Stage 1) → Monitoring busbar compartment in feeder 2

  Parameter: **Channel** = ***Arc mod. 1 channel 2*** (Stage 2) → Monitoring CB compartment in feeder 2

  Parameter: **Channel** = ***Arc mod. 1 channel 3*** (Stage 3) → Monitoring cable-connection compartment in feeder 2

Stage 4 (External trip initiation):

- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Operating mode** = ***light only***
- Parameter: **External trip initiation** = ***yes***

  If an arc is detected in the cable-connection compartment of the feeder, the indication *Arc detected* is sent to the protection device in the infeed.

  The protection device in the infeed evaluates the current. If the measured current exceeds the thresholds **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed picks up. The pickup indication from the protection device in the infeed is injected via this stage into the feeder protection device. This makes a selective tripping in the feeder possible.

Setting Information for the Protection Device in the Infeed

If arcs in the cable-connection compartments of the feeder shall be switched off selectively by the protection device in the feeder, the following setting notes for the protection device in the infeed apply.

The **Arc protection** function operates with **9** stages.

Stage 1 (busbar-compartment monitoring):

- Parameter: **Operate & flt.rec. blocked** = ***no***

  If an arc is detected in the busbar compartment of the infeed, an operate indication is generated immediately.
- Parameter: **Channel** = ***Arc mod.. 1 channel 1***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **External trip initiation** = ***no***

Stage 2 (CB compartment monitoring):

- Parameter **Operate & flt.rec. blocked** = ***yes***

  If an arc is detected in the CB compartment of the infeed (light-gray sensors in *Figure 6-673*), a pickup indication is generated immediately. The arc is cleared by a superordinate protection device.
- Parameter: **Channel** = ***Arc mod.. 1 channel 2***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **External trip initiation** = ***no***

Stage 3 (cable-connection compartment monitoring):

- Parameter: **Operate & flt.rec. blocked** = ***yes***

  If an arc is detected in the cable-connection compartment of the infeed (light-gray sensors in *Figure 6-673*), a pickup indication is generated immediately. The arc is cleared by a superordinate protection device.

  Depending on the arc location in the cable-connection compartment of the infeed, it is not always possible to measure the current. If an arc is detected in the cable-connection compartment of the infeed, the current must be evaluated by the superordinate protection device.
- Parameter: **Channel** = ***Arc mod.. 1 channel 3***
- Parameter: **Operating mode** = ***light only***
- Parameter: **External trip initiation** = ***no***

Stage 4 to 7 (External trip initiation):

- Parameter: **Operate & flt.rec. blocked** = ***no***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **External trip initiation** = ***yes***

If an arc is detected in the busbar compartment or the CB compartment of the feeders, the feeder device sends the indication *Arc detected* to the infeed device. An external trip initiation via these stages is effective only if the indication *Arc detected* is connected with the signal *>External Arc* in the infeed device.

The protection device in the infeed evaluates the current. If the measured current exceeds the thresholds **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed clears the arc.

Stage 8 and 9 (External trip initiation):

- Parameter: **Operate & flt.rec. blocked** = ***yes***
- Parameter: **Operating mode** = ***current and light***
- Parameter: **External trip initiation** = ***yes***

If an arc is detected in the cable-connection compartment of the feeder, the feeder device sends the indication *Arc detected* to the infeed device. An external trip initiation via these stages is effective only if the indication *Arc detected* is connected with the signal *>External Arc* in the infeed device.

The protection device in the infeed evaluates the current. If the measured current exceeds the thresholds **Threshold I>** and/or **Threshold 3I0>**, the protection device in the infeed picks up. The pickup indication

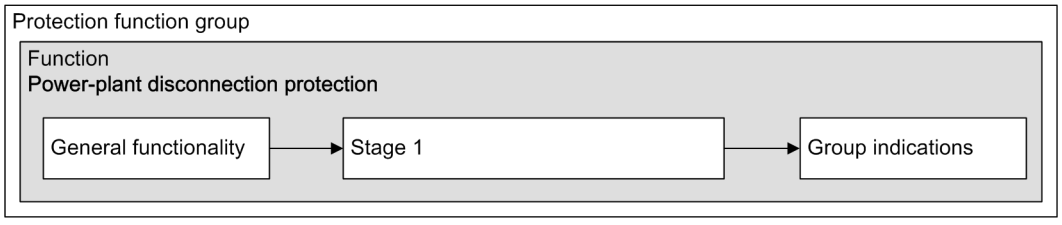
Arc detected will be sent back to the feeder protection device. This makes a selective tripping in the feeder possible.

6.67 Power-Plant Disconnection Protection

6.67.1 Overview of Functions

The **Power-plant disconnection protection** function (ANSI 37 (-dP)):

- Detects external short circuits in the vicinity of the power plant (line, busbar) and opens the high-voltage circuit breaker if the fault duration is long.
- Prevents an impermissible stress on the shaft assembly due to high mechanical stress as a result of an abrupt active-power unloading.
- Prevents power swings of the power-plant unit with the electrical power system as a result of excessively long fault-clearing times.
- Protects the stator winding from excessively long short-circuit current stress.



6.67.2 Structure of the Function

The **Power-plant disconnection protection** function is used in the **Generator stator** protection function group. It can also run in the **3-phase voltage-current** function group.

You can copy the function during engineering into the appropriate function group.

The **Power-plant disconnection protection** function consists of 1 stage, which contains the necessary function blocks.

The function processes the 3-phase voltage of the main generator lead and the current of the **Generator stator** function group. The following figure shows the basic structure of the function.

[dw_PPD_structure, 2, en_US]

Figure 6-674 Structure/Embedding of the Function

6.67.3 Function Description

Basic Principle of Power-Plant Disconnection Protection

In the event of system incidents, the sudden change of the electric torque of the generator leads to torsional vibrations in the shaft assemblies of power-plant units. These lead to increased mechanical stress and, in the extreme case, to the destruction of the shaft assembly.

In the event of an external, 3-phase short circuit, there is an abrupt active-power unloading in the power-plant unit, which causes a change of the electric torque. Due to the relief of torque, the angular velocity of the rotor increases and the rotor angle increases. The rotor angle describes the torsional state of the shaft. The rotor angle is the angle difference between the angle of the synchronous generated voltage of the generator and the power-system voltage (reference point in the power system).

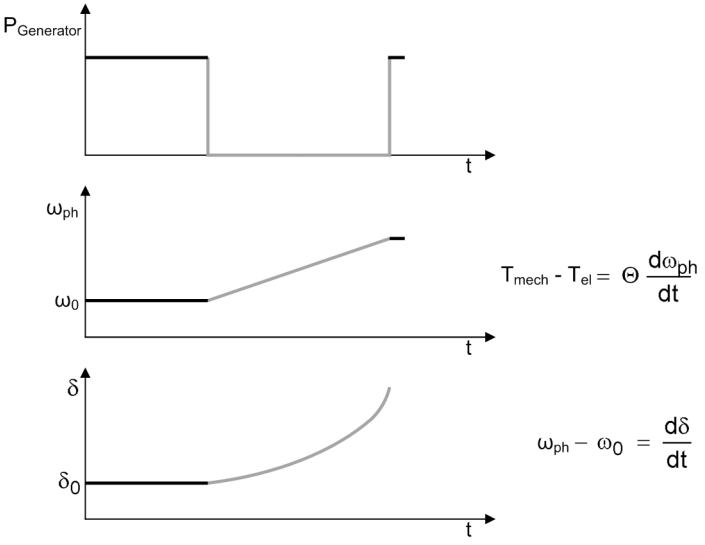
NOTE

The rotor angle, which is shown among the functional measured values in the **Generator stator** function group, relates to the terminal voltage of the generator and is somewhat smaller.

The equations presented below show, in simplified form, basic relationships of the resulting stress.

$$\omega_L = \frac{1}{\Theta} \cdot \Delta T t_F + \omega_0;\ \Delta T = T_{mech} - T_{el}$$

[fo_powerplant_stress_01, 2, en_US]



$$\delta = \frac{1}{\Theta} \cdot \Delta T (t_F)^2 + \delta_0$$

[fo_powerplant_stress_02, 2, en_US]

with

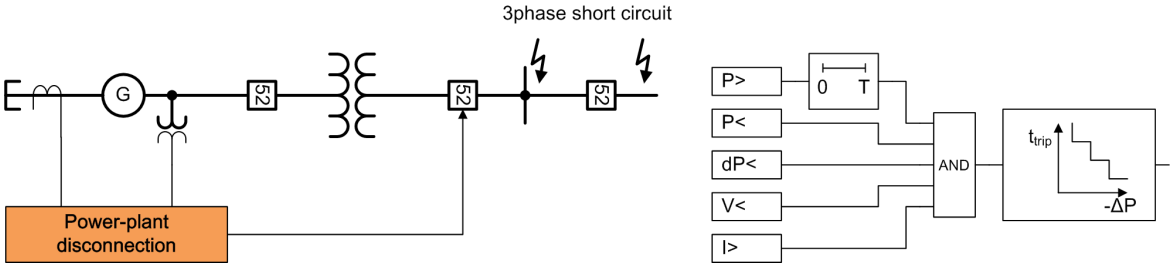
T_{mech}	Mechanical torque (turbine torque)
T_{el}	Electric torque (air gap torque)
Θ	Mass moment of inertia of the shaft
ω_L	Angular velocity of the rotor
ω_0	Synchronous angular velocity (constant: $\omega_0 = 2\pi f$)
t_F	Fault-clearing time
δ	Rotor angle of the generator
δ_0	Rotor angle before fault inception

The following figure schematically shows the effect of the sudden active-power jump.

[dw_PPD_rotor-angle, 2, en_US]

Figure 6-675 History of the Rotor Angle for Short Circuit near the Power Plant

As the electric torque changes, the angular velocity of the rotor changes linearly with the fault duration. The rotor angle increases quadratically with the fault duration. The rotor angle at the time when the fault is cleared has a considerable influence on the mechanical stress on the shaft assembly.



If the voltage does not collapse at the interconnection point, active power can still be output into the power system during the fault. Thereby the change of electric torque is smaller and the stress on the shaft assembly is lower. This means that a longer fault duration is permissible.

Power-plant disconnection avoids an impermissible stress on the shaft assembly. The evaluation of multiple criteria ensures safe functionality:

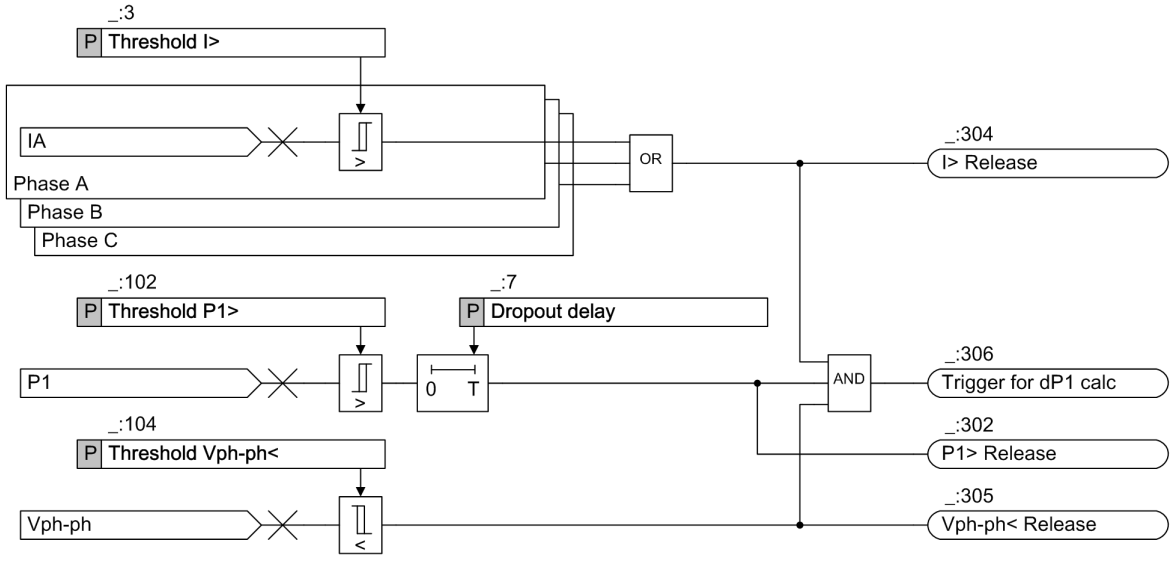
- Overcurrent — Criterion for detecting short circuits
- Undervoltage — Criterion for detecting undervoltage
- Active power P< — Criterion for detecting active-power decrease

- Active-power release P> — Criterion that the generator has output sufficient active power to the electrical power system before fault inception
- Active-power change dP< — Decisive criterion for determining the stress on the shaft assembly. A multi-stage characteristic curve is possible→ $t_{out} = f(\Delta P)$.

The following figure shows the basic structure. You can find detailed information regarding the implementation under *Logic of the Function, Page 1762* and in chapter *6.67.4 Application and Setting Notes*.

[dw_PPD_power-plant-coupler, 2, en_US]

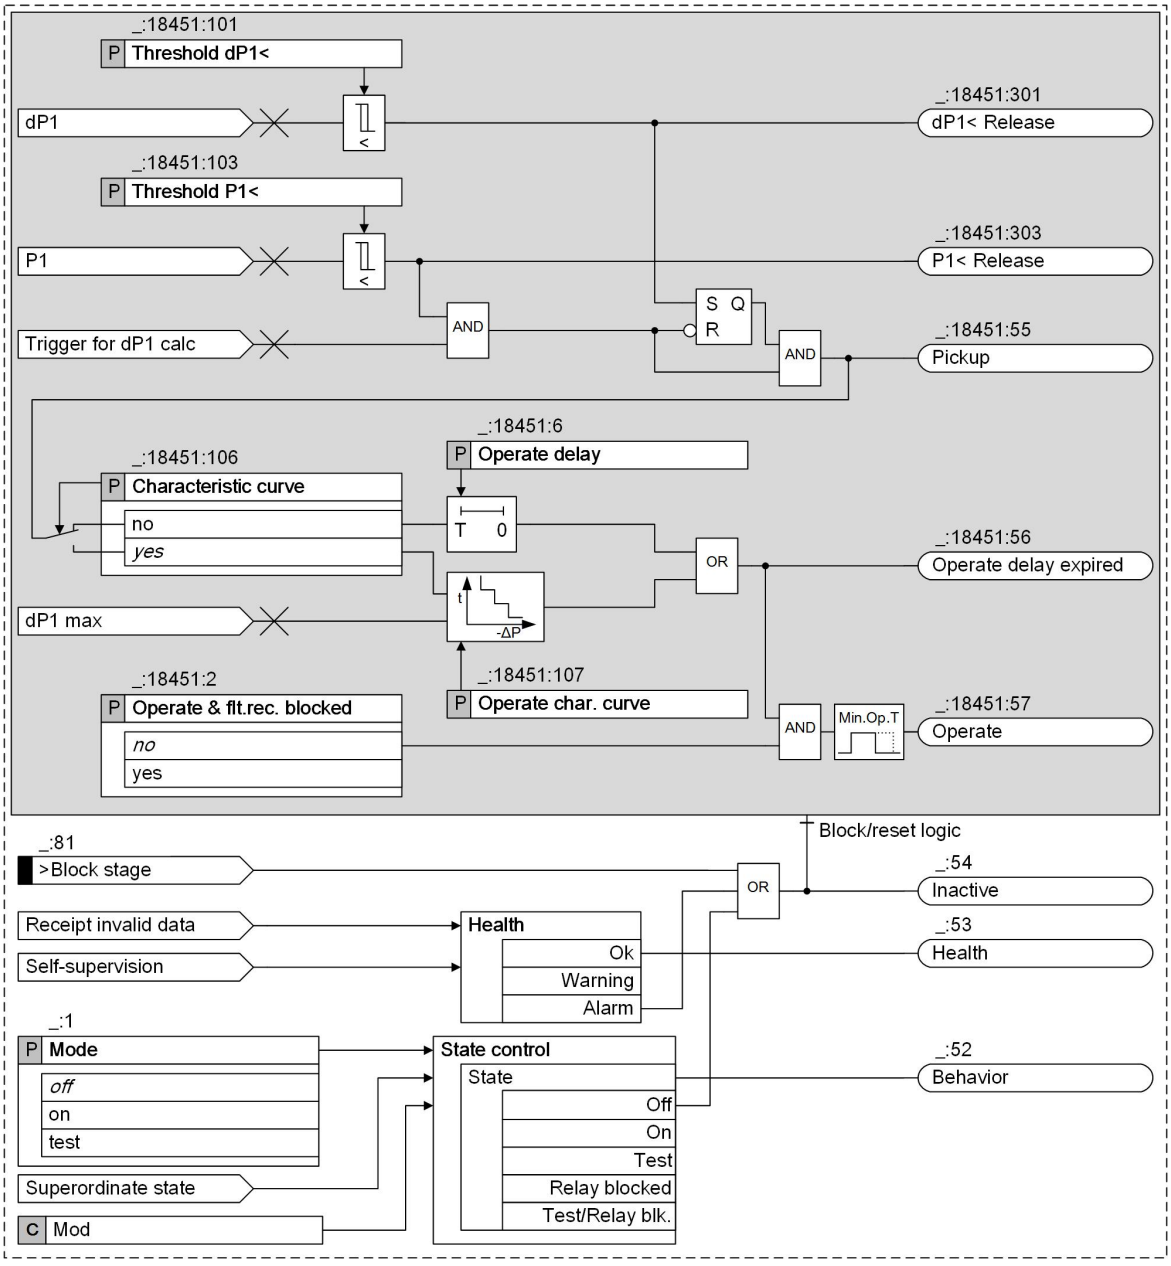
Figure 6-676 Basic Structure of Power-Plant Disconnection



Logic of the Function

The **Power-plant disconnection protection** function includes multiple different criteria. *Figure 6-677* shows the logic for enabling active-power change measurement (dP measurement).

If the following criteria are satisfied, the indication *Trigger for dP1 calc.* is output and the calculation of the active-power difference begins:



- Overcurrent pickup
- Undervoltage pickup
- Infeed of an appropriate active power from the power-plant unit into the power system

The indication *Trigger for dP1 calc.* describes the calculation time, starting from which the active power before fault inception, P1(t_{prior}) is stored internally. In order to avoid an incorrect measurement during transition processes, the active power is not measured at the time of the trigger; instead the value of approx. 2 cycles before the trigger time is used.

[lo_PPD_db_measurement, 2, en_US]

Figure 6-677 Logic Diagram for Release of dP Measurement

[lo_PPD_function, 3, en_US]

Figure 6-678 Logic Diagram of the Function

Figure 6-678 gives an overview of the implementation and the effect of the individual criteria. The measurands are evaluated every 1/4 cycle so that the function can respond quickly to changes in the power and can – if necessary – quickly fall back. The evaluation of the tracked voltage and current signals at the sampling frequency ensures the high level of measuring accuracy over a wide frequency range.

The measured active power is evaluated solely in percent related to the generator apparent power. It is therefore always less than 100 % and the maximum value is determined under rated conditions by cos φ (power factor). The percentage value for the phase currents is related to the generator rated current; the percentage value for the phase-to-phase voltage is related to the generator rated voltage.

Table 6-29 Implementation and Effect of the Individual Criteria

Criterion	Method of Measurement/Description
I>	Phase-segregated calculation of the fundamental component RMS value • The overcurrent criterion detects the short circuit. The currents are detected on a phase-segregated basis. The vector group of the generator transformer leads only to 2-phase or 3-phase fault currents on the generator side (also see the **Impedance protection** function).
V_{PP}<	Phase-to-phase voltage of the fundamental phasor • The undervoltage criterion detects an external short circuit. In case of a fault, the voltage must be below the threshold value. The undervoltage criterion also makes it possible for the function to drop out if the fault is cleared by the line protection.
P1>	Positive-sequence system active power P1 • If a power plant is operated in the partial-load range, a relatively low load on the shaft assembly can be expected. For this reason, it is checked whether the power-plant unit is feeding in a minimum demand. The criterion is dropout-delayed (parameter: **Dropout delay**), since the threshold value will be undershot in case of a fault.
P1<	Positive-sequence system active power P1 • Falling below an active-power threshold is an additional criterion for fault detection. In the event of a fault, the measured active power must be less than the threshold value.
dP1	$dP1(t) = P1(t_{prior}) - P1(t)$ • This calculates the change of active power starting from fault inception. When a short circuit is detected, the calculation of the power difference begins. The criterion calculates the power difference from the active power before fault inception and the actual active power at the calculation time. For fault detection, the 1st active-power jump is detected and stored in the RS flip-flop. If the preceding conditions are fulfilled and the dP threshold value (query of a negative jump) has been fallen below, the function picks up and the timer is started. If only a fixed time stage (**Characteristic curve** = ***no***) is active, there is tripping after expiration of the time, presuming that all the above conditions are still fulfilled.
dP1max	$dP1(t)max = Max (P1(t_{prior}) - P1(t))$ • If the characteristic curve for protection tripping is to be used, the active-power difference is measured continuously from the trigger time. In contrast to the dP measurement, the maximum active-power difference detected during the pickup is used as a variable in the characteristic curve. This characteristic curve offers the benefit that you can respond according to the level of the active-power change.

By using a multi-stage characteristic curve, you can assign a permissible tripping time to the maximum active-power difference. You can define the number of stages from 2 to 5 and thus optimally adapt the function to the system conditions. Longer tripping times are permitted for small active-power differences.

You can also select only 1 stage. Select between the stagewise operate curve or the defined time.

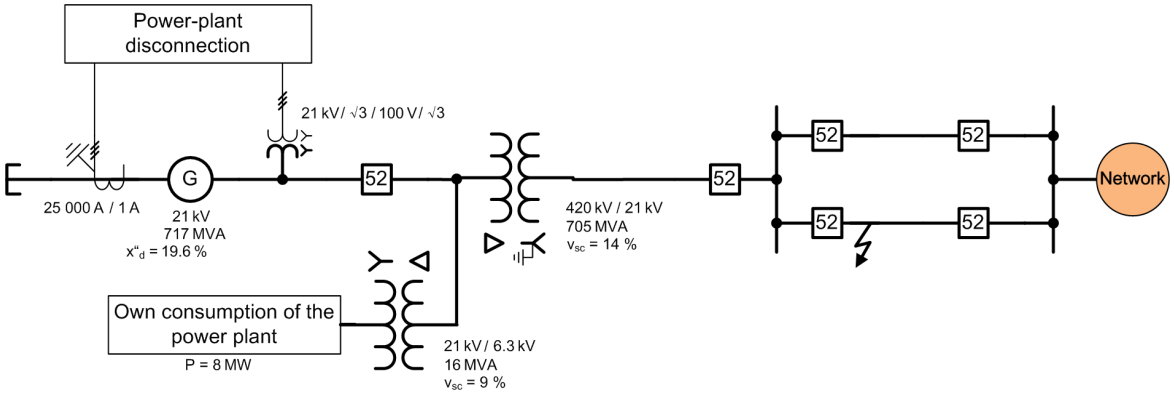
Functional Measured Values

Functional measured values are available to you so that you can better evaluate the behavior of the function. You can collect these functional measured values in a fault record for example.

Measured Value	Description
P1(t)	Positive-sequence system active power, which is evaluated by the function. The measured value is calculated every 1/4 cycle.
dP1(t)	Continuous representation of the active-power change, starting from the trigger time. With this, you can evaluate the change of the active-power difference at the prefault instant (t_{prior}).
dP1(t)max	This measured value flows into the characteristic curve. It represents the maximum active power during the duration of the fault.

Blocking the Function

You can completely reset the function by using the binary input signal **> Blocking stage**.



If internal supervision picks up, for example, by interrupting the voltage measuring circuit, the function is blocked.

6.67.4 Application and Setting Notes

For a typical application for a power-plant unit, Siemens recommends the following basic settings. A setting tailored to the power-plant unit, particularly regarding active-power difference and the permissible time delay, is possible only with a power-system study with the specific plant parameter settings. *Figure 6-679* and *Figure 6-680* show typical system configurations and also contain relevant technical data. Preferably load the function into the **Generator stator** or **Voltage-current, 3-phase** function group.

Generator-Stator Function Group

If the function is loaded into the **Generator-stator** function group (see the connection example in *Figure 6-679*), the function must be blocked with the generator circuit breaker open. In the event of a fault in the generator, a fault current still flows for a short time after fault clearing, that is, with an open generator circuit breaker, and therefore there is a risk of an overfunction. Power-plant disconnection remains picked up and opens the high-voltage circuit breaker. This means that you lose the generator transformer and the infeed for internal demand.

[dw_PPD_connection-examples, 2, en_US]

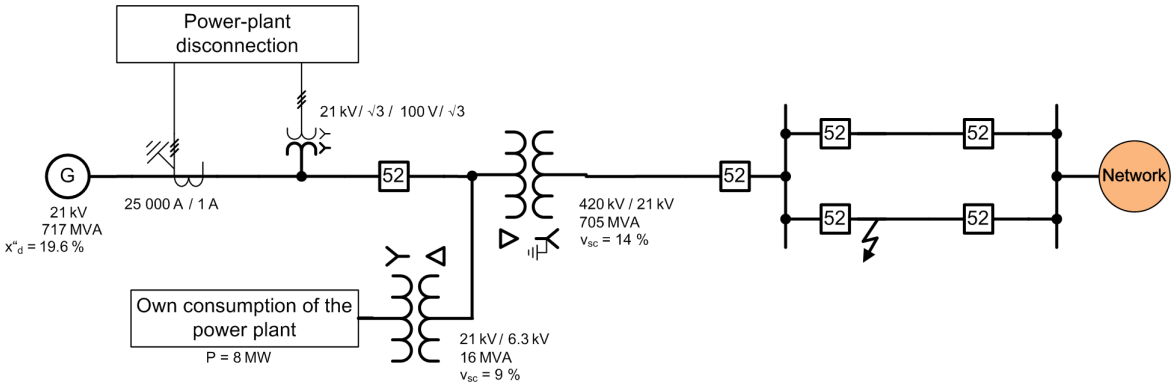
Figure 6-679 Connection Example for the Generator-Stator Function Group

Make the following settings in the **Generator-stator** function group. If calculating with per-unit values, these settings are necessary for scaling the quantities.

NOTE

Make sure that you set the correct generator data in the power-system data.

Parameters: `Rated apparent power`



With the parameter **`(_:14671:103) Rated apparent power`**, you set the rated apparent power for the generator to be protected. In the connection example (*Figure 6-679*), that is 717 MVA.

Parameters: `Rated voltage`

With the parameter **`(_:14671:102) Rated voltage`**, you set the rated voltage for the generator to be protected. In the connection example (*Figure 6-679*), that is 21 kV.

The settings for **`Rated apparent power`** and **`Rated voltage`** yield a **`Rated current`** of 717 MVA / (√3 · 21 kV) = 19 712 A.

Load into the Voltage-Current 3-Phase Function Group

[dw_PPD_connection-example 2, 1, en_US]

Figure 6-680 Connection Example for the Voltage-Current 3-Phase Function Group

Make the following settings in the **Voltage-current 3-phase** function group. If calculating with per-unit values, these settings are necessary for scaling the quantities.

NOTE

Make sure that you set the correct generator data in the power-system data.

NOTE

If the current transformer is grounded towards the generator (see *Figure 6-680*), set the parameter **`Neutr.point in dir.of ref.obj`** to ***no***. The parameter can be found in the DIGSI 5 project tree under **Name of the device** → **Settings** → **Power system** → **Measuring point I 3-phase**.

Parameters: `Rated current`

With the parameter **`(_:9451:101) Rated current`**, you set the rated current for the generator to be protected. In the connection example (*Figure 6-680*), that is 19 712 A.

Parameters: `Rated voltage`

With the parameter **`(_:9451:102) Rated voltage`**, you set the rated voltage for the generator to be protected. In the connection example (*Figure 6-680*), that is 21 kV.

The settings for **`Rated current`** and **`Rated voltage`** yield a **`Rated apparent power`** of $\sqrt{3} \cdot 21\ \text{kV} \cdot 19\,712\ \text{A} = 717\ \text{MVA}$.

NOTE

The default settings of the following threshold values are given in percent. In DIGSI 5, you can show the **Percent** mode in the path **Project** → **Device** → **Settings** → **Device settings** → **Edit mode**. You can find more information about the mode in *3.10 General Notes for Setting the Threshold Value of Protection Functions*.

Parameter: `Threshold P1>`

- Default setting **`(_:18451:102) Threshold P1>`** = ***60 %***

With the **`Threshold P1>`** parameter, you can set the active power that a generator must feed into the power system before a short circuit occurs. If the active power fed in is lower than the set value, power-plant disconnection does not pick up.

A typical cos φ value of 0.8 to 0.9 yields a percentage of 80 % to 90 % active power (reference power is the apparent power). Therefore the setting value is more than half the maximum active power. Siemens recommends a value of > 50 % ($P1/S_{rated,Gen}$).

Parameter: Dropout delay

- Default setting **(_:18451:7) Dropout delay** = ***0.5 s***

You must set the parameter **Dropout delay** to be longer than the maximum tripping delay. Also take into account the setting values of the characteristic curve (see *Table 6-30*). After expiration of this time, the storage of the active power before fault inception $P1(t_{prior})$ will be canceled. The determined active-power change relates to $P1(t_{prior})$. The **Dropout delay** is an additional safety criterion for avoiding faulty calculation of the active-power difference.

The default setting is a practicable value. If necessary, you must increase the time somewhat.

Parameter: Threshold P1<

- Default setting **(_:18451:103) Threshold P1<** = ***30 %***

With this parameter, you can set the active power that must be undershot in the case of a short circuit. If the active power is less than the set power, a release signal will be issued. The setting value must be smaller than the **Threshold P1>** setting value. To enable a pickup at residual voltage, you must not set the parameter **Threshold P1<** too low.

The default setting is a practicable value.

Parameter: Threshold Vph-ph<

- Default setting **(_:18451:104) Threshold Vph-ph<** = ***70 %***

To guarantee a reliable pickup, the terminal voltage of the generator during the short circuit close to the power plant must certainly be below the parameter **Threshold Vph-ph<**. This means that you must not set the parameter **Threshold Vph-ph<** too low. On the other hand, you must take the defined voltage range into consideration (typically: +/- 5 % or 7.5 %). It must also be ensured that the voltage safely drops out after fault clearing.

If there are unbalanced short circuits in the power system, unbalanced phase-to-phase voltages will also be measured on the generator side. If there is a 1-phase short circuit on the high-voltage side, only 1 phase-to-phase voltage will dip on the generator side. The voltage threshold is also a criterion for determining the time for the active power before fault inception.

A typical setting range is between 50 % and 75 %. The default setting is a practicable value.

NOTE

When determining the **Threshold Vph-ph<** parameter, note that the fault current leads to a voltage drop across the generator transformer. You must additionally take into account the short-circuit impedance of the transformer (in simplified form, the short-circuit voltage v_{sc}) in this case.

The possible generator-side terminal voltage can be estimated as follows:

$$V\,[\%] \approx v_{sc}\,[\%] \cdot \frac{I''_{3-phase}}{I_{rated,Gen}}$$

[fo_generator terminal voltage, 2, en_US]

Example

v_{sc} = 14 %

$I''_{3\text{-phase}} = 3I_{rated,Gen}$

$$V\,[\%] \approx v_{sc}\,[\%] \cdot \frac{I''_{3-phase}}{I_{rated,Gen}} = 14\,\% \cdot \frac{3I_{rated,Gen}}{I_{rated,Gen}} = 42\,\%$$

[fo_generator terminal voltage, example, 2, en_US]

Parameter: Threshold I>

- Default setting **(_:18451:3) Threshold I>** = *130 %*

In order to detect an external short circuit, define the current pickup value with the **Threshold I>** parameter. The default setting is a practicable value.

You can estimate the initial short-circuit alternating current with the subtransient reactance of the generator x''_d and the short-circuit voltage v_{sc} of the transformer:

$$I''_{3-phase} = \frac{I_{rated\ ,Gen}}{x''_d + v_{sc}}$$

[fo_shortcircit AC current, 2, en_US]

For the numerical example:

$$I''_{3-phase} \approx \frac{I_{rated,Gen} \cdot 100\,\%}{19.6\,\% + 14\,\%} \approx 3I_{rated,Gen}$$

[fo_shortcircit AC current, example, 2, en_US]

The default setting is a practicable value.

Parameter: Threshold dP1<

- Default setting **(_:18451:101) Threshold dP1<** = *-70 %*

With the **Threshold dP1<** parameter, you set the value that leads to pickup of the **Power-plant disconnection** function. The prerequisite is that the above-mentioned conditions have been satisfied. The level of the threshold value is determined, among other things, by the following settings. If you want only 1 fixed stage with a defined tripping time (parameter **Characteristic curve** = *no*), you must set a larger negative threshold value for the active-power change. Assume a 3-phase close-up short circuit without residual voltage. If cos φ = 0.8 and full-load operation is assumed, then the *ideal* active-power change is approx. -80 % (at full load, the active power is 80 % $P/S_{rated,Gen}$ and in the fault case 0 %); this *ideal* state cannot be achieved.

The default setting is a practicable value. The turbo-generator set manufacturer must supply the final value or you determine the value from the dynamic calculations.

If you want to use the characteristic curve (parameter **Characteristic curve** = *yes*), set the parameter **Threshold dP1<** to the lowest threshold value of the characteristic curve (see *Table 6-30*).

Parameter: Operate delay

- Default setting **(_:18451:6) Operate delay** = *0.15 s*

You must set the **Operate delay** parameter on the basis of the application. The turbo-generator set manufacturer will specify the time. Take account of the *Fault Ride Through* capability (FRT capability) from the requirements of the *Grid Code* (grid and system rules of the power-system operator). The FRT capability means that the power-plant unit must remain stable on the power system in the event of a 3-phase short circuit and must not lose synchronism after a fault clearing (asynchronous active-power swing with the power system). A typical FRT time is 0.15 s, which is also the default time delay. Assume an additional pickup delay of approx. 25 ms. The dropout delay is on the same order of the magnitude. 20 ms is used for the estimation.

The **Operate delay** can be estimated as follows:

$$t_{pickup\ -ind.} \geq t_{fault} - t_{pickup} + t_{dropout}$$

[fo_pickupInd.Time, 1, en_US]

$$\text{Operate delay} > t_{\text{pickup -ind.}} + \text{Safety time}$$

[fo_op.DelayTime, 1, en_US]

With:

$t_{\text{pickup-ind.}}$	Pickup indication time
t_{fault}	Maximum permissible fault-clearing time
t_{pickup}	Pickup delay
t_{dropout}	Dropout delay

EXAMPLE

$t_{\text{fault}} = 140$ ms

$t_{\text{pickup}} = 25$ ms

$t_{\text{dropout}} = 20$ ms

$$t_{\text{pickup -ind.}} \geq t_{\text{fault}} - t_{\text{pickup}} + t_{\text{dropout}} = 140\ \text{ms} - 25\ \text{ms} + 20\ \text{ms} = 135\ \text{ms}$$

[fo_pickupInd.Time with data, 1, en_US]

$$\text{Operate delay} > t_{\text{pickup -ind.}} + \text{Safety time} = 135\ \text{ms} + 10\ \text{ms} = 145\ \text{ms}$$

[fo_op.DelayTime with data, 1, en_US]

The parameter **Operate delay** is set to 150 ms (0.15 s).

Parameter: Characteristic curve

- Default setting **(_:18451:106) Characteristic curve** = ***yes***

With the **Characteristic curve** parameter, you specify whether you want to use the characteristic curve or a fixed tripping delay (**Characteristic curve** = ***no***). Siemens recommends the default setting, because you can act with different delays on different active-power changes with the characteristic curve. In that way, you increase the security of supply and avoid an excessively fast power-system disconnection if there are small active-power changes.

Parameters: Operate char. curve

If you use the characteristic curve, you can set the number of desired stages. The number of table values is visible, depending on the setting. 3 stages is a pragmatic approach.

Small active-power changes lead to a smaller stress. For this reason, longer tripping times are permissible. You must request the final values from the turbo-generator set manufacturer or determine them with a dynamic system calculation program that takes account of the system parameter settings.

NOTE

In DIGSI, set the active-power jump of the operate curve in the descending order.

The following table shows an example of a rough estimation of the operate curve setting.

Table 6-30 Operate-Curve Settings of the 3 Stages

Negative Active-Power Jump	Permissible Time Delay
-40 %	0.30 s
-50 %	0.20 s
-65 %	0.15 s

NOTE

Set the **Threshold dP1<** parameter to the smallest value of the characteristic curve.

6.68 Inrush-Current and 2nd Harmonic Detection

6.68.1 Inrush-Current Detection

6.68.1.1 Overview of Functions

The function **Inrush-current detection**

- Recognizes an inrush process on transformers
- Generates a blocking signal for protection functions that protect the transformer (protected object) or for protection functions that are affected in undesirable ways when transformers are switched on
- Allows a sensitive setting of the protection functions

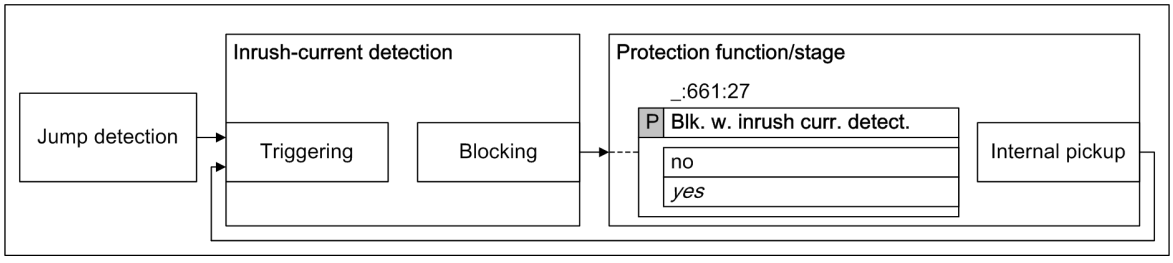
The following protection functions evaluate the blocking signal

- Overcurrent protection with a pickup value below the maximum inrush current
- Negative-sequence protection as sensitive backup protection for transformers
- Distance protection for impedance stages graded through the transformer

NOTE

The Transformer differential protection has its own inrush-current detection.

You can find more information in chapter *6.2.3.6 Differential Protection Function (I-DIFF)* under the section *Inrush-Current Detection*.



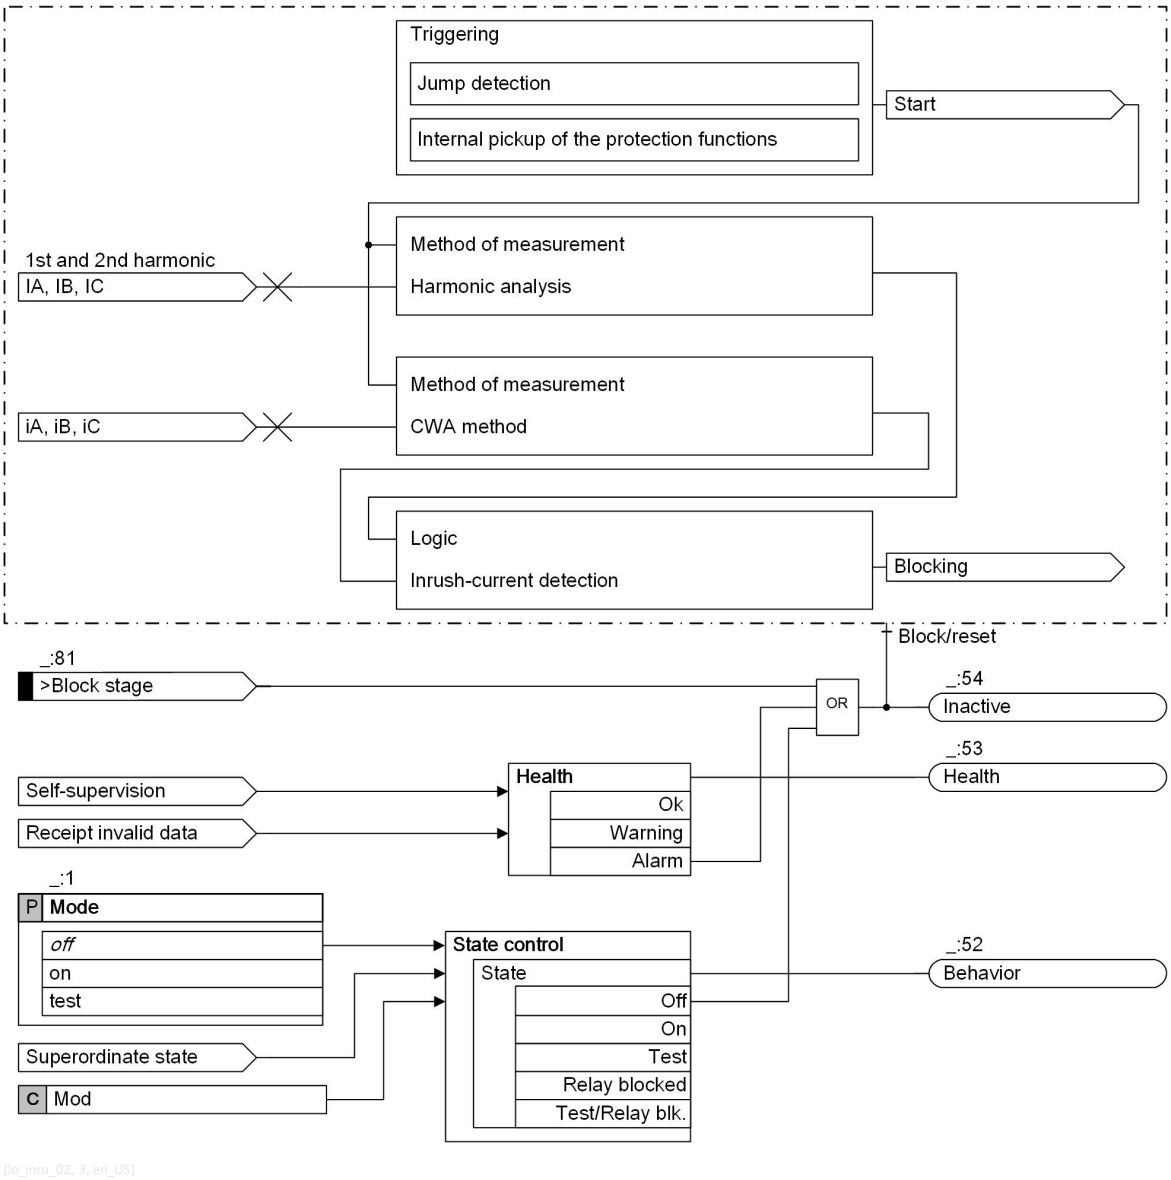
6.68.1.2 Structure of the Function

The function **Inrush-current detection** is not an individual protection function. In the connection process of a transformer, it transmits a blocking signal to other protection functions. For this reason, the inrush-current detection must be in the same function group as the functions that are to be blocked.

The following figure shows the embedding of the function. The setting parameter **`Blk. w. inrush curr. detect.`** establishes the connection between inrush-current detection and the functions that are to be blocked. If the parameter is set to ***`yes`***, the connection is effective.

A jump detection or the threshold value exceeding of the functions to be blocked is used as trigger signal for synchronization of the internal measurement methods.

The jump detection reacts to changes in the current. The threshold value exceeding is recognized due to an internal pickup of the protection function that is to be blocked.



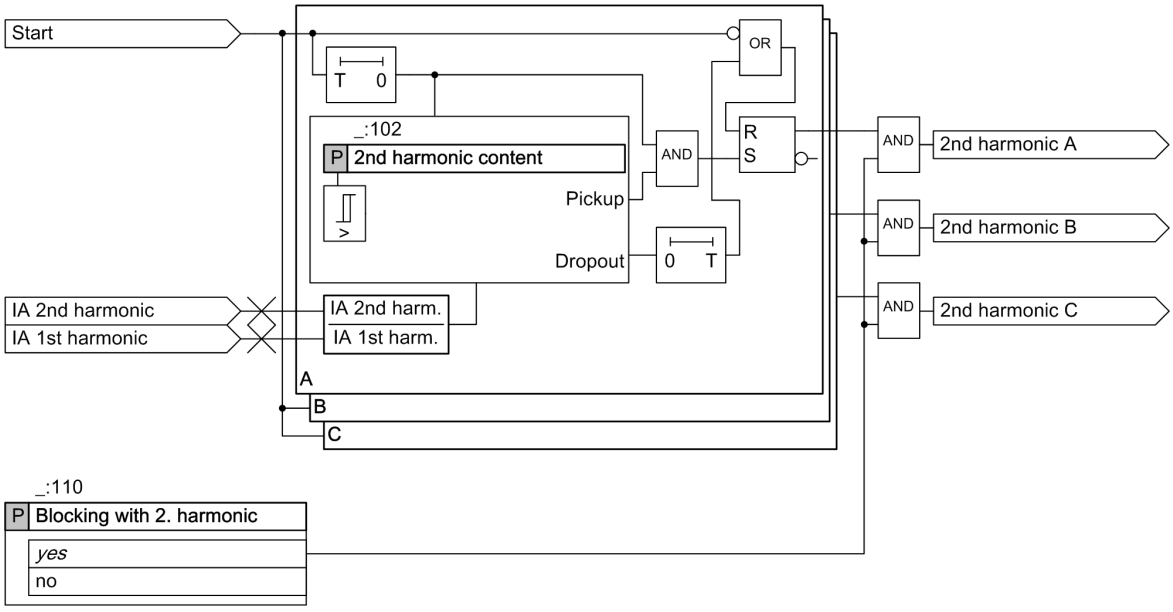
[dw_irsh01, 1, en_US]

Figure 6-681 Structure/Embedding of the Function

6.68.1.3 Function Description

The function **Inrush-current detection** analyzes the trigger signal of the jump detection or the threshold-value violation of the function to be blocked in a start logic and synchronizes the method of measurement. In order to securely record the inrush processes, the function uses the methods of measurement **Harmonic Analysis** and the **CWA method** (current wave shape analysis). Both methods work in parallel and link the results with a logical OR.

If you wish to work with only one process, deactivate the other method by way of the parameters **`Blocking with 2. harmonic`** or **`Blocking with CWA`** .

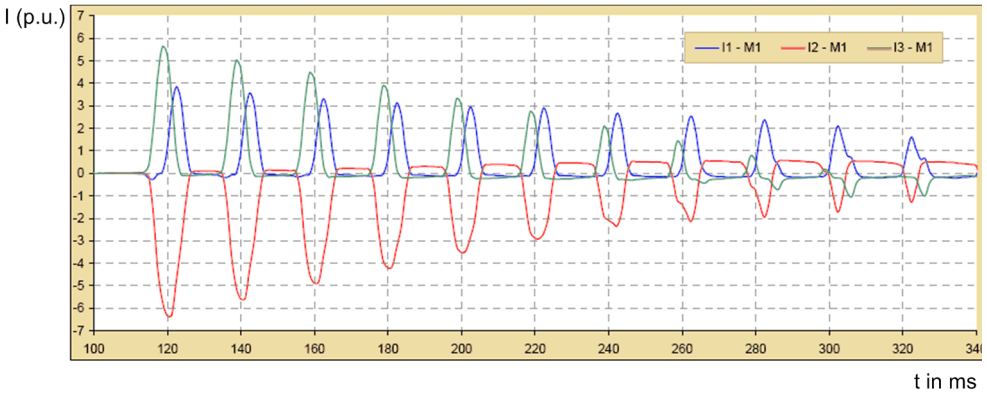


[lo_inru_02, 3, en_US]

Figure 6-682 Basic Structure of the Inrush-Current Detection

Harmonic Analysis

For this method of measurement, the content of the 2nd harmonic and the fundamental component (1st harmonic) are determined for each of the phase currents I_A, I_B, and I_C and the quotient $I_{2nd\ harm}$ / $I_{1st\ harm}$ is formed from this. If this quotient exceeds the set threshold value, a phase-selective signal is issued.
If 75 % of the set threshold value is exceeded, this leads to a pickup reset (dropout ratio = 0.75).

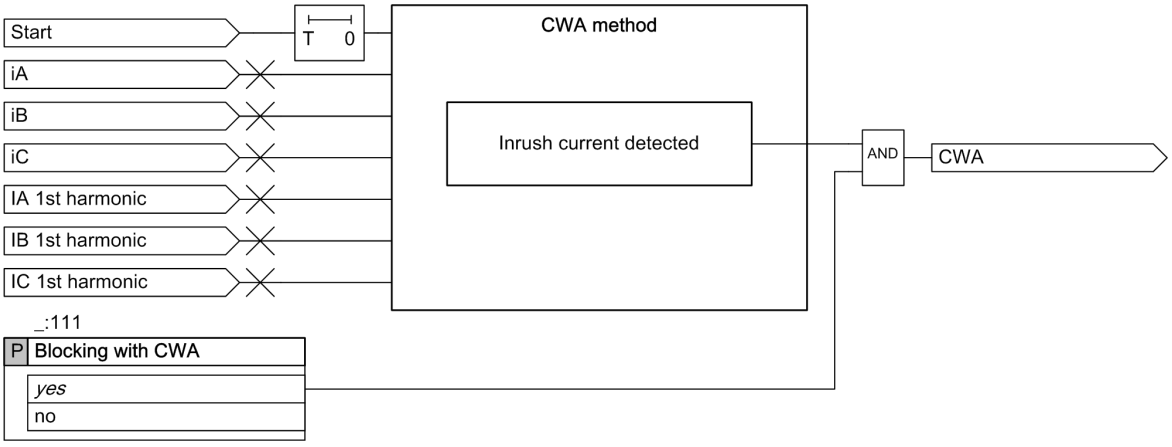


[lo_inrush_10, 1, en_US]

Figure 6-683 Logic of the Harmonic Analysis Function (T = 1 Period)

CWA Method (Current Wave Shape Analysis)

The CWA method executes a wave shape analysis of the phase currents IA, IB, and IC. If all 3 phase currents show flat areas at the same point in time, the inrush-current detection signal will be issued. This signal applies for all 3 phases simultaneously. The following figure shows a typical inrush-current characteristic, with the simultaneously occurring flat areas clearly recognizable.



[dw_inrush_03, 1, en_US]

Figure 6-684 Inrush-Current Characteristic

The following figure shows the logic diagram of the CWA method.

From the present fundamental-component current (1st harmonic), the threshold value for identification of the flat areas is derived via an internal factor.

[lo_inrush_05, 1, en_US]

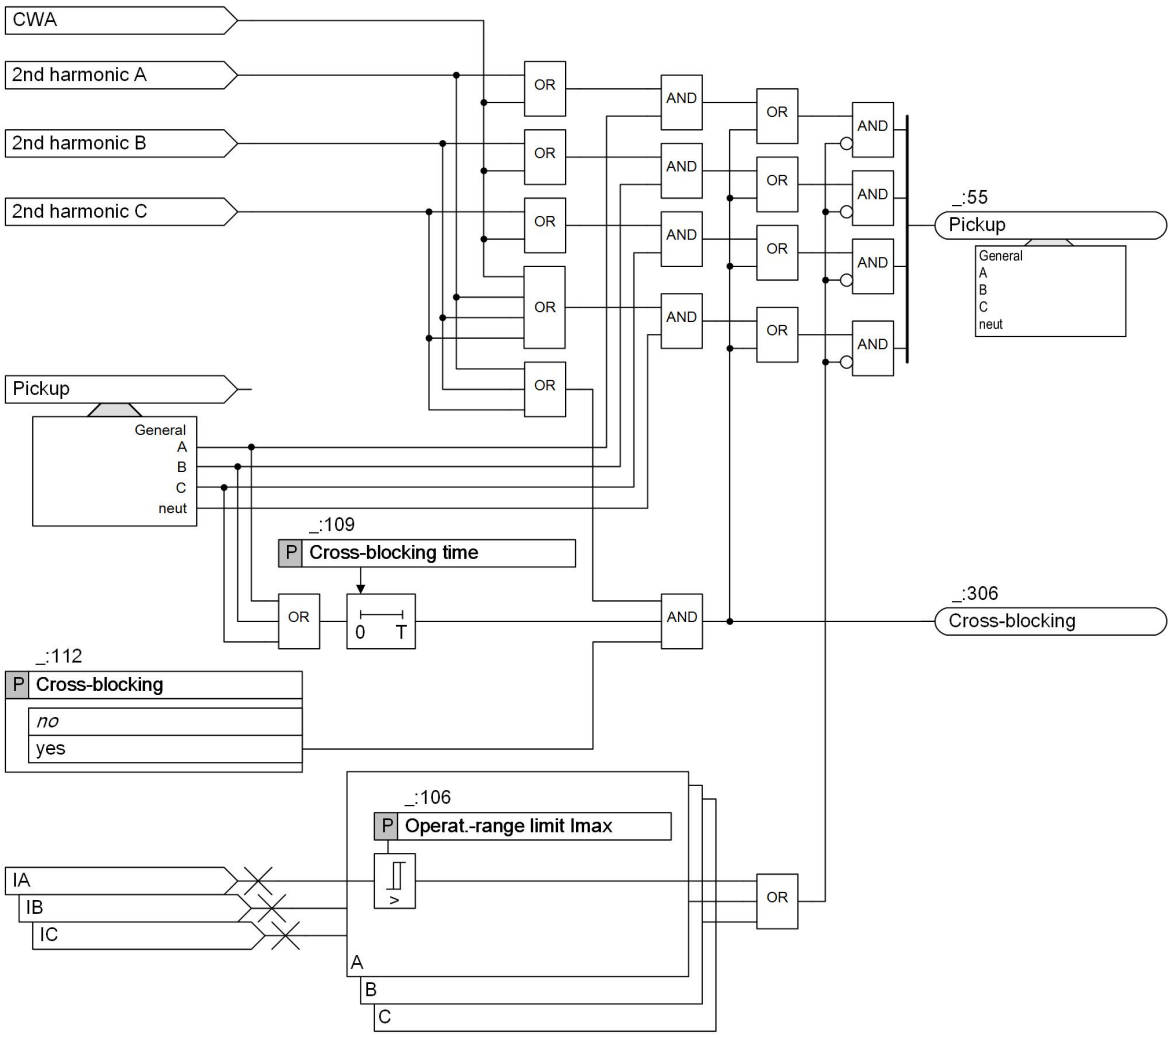


Figure 6-685 Logic of the CWA-Method Function (T = 1 Period)

Logic of the Inrush-Current Detection

The following logic diagram shows the link of the 2 methods of measurement **Harmonic Analysis** and **CWA method**.

The crossblock function influences the **Harmonic Analysis** process. If you have set the parameter **`Cross-blocking`** to ***`yes`***, you will receive a blocking indication in the event of threshold-value violation for all 3 phase currents and the measured or calculated zero-sequence current ($I_{2nd\ harm}$ / $I_{1st\ harm}$). The crossblock function works via a timer. Set parameters for time depending on the expected duration factor via the parameter **`Cross-blocking time`**.

If the phase current exceeds the maximum permissible current **`Operat.-range limit Imax`**, the inrush-current detection will be blocked.

[lo_inrush_12_2_en_US]

Figure 6-686 Logic Diagram of the Inrush-Current Detection

6.68.1.4 Application and Setting Notes

Parameter: Operat.-range limit Imax

- Recommended setting value **(_:106) Operat.-range limit Imax** = ***7.5 A***

  With the parameter **Operat.-range limit Imax**, you can specify at which current the inrush-current detection is blocked internally. Set the value to be greater than the RMS value of the maximum inrush current of the transformer. A practicable value is 7.5 times the transformer rated current.

Parameter: Blocking with CWA

- Recommended setting value = **(_:111) Blocking with CWA** = ***yes***

Parameter Value	Description
yes	**CWA process** activated.
no	**CWA process** deactivated.

Parameter: Blocking with 2. harmonic

- Recommended setting value **(_:110) Blocking with 2. harmonic** = ***yes***

Parameter Value	Description
yes	**Harmonic analysis** process activated.
no	**Harmonic analysis** process deactivated.

NOTE

Make sure that at least one process is activated. Siemens recommends retaining the advised setting values.

Parameter: 2nd harmonic content

- Recommended setting value **(_:102) 2nd harmonic content** = ***15 %***
  With the parameter **2nd harmonic content**, you can specify the pickup value of the harmonic analysis function. The setting value of 15 % is practicable for most transformers.

Parameter: Cross-blocking

- Recommended setting value **(_:112) Cross-blocking** = ***no***

Parameter Value	Description
no	Through the CWA process working in parallel in the inrush-current detection, the function is not activated as standard.
yes	If a subfunction of the inrush-current detection is identified in the course of the closure trials during commissioning, set the parameter **Cross-blocking** to ***yes***.

Parameter: Cross-blocking time

- Default setting **(_:109) Cross-blocking time** = ***0.06 s***
  You define the duration of this blocking with the **Cross-blocking time** parameter. The default setting of ***0.06 s*** (about 3 periods) has proven practicable. Set the time as short as possible and check the value during the closure trials. The parameter **Cross-blocking time** is inactive at **Cross-blocking** = ***no***.

Parameter: Start flt.rec

- Default setting **(_:114) Start flt.rec** = ***yes***
  With the **Start flt.rec** parameter, you determine whether a fault record should be started upon pickup of the inrush-current detection. The following settings are possible:

Parameter Value	Description
no	No fault recording starts with pickup.
yes	The fault recording starts with pickup. When the protection function is blocked by the inrush-current detection, a fault recording is started nevertheless.

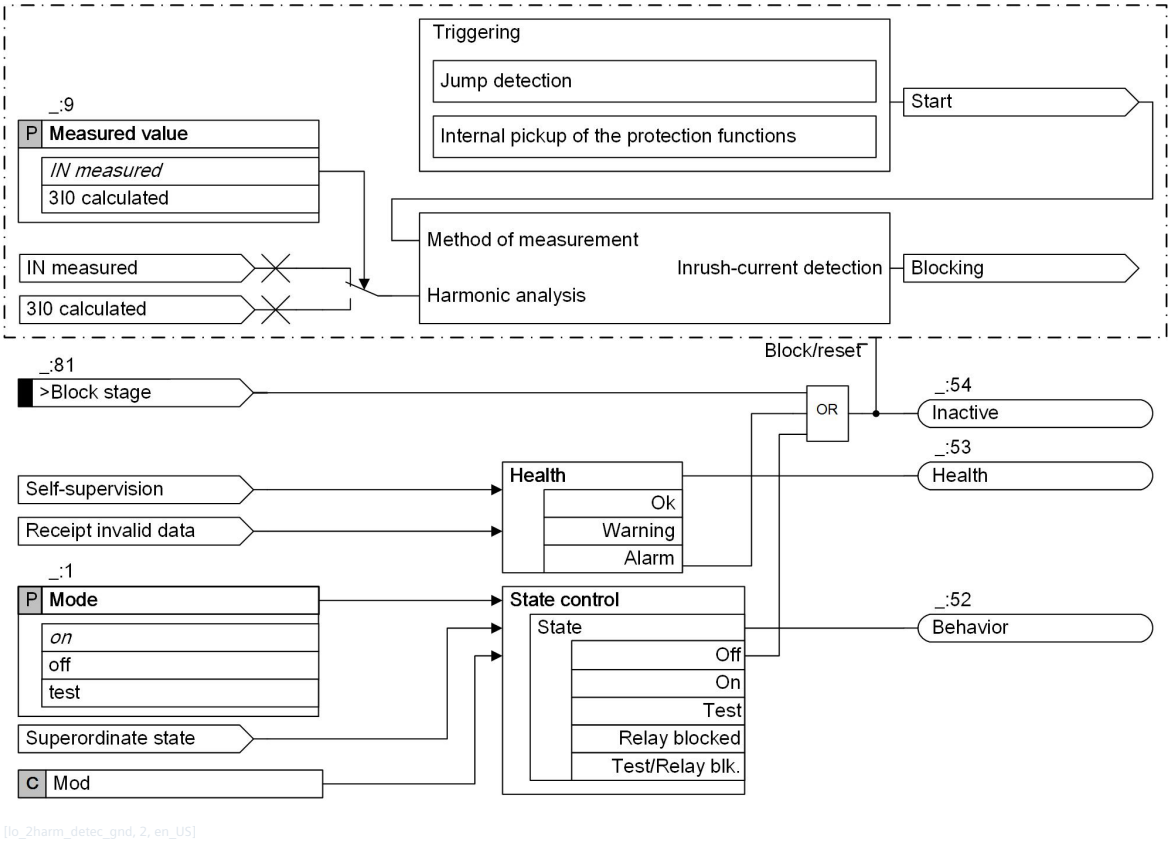
6.68.2 2nd Harmonic Ground Detection

6.68.2.1 Overview of Functions

The **2nd harmonic to ground detection** function:

- Detects the content of 2nd harmonics in the neutral-point phase current **IN** or in the calculated zero-sequence current **3I0**.
- Generates a blocking signal for protection functions that use the neutral-point phase current **IN** or the calculated zero-sequence current **3I0** as a measured value
- Allows a sensitive setting of the protection functions

The following protection functions analyze the blocking signal:



- Overcurrent protection, ground
- Directional sensitive ground-fault detection
- Non-directional sensitive ground-fault detection

6.68.2.2 Structure of the Function

The **2nd harmonic ground detection** function is not an autonomous protection function. In the connection process of a transformer, it sends a blocking signal to other protection functions. For this reason, the **2nd harmonic ground detection** function must be in the same function group as the functions that are to be blocked.

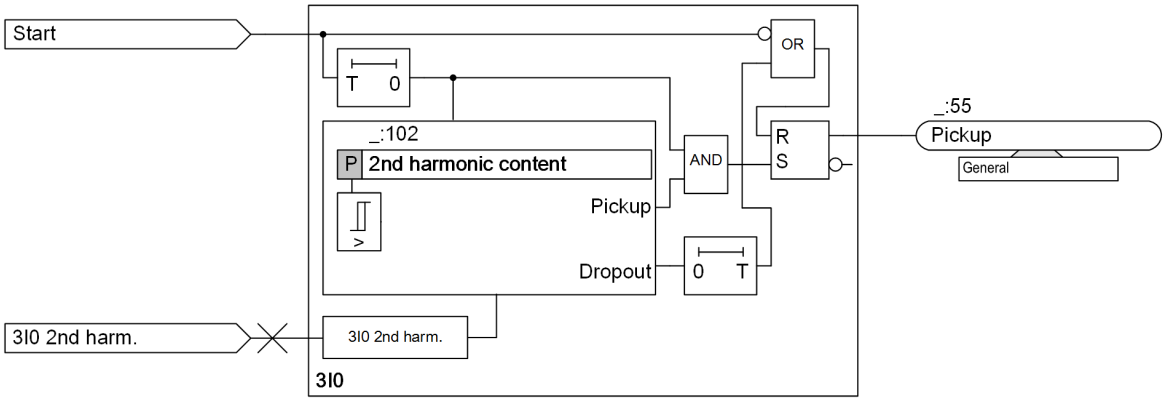
6.68.2.3 Function Description

Logic

[lo_2harm_detec_gnd, 2, en_US]

Figure 6-687 Logic of 2nd Harmonic Detection Ground

Harmonic Analysis



For this method of measurement, the content of the 2nd harmonic and the fundamental component (1st harmonic) is determined for the neutral-point phase current **IN** or the calculated zero-sequence current **3I0** and the quotient $I_{2nd\ harm}/I_{1st\ harm}$ is formed from this. If this quotient exceeds the set threshold value, a blocking signal is issued.

NOTE

During a transformer saturation, the high content of the 2nd harmonic in the ground current must not lead to a pickup of the function.

NOTE

If the ground current is measured in case of a sensitive transformer and the measured value exceeds the saturation threshold of 1.6 · IN, the function switches to the calculated 3I0 value.

[lo_harmon-analyse, 1, en_US]

Figure 6-688 Logic of the Harmonic Analysis Function

6.68.2.4 Application and Setting Notes

Parameter: Measured value

- Default setting = **(_:9) Measured value** = ***IN measured***

Parameter Value	Description
IN measured	The function evaluates the measured neutral-point phase current **IN**.
3I0 calculated	The function evaluates the calculated zero-sequence current **3I0**.

Parameter: 2nd harmonic content

- Default setting **(_:102) 2nd harmonic content** = ***15 %***

With the parameter **2nd harmonic content**, you can specify the percentage content of the 2nd harmonic in ***IN measured*** or in ***3I0 calculated*** at which the inrush-current detection is blocked internally.

6.68.3 2nd Harmonic Detection 1-Phase

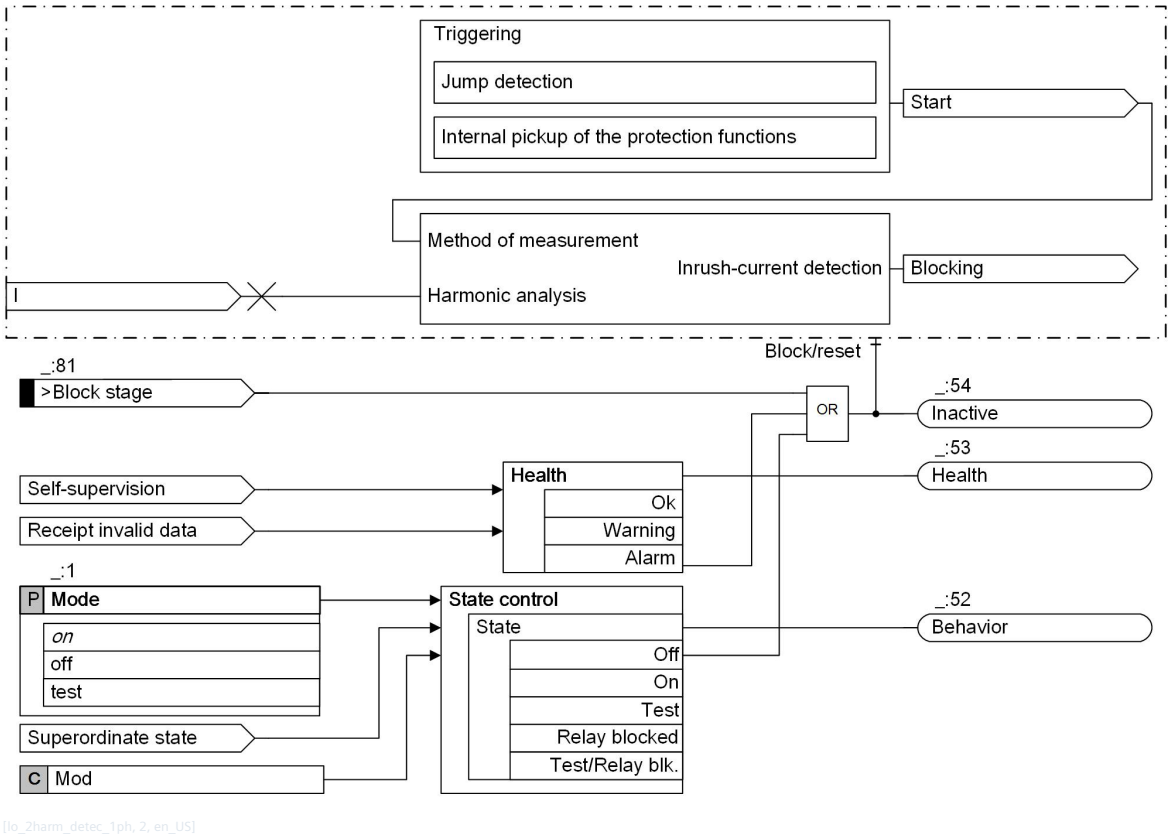
6.68.3.1 Overview of Functions

The **2nd harmonic detection 1-phase** function:

- Detects the content of 2nd harmonics of a 1-phase current
- Generates a blocking signal for protection functions that use this 1-phase current as a measured value
- Allows a sensitive setting of the protection functions

The following protection functions analyze the blocking signal:

- Overcurrent protection, 1-phase



6.68.3.2 Structure of the Function

The function **2nd harmonic detection 1-phase** is not an autonomous protection function. In the connection process of a transformer, it sends a blocking signal to other protection functions. For this reason, the function **2nd harmonic detection 1-phase** must be instantiated in the same function group as the function **Inrush-current detection** and the functions that are to be blocked.

If the function **2nd harmonic detection 1-phase** and the functions to be blocked are not instantiated in the same function group, you must interconnect the protection function groups. Interconnect the protection function groups in the DIGSI 5 **Project tree > Function-group connections > Protection-FG <-> Protection-FG**.

6.68.3.3 Function Description

Logic

[lo_2harm_detec_1ph, 2, en_US]

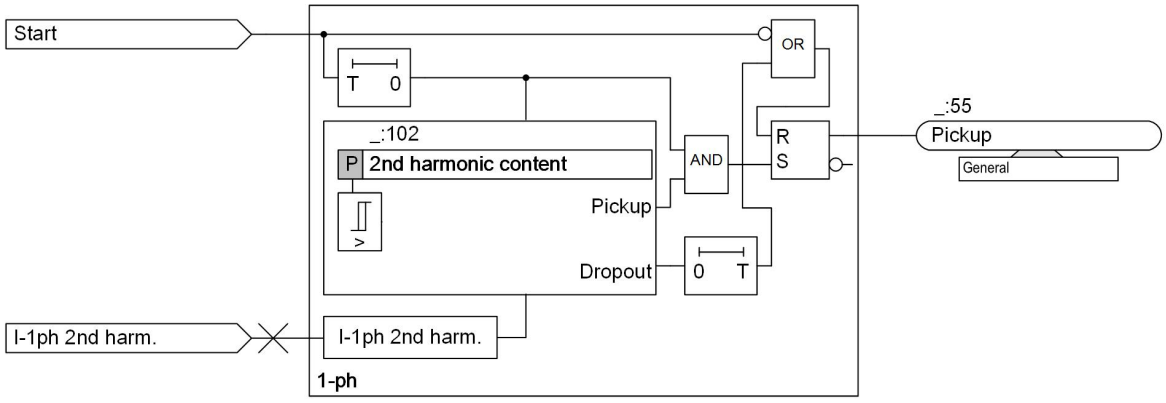


Figure 6-689 Logic of 2nd Harmonic Detection 1-Phase

Harmonic Analysis

For this method of measurement, the content of the 2nd harmonic and the fundamental component (1st harmonic) is determined for the 1-phase current and the quotient $I_{2nd\ harm}/I_{1st\ harm}$ is formed from this. If this quotient exceeds the set threshold value, a blocking signal is issued.

NOTE

During a transformer saturation, the high content of the 2nd harmonic in the 1-phase current must not lead to a pickup of the function.

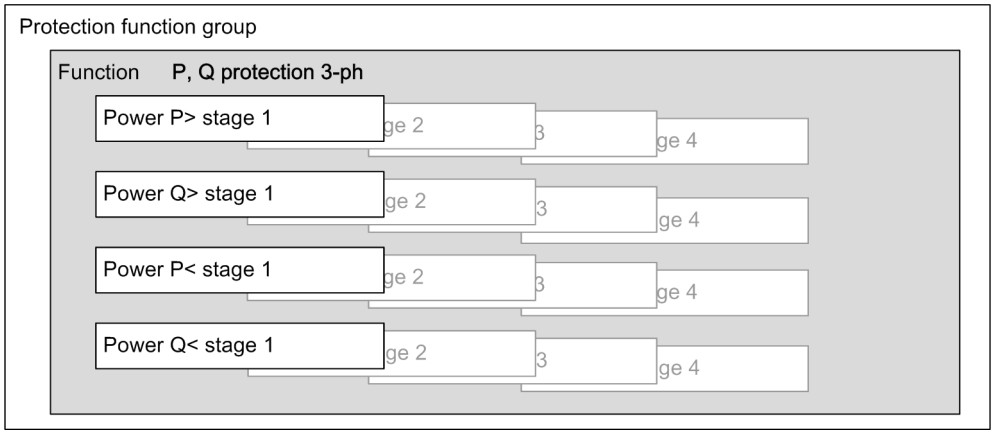
6.69 Power Protection (P,Q), 3-Phase

6.69.1 Overview of Functions

The **3-phase power protection (P, Q)** function (ANSI 32) is used to:

- Detect whether the active or reactive power rises above or drops below a set threshold
- Monitor agreed power limits and output warning indications
- Detect both active and reactive power feedback in the power systems or on electric machines
- Detect machines (motors, generators) running without load and output an indication to shut them down.
- Be integrated into any automation solution, for example, to monitor very specific power limits (further logical processing in CFC)



6.69.2 Structure of the Function

The **3-phase power protection (P, Q)** function can be integrated in function groups, which provide measured voltages and currents of the 3-phases for calculation of the power.

The **3-phase power protection (P,Q)** function comes with one factory-set stage each for the active and the reactive power. The following stages are preconfigured:

- Power P>
- Power Q>
- Power P<
- Power Q<

A maximum of 4 active power stages and 4 reactive power stages can be operated simultaneously in the function. The tripping stages have an identical structure.

[dw_GPP 3-phase structure, 2, en_US]

Figure 6-691 Structure/Embedding of the Function

Logical Combination of Output Signals

The operate indications of the active and reactive power stage(s) can be logically combined in CFC. When an operate indication is present in both the active and the reactive power stage, an alarm indication is generated.

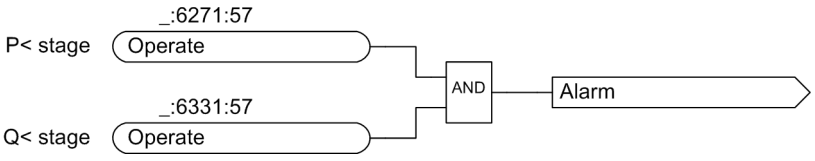


Figure 6-692 Logical Combination of Operate Indications in CFC

6.69.3 Active Power Stage

Logic of a Stage

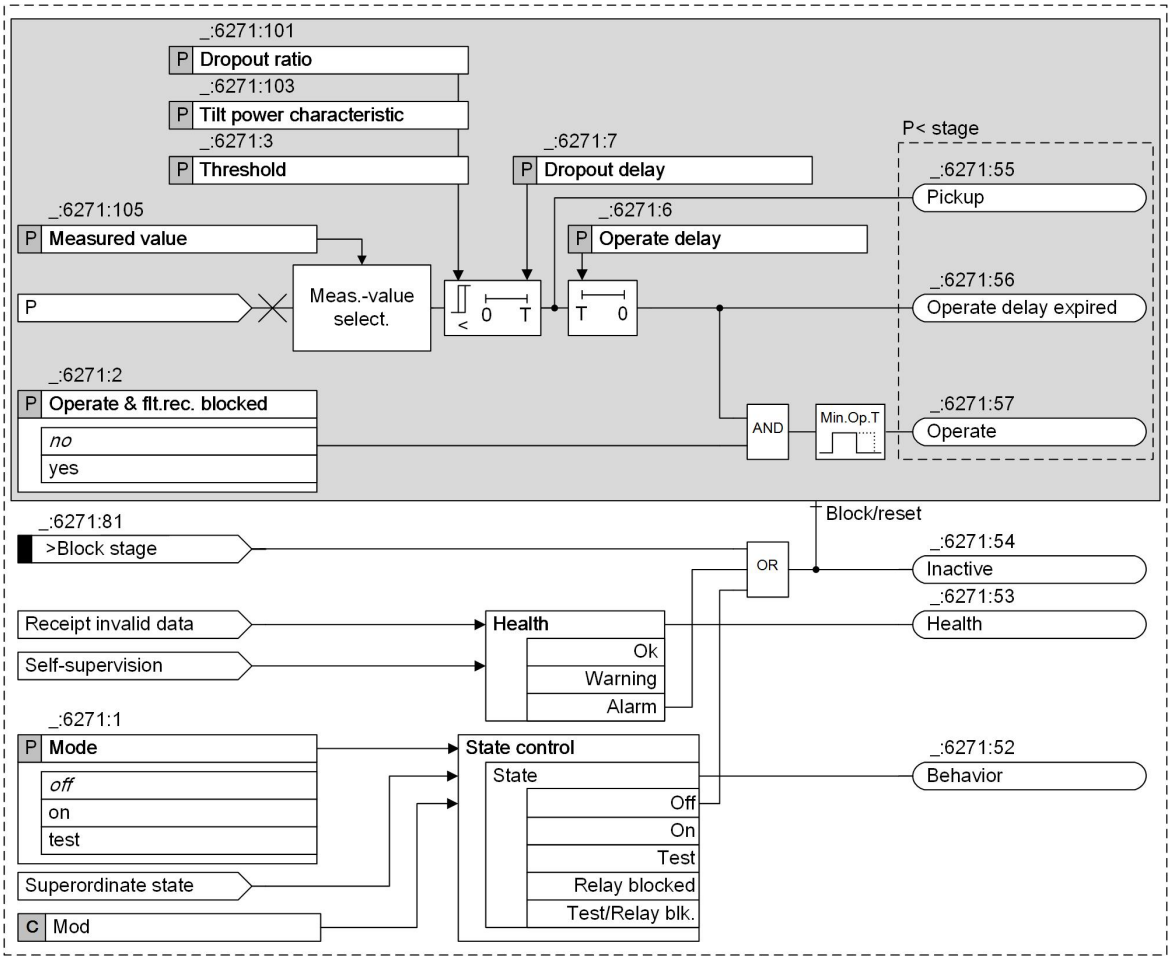

Figure 6-693 Logic Diagram of the Active Power Stage (Stage Type: Power P<)

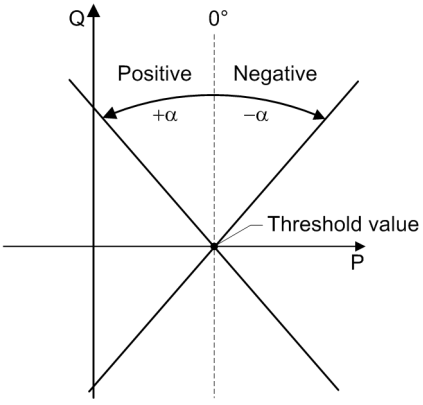


Measured Value

The **Measured value** parameter is used to specify which measured power value is analyzed by the tripping stage. Possible settings are ***positive seq. power*** and the phase-selective powers ***power of phase A***, ***power of phase B*** or ***power of phase C***.

Pickup Characteristic

With the stage type you specify if the stage work as a **greater stage** (stage type: **Power P>**) or as a **smaller stage** (stage type: **Power P<**).

The **Threshold** parameter is used to define the pickup threshold of the stage. The **Tilt power characteristic** parameter is used to define the tilt of the pickup characteristic. The figure below shows the definition of the signs.

[dw_tilt-power active power, 2, en_US]

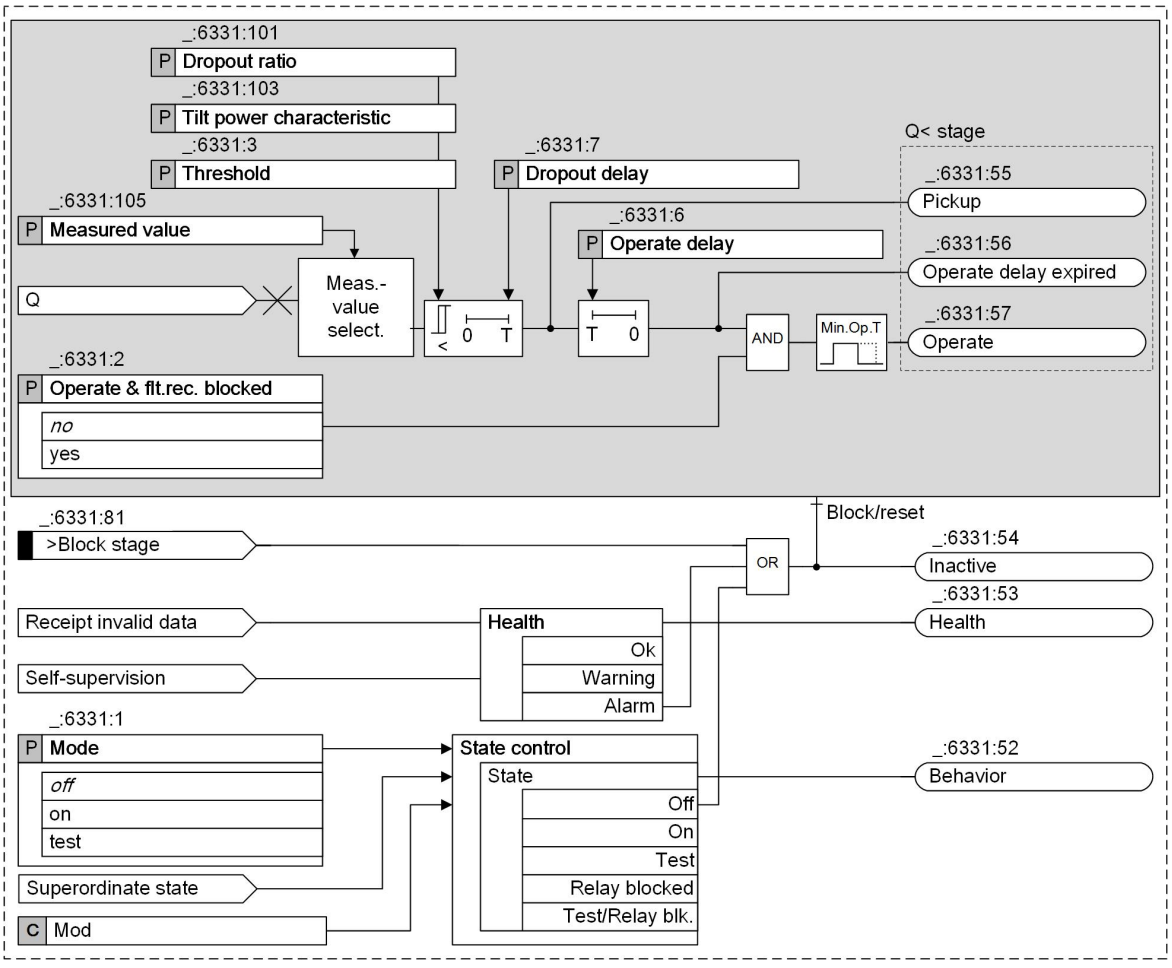
Figure 6-694 Tilt-Power Characteristic

Pickup

The stage compares the selected power value with the set **Threshold**. Depending on the stage type (**Power P>** or **Power P<**) being above or falling below the threshold value will lead to a pickup.

Dropout Delay

A delay can be set for the dropout when the measured value falls below the dropout threshold. The pickup is maintained for the specified time. The time delay of the tripping (parameter **Operate delay**) continues to run. Once the **Operate delay** has elapsed, the stage trips.



Blocking the Stage

In the event of blocking, a picked-up stage is reset. The following blocking options are available for the stage:

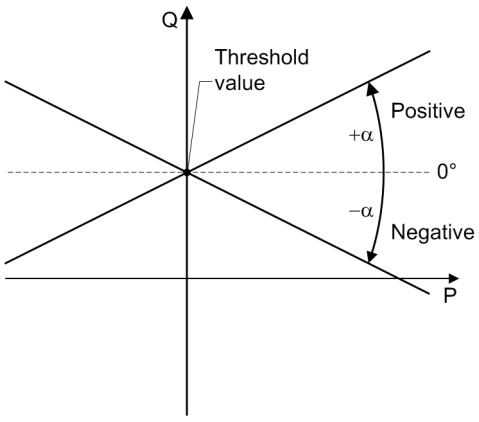
- Internally or externally via the binary input signal *>Block stage*
- The frequency is less than or equal to 10 Hz.

6.69.4 Reactive Power Stage

Logic of a Stage

[lo_3phase reactive power, 3, en_US]

Figure 6-695 Logic Diagram of the Reactive Power Stage (Stage Type: Power Q<)



Measured Value

The **Measured value** parameter is used to specify which measured power value is processed by the tripping stage. Possible settings are ***positive seq. power*** and the phase-selective powers ***power of phase A***, ***power of phase B*** or ***power of phase C***.

Pickup Characteristic

With the stage type you specify if the stage work as a **greater stage** (stage type: **Power Q>**) or as a **smaller stage** (stage type: **Power Q<**).

The **Threshold** parameter is used to define the pickup threshold of the stage. The **Tilt power characteristic** parameter is used to define the tilt of the pickup characteristic. The figure below shows the definition of the signs.

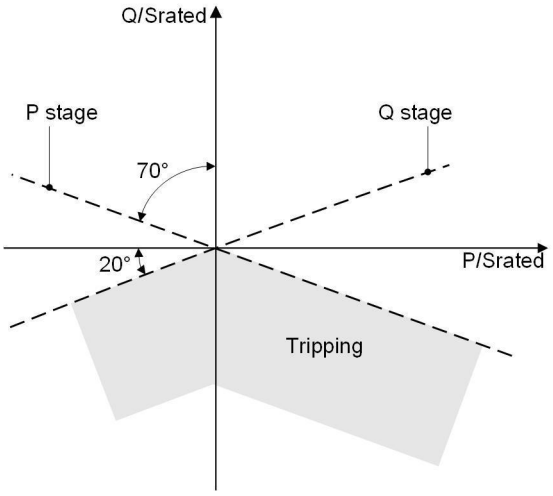
[dw_tilt-power reactive power, 2, en_US]

Figure 6-696 Tilt-Power Characteristic

Pickup

The stage compares the selected power value with the set **Threshold**. Depending on the stage type (**Power Q>** or **Power Q<**) being above or falling below the threshold value will lead to a pickup.

Dropout Delay



A delay can be set for the dropout when the measured value falls below the dropout threshold. The pickup is maintained for the specified time. The time delay of the tripping (parameter **Operate delay**) continues to run. Once the **Operate delay** has elapsed, the stage trips.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking the stage is possible externally or internally via the binary input signal *>Block stage*.

6.69.5 Application Example

The setting of the function will be explained using an active/reactive power range as an example. If the apparent power phasor is within the power range (in *Figure 6-697* tripping zone defined by characteristics), an alarm indication is generated. For this purpose, you have to make an AND operation of the stage indications of the active and reactive power stage in CFC. The function used is 3-phase power measurement. *Figure 6-697* shows the threshold values and the location of the characteristics in the PQ diagram.

[dw_GPP PQ diagram, 2, en_US]

Figure 6-697 Pickup Values and Characteristic Curves

6.69.6 Setting Notes for the Active Power Stage

Stage Type

In the following example, a drop of the active power below a threshold is to be monitored. In the **3-phase circuit breaker (P, Q)** function, work with the stage type **Power P<**.

Parameter: Measured value

- Recommended setting value **(_:6271:105) Measured value** = ***positive seq. power***

The **Measured value** parameter is used to specify which measured power value is evaluated. For 3-phase measurement, Siemens recommends to evaluate the positive-sequence system power.

Parameter: Threshold

- Recommended setting value **(_:6271:3) Threshold** = ***0 %***

The **Threshold** parameter is used to define the pickup threshold of the active power stage. In the example, the pickup characteristic runs across the point of origin of the coordinates. Set the parameter **Threshold** to ***0 %***.

NOTE

If you use several settings groups, consider the following:

- The threshold of a stage must have the same sign in all settings groups.
- Switching from a positive threshold to a negative threshold or vice versa is not allowed. As a result, DIGSI reports an inconsistency.
- If you want to change the sign of the threshold of a stage in an additional settings group, instantiate a new stage and enable it. If the new stage should not be effective in another settings group, disable the stage there.

Parameter: Dropout ratio

- Recommended setting value **(_:6271:101) Dropout ratio** = ***1.05***

A hysteresis of 5 % is sufficient for most applications. The setting value for the **lower stage** is therefore 1.05.

Parameter: Tilt power characteristic

- Recommended setting value **(_:6271:103) Tilt power characteristic** = ***+70°***

The **Tilt power characteristic** parameter is used to incline the pickup characteristic. In the above example, an inclination is required. The setting value is ***+70°*** (for a definition of the sign, see *Figure 6-694*).

Parameter: Dropout delay

- Recommended setting value **(_:6271:7) Dropout delay** = ***20 ms***

The **Dropout delay** parameter maintains the pickup even if the measured value drops momentarily below the threshold value. A delay is required for very low pickup values to prevent a so-called chattering of the function. In the example, the setting value is 20 ms.

Parameter: Operate delay

- Recommended setting value **(_:6271:6) Operate delay** = ***100 ms***

The **Operate delay** must be set for the specific application. In the example, a setting value of 100 ms has been selected.

6.69.7 Setting Notes for the Reactive Power Stage

Stage Type

In the example, the reactive power is to be monitored if it falls below the threshold. In the **3-phase circuit breaker (P, Q)** function, work with the stage type **Power Q<**.

Parameter: Measured value

- Recommended setting value **(_:6331:105) Measured value** = ***positive seq. power***

The **Measured value** parameter is used to specify which measured power value is evaluated. For 3-phase measurement, Siemens recommends to evaluate the positive-sequence system power.

Parameter: Threshold

- Recommended setting value **(_:6331:3) Threshold** = ***0 %***

The **Threshold** parameter is used to define the pickup threshold of the reactive power stage. In the example, the pickup characteristic runs across the point of origin of the coordinates. Set the parameter **Threshold** to ***0 %***.

NOTE

If you use several settings groups, consider the following:

- The threshold value of a stage must have the same sign in all settings groups.
- Switching from a positive threshold value to a negative threshold value or vice versa is not allowed. As a result, DIGSI reports an inconsistency.
- If you want to change the sign of the threshold value of a stage in an additional settings group, instantiate a new stage and enable it. If the new stage should not be effective in another settings group, disable the stage there.

Parameter: Dropout ratio

- Recommended setting value **(_:6331:101) Dropout ratio** = ***0.95***

A hysteresis of 5 % is sufficient for most applications. The setting value for the **lower stage** is therefore 0.95.

Parameter: Tilt power characteristic

- Recommended setting value **(_:6331:103) Tilt power characteristic** = ***+20°***

The **Tilt power characteristic** parameter is used to incline the pickup characteristic. In the example (see *Figure 6-697*), the power characteristic has a tilt of 20°. Set the **Tilt power characteristic** parameter to ***+20°*** (for a definition of the sign, see *Figure 6-696*).

Parameter: Dropout delay

- Recommended setting value **(_:6331:7) Dropout delay** = ***20 ms***

The **Dropout delay** parameter maintains the pickup even if the measured value drops momentarily below the threshold value. A delay is required for very low pickup values to prevent a so-called chattering of the function. In the example, the setting value is 20 ms.

Parameter: Operate delay

- Recommended setting value **(_:6331:6) Operate delay** = ***100 ms***

The **Operate delay** must be set for the specific application. In the example, a setting value of 100 ms has been selected.

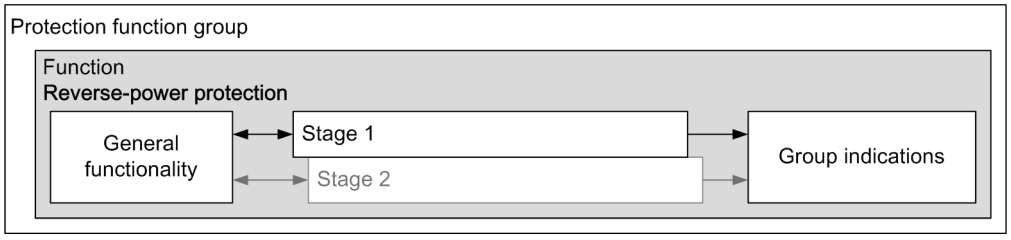
6.70 Reverse-Power Protection

6.70.1 Overview of Functions

The **Reverse-power protection** function (ANSI 32R):



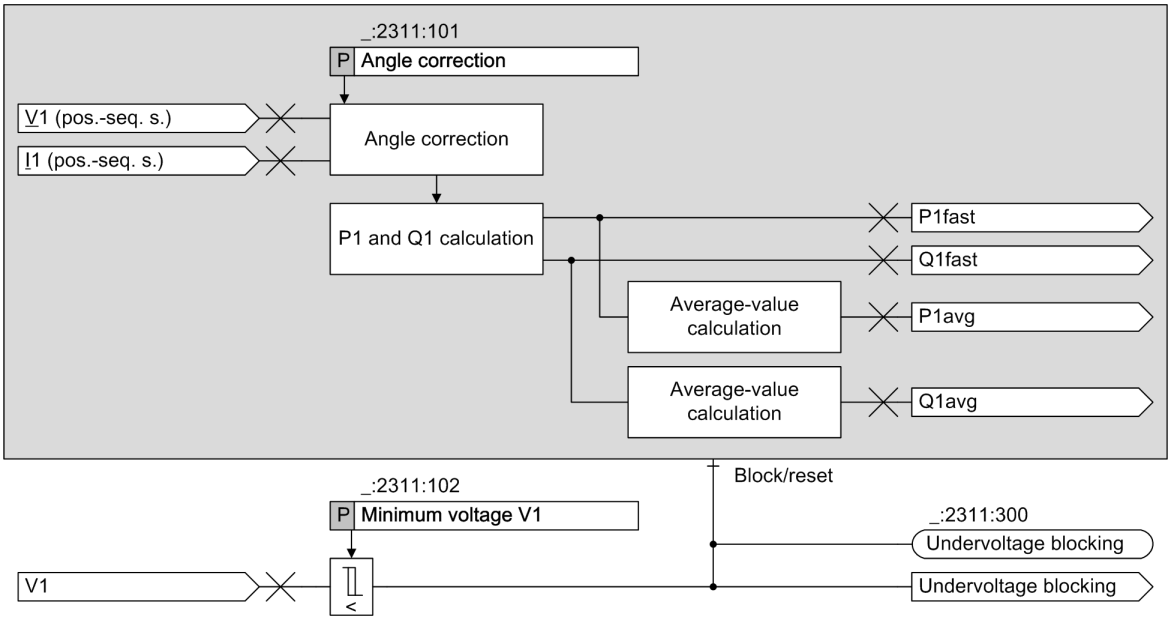
- Monitors the motor operation of generators and thus detects driving-power failure
- Prevents endangering the turbine (e.g. the turbine-blade damage due to overheating) by opening the circuit breaker of the system
- Protects a turbo-generator set

For the generator, there is a danger that the turbo-generator set accelerates and reaches overspeed in case of an incorrect residual-steam passage (quick-stop valves defective) after the circuit breaker has opened. Consequently, disconnecting the system (opening the circuit breaker of the system) shall only occur after reverse power (active-power consumption) has been detected.

6.70.2 Structure of the Function

The **Reverse-power protection** function comes factory-set with 1 stage. A maximum of 2 stages can be operated simultaneously within the function.

In all function groups, the function works with a 3-phase voltage and current interface. Depending on the current transformer used, this is the **Voltage/current 3-phase** function group or the **Generator stator** function group.



[dw_rpp_structure, 3, en_US]

Figure 6-698 Structure/Embedding of the Function

6.70.3 General Functionality

6.70.3.1 Description

Logic of the Function

[lo_RPP general functionality, 2, en_US]

Figure 6-699 Logic Diagram of the Cross-Stage Functionality

Calculating the Reverse Power

The reverse-power protection calculates the active power from the symmetrical components of the fundamental components of the voltages and currents. It generates the average value of the active power over a fixed number of cycles. Since positive-sequence variables are used for evaluation, the reverse power is determined independently of unbalance in currents or voltages. The frequency-tracking sampled values are used for calculation. The determined reverse power corresponds to the load on the driving-power side. The calculated active-power value corresponds to the total active power.

Taking the phase-displacement angle of the voltage and current transformers into account, the function calculates the exact active power even with a high apparent power and a small cos φ. A constant correction angle φ_{corr} makes correction possible. The influence of the current-transformer angle error is predominant here. Determine this constant correction angle when you commission the protection device in the plant and adjust it as specified in the table (see *Table 11-6*).

Power Calculation and Angle Correction

To satisfy the high measuring-accuracy requirements, the power measured value is additionally averaged over 16 cycles before it is supplied to the protection function. The active power is calculated from the symmetrical-component vectors of voltage V1 and current I1. The total power is evaluated as power. The complex apparent power results from the following relationship. The real component is the active power:

$\underline{S} = 3\underline{V}_1 \cdot \underline{I}_1^{\,*} = 3V_1\, e^{j\phi V} \cdot I_1\, e^{-j\phi I} = 3V_1\, I_1\, e^{j(\phi V - \phi I)}$

$P = 3V_1\, I_1 \cos(\varphi_V - \varphi_I)$

The angle error between voltage transformer and current transformer has a strong influence on the measuring accuracy. With the parameter **(_:2311:101) Angle correction** , you can correct the angle error. The following 2 methods are possible here:

- Determine the angle error from the transformer test report data. Ask the transformer manufacturer for these values when you order the transformer.
- While the generator is connected to the power system, measure to determine the angle error (see chapter *11.16.2 Primary Test*).

The influence on the power-system voltage makes it very difficult to test high-power generators with a measurement while the generator is connected to the power system. In this case, you must determine the angle error from the transformer test report data (see chapter *6.70.3.2 Application and Setting Notes*). Alternatively, you can use instrument transformers with small angle errors. This is ensured with class 0.2 instrument transformers (voltage and current). The following equation describes the influence of the angle error:

$P = 3V_1\, I_1 \cos(\varphi_V + \varphi_{V,F} - (\varphi_I + \varphi_{I,F})) = 3V_1\, I_1 \cos(\varphi_U - \varphi_I + (\varphi_{V,F} - \varphi_{I,F}))$

The angle error to be corrected results as:

$\phi_{Corr} = \varphi_{V,F} - \varphi_{I,F}$

To rotate in the correct direction, the correction angle is considered with inverted sign inside the unit.

Functional Measured Values

You can use the following functional measured values to check the behavior of the protection function and to support commissioning. The total power is represented as the measured value.

Measured Value	Description	
P1fast	Positive-sequence system active power calculated per cycle	Angle correction influences the measured value
Q1fast	Positive-sequence system reactive power calculated per cycle	Angle correction influences the measured value
P1avg	Positive-sequence system active power calculated from **P1fast** over 16 cycles	Input value for Reverse-power protection
Q1avg	Positive-sequence system reactive power calculated from **Q1fast** over 16 cycles	–

6.70.3.2 Application and Setting Notes

In the general functionality, you can adjust the parameter **(_:2311:101) Angle correction**. The parameter results from the angle error of the primary transformer. In SIPROTEC 5, the input transformers are calibrated so that the angle error is negligible. You can assume an error of < 0.1°. There is no difference between a protection input and an instrument-transformer input.

NOTE

If you use class 0.2 instrument transformers on the primary side to avoid the influence of the angle, you can connect a protection device with a protection current transformer without any problems.

Class 0.2 voltage transformers have a maximum admissible angle error of 10 min (0.17°). The angle error of a class 0.2 measuring current transformer at rated current is approximately 10 min, at 0.2 I_{rated} = 15 min, and at 0.05 I_{rated} = 30 min.

Parameter: Angle correction

- Default setting **(_:2311:101) Angle correction** = 0°

To determine the correction angle via measurement with the primary system, follow the instructions in chapter *11.16.2 Primary Test*.

You can use the method that is explained in the following section to derive the necessary correction angle from the transformer measuring reports.

Example

This example uses a class 0.2 voltage transformer with a rated burden of 45 VA. The following data was taken from the measuring report.

Table 6-31 For Phase A

V/Vn	$S_b = S_{br}$		$S_b = S_{br}/4$	
	ϵ_v [%]	δ_v [min]	ϵ_v [%]	δ_v [min]
0.8	-0.14	0.31	0.16	-0.34
1	-0.15	0.43	0.15	-0.24
1.2	-0.16	0.68	0.14	-0.06

The values resulting for the phases B and C are almost identical.

Furthermore, a termination with a rated burden (other measuring devices are still connected) is assumed so that an angle error of +0.43 min (rated-voltage value) is used as the calculation variable.

A current transformer of type 5PR is used here. This current transformer features a gap that limits the remanence to 10 %. However, this gap results in larger angle errors. The following tables show excerpts from the test reports.

Table 6-32 Phase A

I/I_n [%]	$Sb = S_{br}$ (cos β = 0.8)	
	ϵ_i [%]	δ_i [min]
100	0.314	46.40

Table 6-33 Phase B

I/I_n [%]	$Sb = S_{br}$ (cos β = 0.8)	
	ϵ_i [%]	δ_i [min]
100	0.247	35.10

Table 6-34 Phase C

I/I_n [%]	$Sb = S_{br}$ (cos β = 0.8)	
	ϵ_i [%]	δ_i [min]
100	0.702	41.10

Since the positive-sequence system power is evaluated in the device, take the sign into account when you add the angle errors per phase, and divide the result by 3.

The following value results in this example:

$$\delta_i[\text{min}] = \frac{1}{3}\left(\delta_{i,A} + \delta_{i,B} + \delta_{i,C}\right) = \frac{1}{3}(46.40 + 35.10 + 41.10) = 40.87\ \text{min}$$

The resulting correction angle is:

$$\varphi_{corr}\,[\text{min}] = \varphi_{V,F} - \varphi_{I,F} = 0.43\ \text{min} - 40.87\ \text{min} = -40.44\ \text{min}$$

$$\varphi_{corr}[^\circ] = \frac{\varphi_{corr[\text{min}]}}{60} \cdot 1^\circ = \frac{-40.44}{60} \cdot 1^\circ = -0.674^\circ$$

Set the parameter **(_:2311:101) Angle correction** = ***-0.67***°.

Parameter: **`Minimum voltage V1`**

- Default setting **`(_:2311:102) Minimum voltage V1`** = 5.000 V

With the parameter **`Minimum voltage V1`**, you can limit the operating range of the reverse-power protection. If the positive-sequence voltage falls below the set value, the reverse-power protection is deactivated. If no other restrictions are known, Siemens recommends using the default setting.

6.70.4 Stage Description

6.70.4.1 Description

Logic of the Stage

[lo_RPP stage, 4, en_US]

Figure 6-700 Logic Diagram of the Reverse-Power Protection Stage

Trip Command

To bridge brief power consumption during synchronization or during power swings caused by system incidents, tripping (shutdown of the generator via reverse power) is delayed by a settable time (for example, 10 s).

A brief delay is enough when the quick-stop valve is closed. Couple the position of the quick-stop valve via the binary input signal **>Stop valve closed** . When quick stop is tripped, the short Operate delay thus becomes effective.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. Blocking of the stage is possible externally or internally via the binary input signal **>Block stage** .

6.70.4.2 Application and Setting Notes

If reverse power occurs in a power plant, the turbo-generator set must be disconnected from the electrical power system. Operating the turbine without the minimum steam flow (cooling effect) is dangerous. For a gas turbine cogeneration unit, the motor load can also be too great for the electrical power system.

Parameter: `Threshold`

- Recommended setting value **`(_:991:3) Threshold`** = ***`-1.00 %`***

The friction losses that have to be overcome mainly determine the active power consumed by a turbo-generator set. Depending on the plant, the consumed active power is of the following ranges:

Steam turbines	$P_{reverse}/S_{rated}$ = 1.00 % to 3.00 %
Diesel drives	$P_{reverse}/S_{rated}$ > 5.00 %
Gas turbines	$P_{reverse}/S_{rated}$ = up to 30.00 %

You can measure the reverse power of the turbo-generator set yourself in a primary test by using the protection function. Set the setting value **`P`** $_{reverse}$, for example, to 0.5 times the value of the measured reverse power. This power is shown additionally in the functional measured values in the **Reverse-power protection** function (**`P1avg`**). For large machines with very small reverse power, you must use the angle-error correction option of the current and voltage transformers.

NOTE

In the current-input selection, you can select protection current transformers or instrument transformers on the device side. Since the transformers are calibrated at the factory, there are hardly any differences between the transformers for the **Reverse-power protection** function. You can thus always select device inputs with a protection current transformer.

In contrast, a primary current transformer significantly influences the measuring accuracy via its angle error. The angle error of a class 0.2 instrument transformer is significantly smaller than the angle error of a class 5P protection current transformer. A separate function group is necessary for the connection to an instrument transformer. Use a **Voltage/current 3-phase** function group and load the **Reverse-power protection** function from the library.

Do not connect the **Reverse-power protection** function to a linear core-type transformer (for example, a TPZ type), as these transformers have a large angle error (for example, approx. 180 min).

Parameter: Dropout delay

- Recommended setting value **`(_:991:102) Dropout delay`** = ***`0.00 s`***

With the **`Dropout delay`** parameter, the pickup can be latched. It is necessary to latch the pickup, for example, if leaking steam valves prevent a constant consumed active power, and pickup starts **chattering**.

Parameter: Dropout ratio

- Recommended setting value **`(_:991:4) Dropout ratio`** = ***`0.60`***

The default value is valid for small reverse power values. It can be increased if the active-power consumption is greater. For an active-power setting of -5 %, for example, a **`Dropout ratio`** of about 0.85 is admissible.

Parameter: Operate delay

- Recommended setting value **`(_:991:6) Operate delay`** = ***`10.00 s`***

With reverse power without quick-stop valve, there can be a brief reverse-power consumption after synchronization and during power swings after a system incident (after a 3-phase short circuit, for example). With the parameter **`Operate delay`**, you can bridge the short reverse-power consumption with an operate delay of approximately 10 s.

Parameter: Operate Delay with Quick-Stop Tripping

- Recommended setting value **(_:991:103) Operate delay stop valve** = ***1.00 s***

If a fault leads to quick-stop tripping, the reverse-power protection switches off after quick-stop tripping with a short delay. This is accomplished with an oil-pressure switch or a limit switch at the quick-stop valve. For the tripping, make sure that the reverse power only results from the missing driving power on the turbine side. A tripping delay is necessary to bridge the active-power transient associated with a sudden valve closing operation until a steady-state active-power value is achieved. To do this, set the parameter **Operate delay stop valve** to approximately ***1.00 s*** to ***3.00 s***. For a gas turbine cogeneration unit, set the value to approximately ***0.50 s***.

The set times are additional time delays. These additional time delays do not include the operating times (measurement, relay) of the protection function.

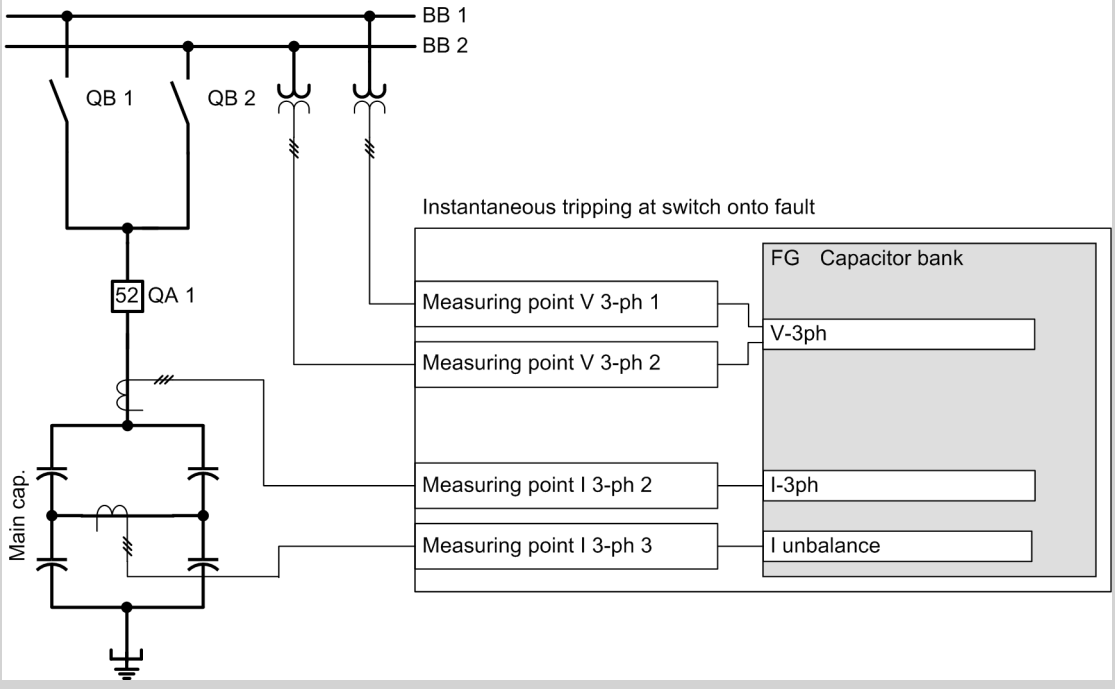
6.71 Voltage Measuring-Point Selection

6.71.1 Overview of Functions

The function block **Voltage measuring-point selection** can:

- Provide the ability to switchover the voltage measuring points to be applied, if various voltage measuring points are connected to the voltage interface of the function group
- Select the correct voltage based on the switch position of the plant

If more than one voltage measuring points are connected to the same voltage interface of the function group, use the **Voltage measuring-point selection** function block in the function group to select the correct voltage based on the switch position of the plant.



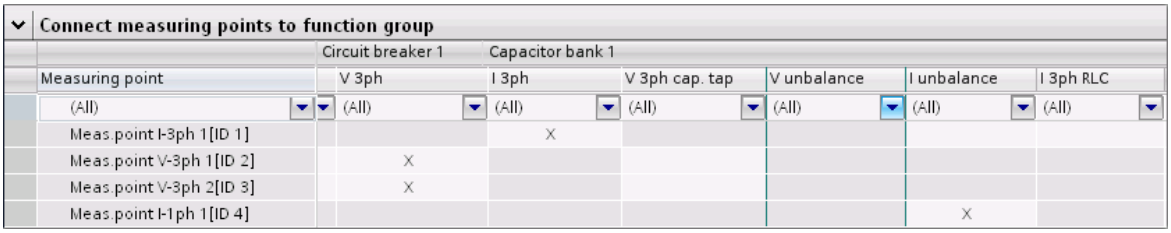
The **Voltage measuring-point selection** is a common functionality for the function groups of the protected objects.

6.71.2 Function Description

The **Voltage measuring-point selection** function block realizes the selection of 1-phase voltage measuring points or of 3-phase voltage measuring points by a logic block chart. The logic block chart controls the input *>MP-ID selection* depending on the switch positions of disconnectors.

Example

Figure 6-701 shows an example of voltage measuring points selection for the function group **Capacitor bank** in a double busbar application.



[dw_busbar_double_2, en_US]

Figure 6-701 Double Busbar with Capacitor Bank

Connecting Measuring Points to Capacitor Bank Function Group

Figure 6-702 shows the connection of the function group **Capacitor bank** with several measuring points in DIGSI. The ID of each measuring point appears in the bracket after the name.

Connect measuring points to function group

	Circuit breaker 1	Capacitor bank 1				
Measuring point	V 3ph	I 3ph	V 3ph cap. tap	V unbalance	I unbalance	I 3ph RLC
(All)	(All)	(All)	(All)	(All)	(All)	(All)
Meas.point I-3ph 1 [ID 1]		X				
Meas.point V-3ph 1 [ID 2]	X					
Meas.point V-3ph 2 [ID 3]	X					
Meas.point I-1ph 1 [ID 4]					X	

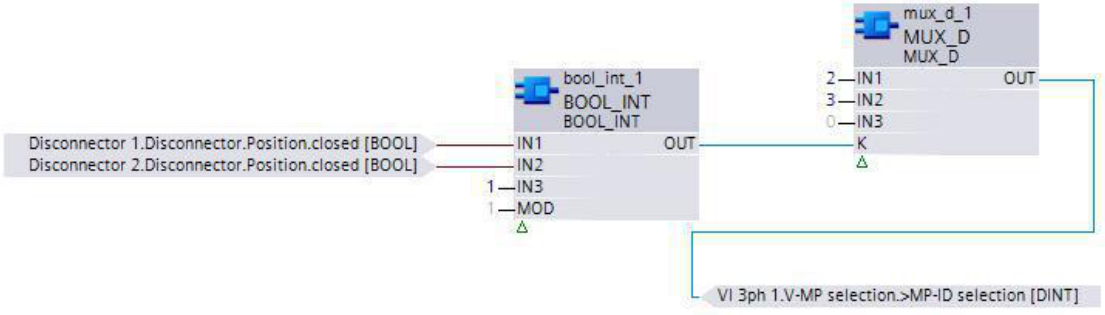
[sc_connection, 1, en_US]

Figure 6-702 Connecting the Measuring Points with the Capacitor Bank Function Group

There are consistency checks that validate the connections of voltage measuring points to the function group:

- The connection type must be identical for all measuring points connected to the same interface of the function group.
- The rated voltage (primary and secondary) must be identical for all measuring points connected to the same interface.
- If more than 1 measuring point is connected to one voltage interface, a function block must be added to enable the selection of the voltage measuring points.

6.71.3 Application and Setting Notes



CFC Control

The voltage measuring point is selected by logic block chart on basis of the measuring point IDs. If more than one measuring point is connected to the interface of the function group, instantiate the function block **Voltage measuring-point selection** from the library in the corresponding function group.

In order to ensure the correct measuring-point connection for the function group, a logic block chart has to define the actual valid IDs for the input *>MP-ID selection* of the function block.

The following logic block chart implementation is based on the example given in *Figure 6-701*.

If the Disconnector 1 (QB1) is closed and no matter what the position the Disconnector 2 (QB2) is, the value 2 is the output of CFC block **mux_d_1** and transferred to the input *>MP-ID selection*. Then, the **Meas.point V-3ph** with ID 2 is selected as the reference voltage. Similarly, the **Meas.point V-3ph** with ID 3 is selected as the reference voltage if the Disconnector 1 (QB1) is not closed (open or in intermediate position) while Disconnector 2 (QB2) is closed.

[sc_lo-cfcVP, 1, en_US]

Figure 6-703 Logic Block Chart: Voltage Selection Using Measuring Point ID

However, the disconnectors might be both open or in a transient state. In this case, the input IN3 of the block **bool_int_1** becomes true, the value 0 is used as the ID for voltage selection input (*>MP-ID selection*). If ID 0 is selected, then all voltage values of the respective function-group interface are set to 0 V immediately. An alarm indication *Selection invalid* is issued and the indication *Health* is issued as *OK*. In case you want to supply the function group with voltage values under the condition that both disconnectors are open or in transient state from one or the other busbar, you can alter the CFC chart respectively.

NOTE

An invalid measuring-point selection (ID < 0 or an ID of a unconnected measuring point) for input *>MP-ID selection* results in the following:

- The voltage measured values are displayed as **failure**.
- The validity of the voltage measured values is set to **invalid**.
- The indication *Health* is set to ***Alarm***.
- The indication *Selection invalid* becomes true.

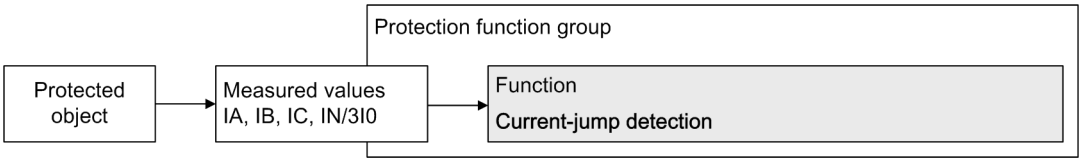
_:301	V-MP selection:Selection invalid	SPS	O

6.72 Current-Jump Detection

6.72.1 Overview of Functions



The **Current jump detection** function has the following tasks:

- Detection of jumps in the phase or zero-sequence current (ΔI)
- Generation of an indication when the measurands change by more than a configured threshold value from one system period to the next.

The function for detecting jumps in the phase or zero-sequence current is an additional function used for indication purposes or for further processing in user-specific CFC logics. Pick up of the function therefore neither opens a separate fault in the fault log nor generates an operate indication.

6.72.2 Structure of the Function

The **Current-jump detection** function is used in protection function groups based on current measurement. It can be instantiated multiple times.

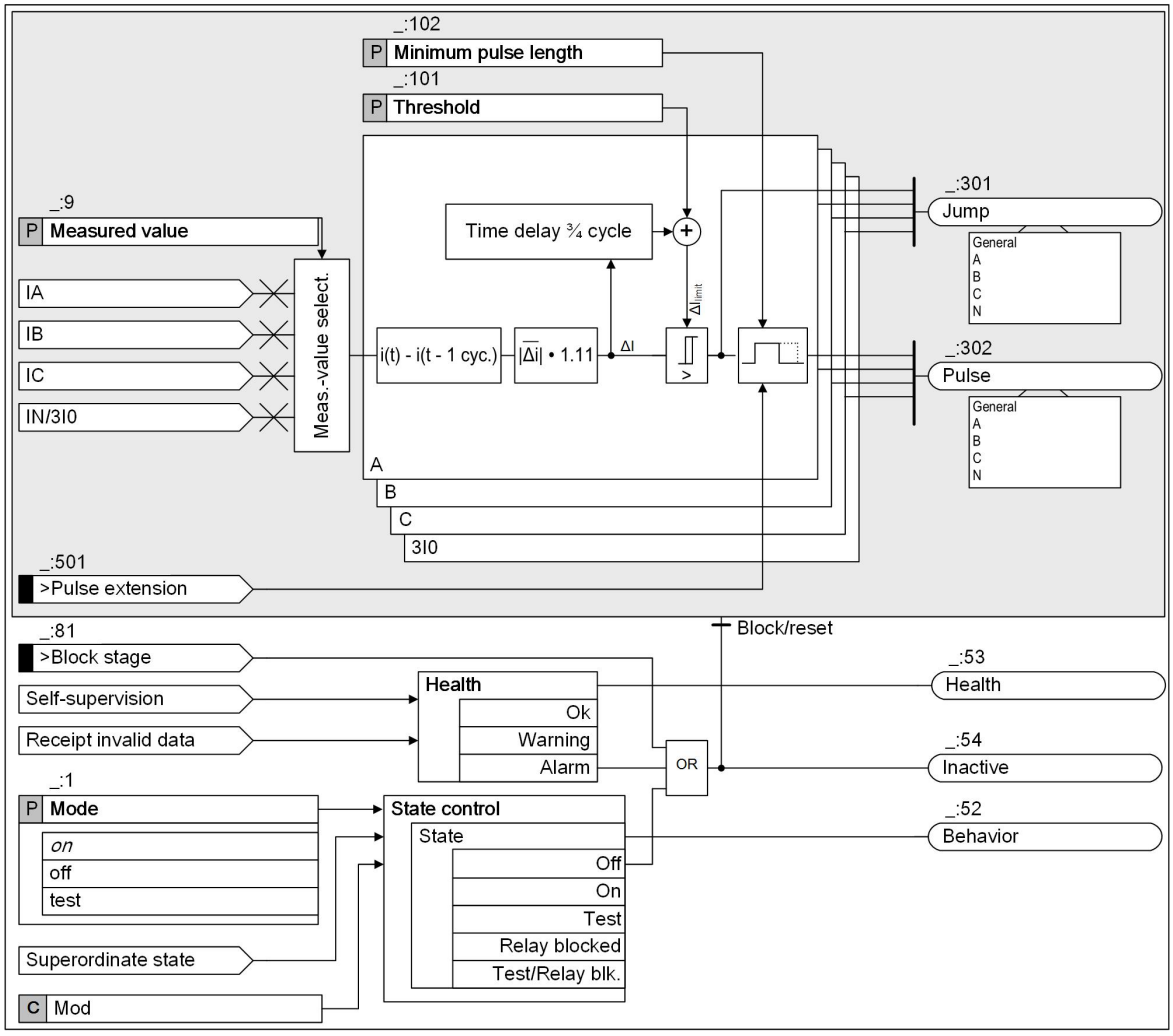
[dw_struki, 1, en_US]

Figure 6-704 Structure/Embedding of the Function

6.72.3 Function Description

Current-jump detection operates directly with the sampled values without numeric filtering. This provides very short response times to sudden changes in the current. The method used is not sensitive to slow changes of amplitude or frequency.

Using a configurable selection of measured values, you can select from 3 line currents or the residual current. Current-jump detection is phase-selective for the line current A, B and C.



The difference from the previous sampled value of the first system cycle is calculated for each sampled value. The rectified average is then determined for a ½ system cycle from this differential signal Δi(t). The rectified average for sinusoidal measurands is then converted to a RMS value ΔI by subsequent multiplication by 1.11. The resultant measurand ΔI is then compared with the threshold value.

If the parameter **(_:101) Threshold** is exceeded, the output indication *Jump* is generated. If you have selected the phase currents for measurement, the output indication data type used includes the separate phase information. If you have selected the residual current for measurement, the output indication data type used includes the NI information. If the current-jump detection responds (ΔI_{Limit}), the general information is generated in the output indication in all cases.

Dropout occurs with a dynamically increased threshold value (ΔI_{Limit}) in accordance with the logic in *Figure 6-705*. Dynamic increase of the dropout threshold value achieves optimally short dropout times.

The output indication *Pulse* is formed with the configurable timer **(_:102) Minimum pulse length**. As a consequence, this output indication has a consistent minimum size. If you activate the binary input *>Pulse extension*, you can prolong the pulse duration even further. If the binary input *>Pulse extension* has been activated, the indication *Pulse* drops off when the configured time has elapsed and the falling edge of the binary input is detected.

Logic

[lo_jump_ii, 2, en_US]

Figure 6-705 Current-Jump Detection Logic

6.72.4 Application and Setting Notes

Parameter: `Measured value`

- Default setting **`(_:9) Measured value`** = ***`phase currents`***

With the parameter **`Measured value`**, you set whether the line current(s) or the residual current is to be used for jump detection.

Parameter Value	Description
`phase currents`	The tripping stage evaluates the line currents IA, IB, and IC phase-selectively to detect a jump.
`zero-sequence current`	The tripping stage evaluates the residual current IN/3I0 to detect a jump.

Parameter: `Threshold`

- Default setting **`(_:101) Threshold`** = ***`0.10 A`*** for I_{rated} = 1A or ***`0.50 A`*** for I_{rated} = 5 A

With the parameter **Threshold**, you set the threshold value for the measurand which, when exceeded, generates the output indication *Jump*.

Parameter: Minimum pulse length

- Default setting **(_:102) Minimum pulse length** = *0.10 s*

With the parameter **Minimum pulse length**, you specify a consistent minimum size for the output indication *Pulse*.

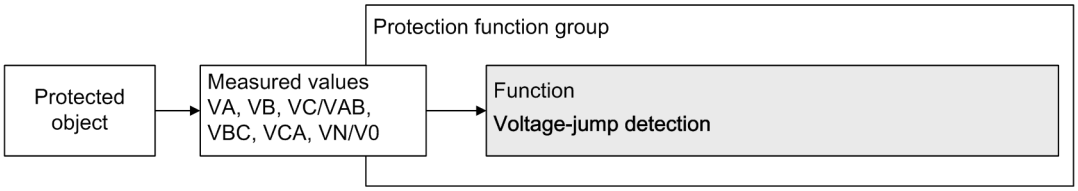
6.73 Voltage-Jump Detection

6.73.1 Overview of Functions



The **Voltage-jump detection** function has the following tasks:

- Recognition of jumps in the phase or zero-sequence voltage (ΔV)
- Generation of an indication when the measurands change by more than a configured threshold value from one system cycle to the next.

The function for detecting jumps in the phase or zero-sequence voltage is an additional function used for indication purposes or for further processing in user-specific CFC logics. Pick up of the function therefore neither opens a separate fault in the fault log nor generates an operate indication.

6.73.2 Structure of the Function

The **Voltage-jump detection** function is used in protection function groups based on voltage measurement. It can be instantiated multiple times.

[dw_struku, 1, en_US]

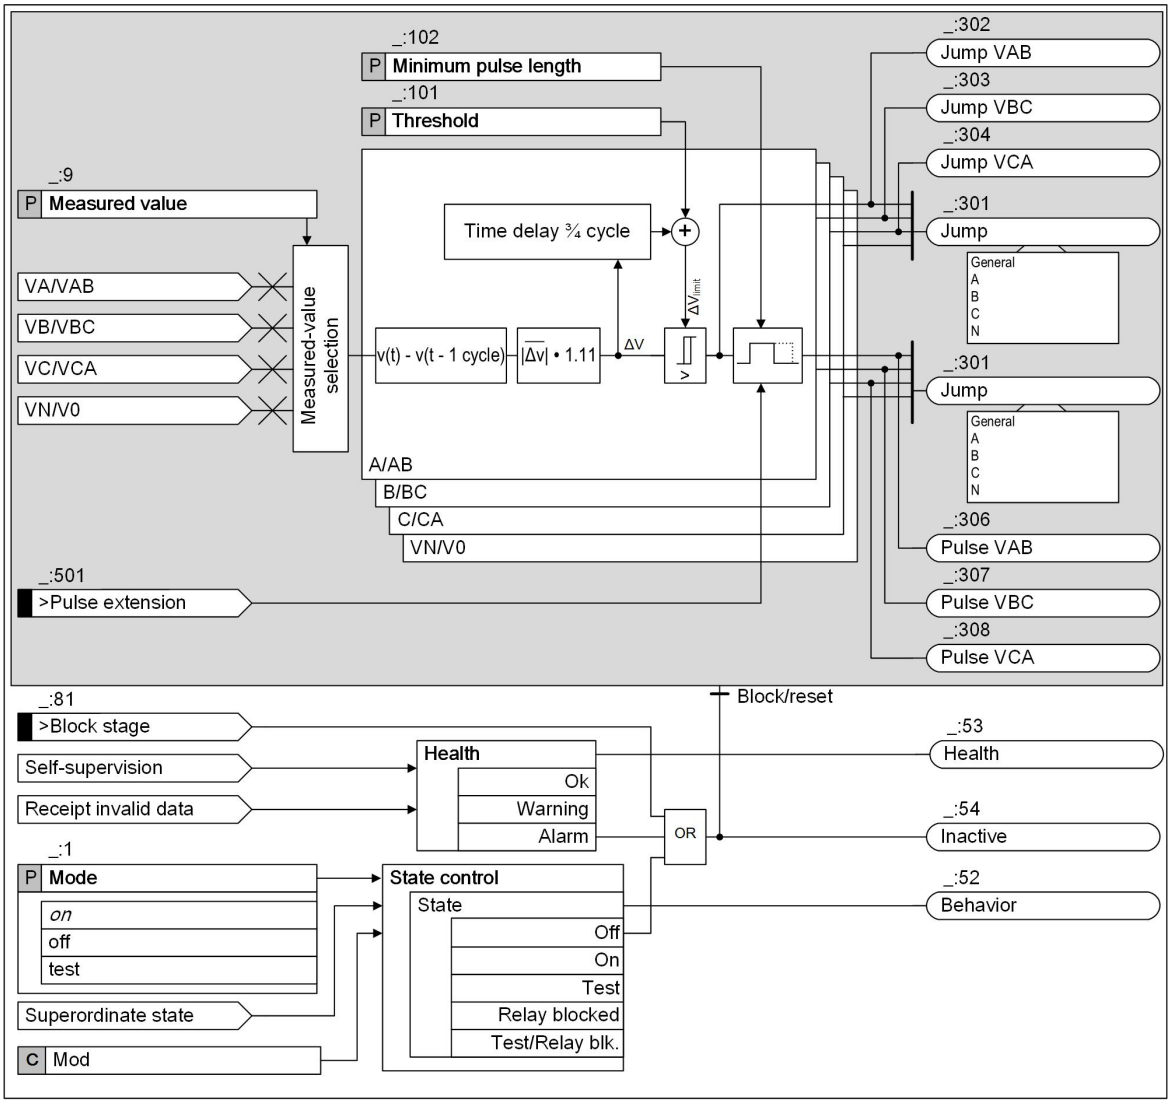
Figure 6-706 Structure/Embedding of the Function

6.73.3 Function Description

Voltage-jump detection operates directly with the sampled values without numeric filtering. This provides very short response times to sudden changes in the voltage. The method used is not sensitive to slow changes of amplitude or frequency.

By using a configurable selection of measured values, you can select from phase-to-ground voltages, phase-to-phase voltages or the zero-sequence voltage. Voltage-jump detection is phase-selective.

The difference from the previous sampled value of a system cycle is calculated for each sampled value. The rectified average is then determined for a ½ system cycle from this differential signal Δv(t). The rectified average for sinusoidal measurands is then converted to a RMS value ΔV by subsequent multiplication by 1.11. The resultant measurand ΔV is then compared with the threshold value.



If the parameter **(_:101) Threshold** is exceeded, the output indication *Jump* is generated. If the measured value is set to phase-to-phase, the sudden change in voltage is signaled selectively for the individual measuring elements that have picked up (*Jump VAB*, *Jump VBC* or *Jump VCA*). If you have selected the phase-to-phase or phase-to-ground voltages for measurement, the output indication data type used includes the separate phase information. If you have selected the zero-sequence voltage for measurement, the output indication data type used includes the N information. If the voltage-jump detection responds (ΔV_{Limit}), the general information is generated in the output indication in all cases.

Dropout occurs with a dynamically increased threshold value ΔU_{Limit} in accordance with the information in *Figure 6-707*. Dynamic increase of the dropout threshold value achieves optimally short dropout times.

A timing element is added to the indication *Jump*. The element generates a pulse from this. The length of this pulse can be set using the parameter **(_:102) Minimum pulse length**. This gives the output indication *Pulse* a reliable minimum size. If you activate the binary input *>Pulse extension*, you can prolong the pulse duration even further. If the binary input *>Pulse extension* has been activated, the indication *Pulse* drops off when the configured time has elapsed and the falling edge of the binary input

is detected. If the measured value is set to phase-to-phase, the pulse duration is signaled selectively for the individual measuring elements that have picked up (*Pulse VAB*, *Pulse VBC* or *Pulse VCA*).

Logic

[lo_jump_uu, 3, en_US]

Figure 6-707 Voltage-Jump Detection Logic

6.73.4 Application and Setting Notes

Parameter: `Measured value`

- Default setting **`(_:9) Measured value`** = ***`phase-to-ground`***

With the parameter **`Measured value`** , you specify which measured values of voltage are to be used for determining the voltage jumps.

Parameter Value	Description
phase-to-ground	The tripping stage evaluates the phase-to-ground voltages VA, VB and VC.
phase-to-phase	The tripping stage evaluates the phase-to-phase voltages VAB, VBC and VCA.
zero-sequence voltage	The tripping stage evaluates the zero-sequence voltage VN/V0.

Parameter: **Threshold**

- Default setting **(_:101) Threshold** = ***5.000 V***

With the parameter **Threshold** , you set the threshold value for the measurand which, when exceeded, generates the output indication *Jump* .

Parameter: **Minimum pulse length**

- Default setting **(_:102) Minimum pulse length** = ***0.10 s***

With the parameter **Minimum pulse length** , you specify a consistent minimum size for the output indication *Pulse* .

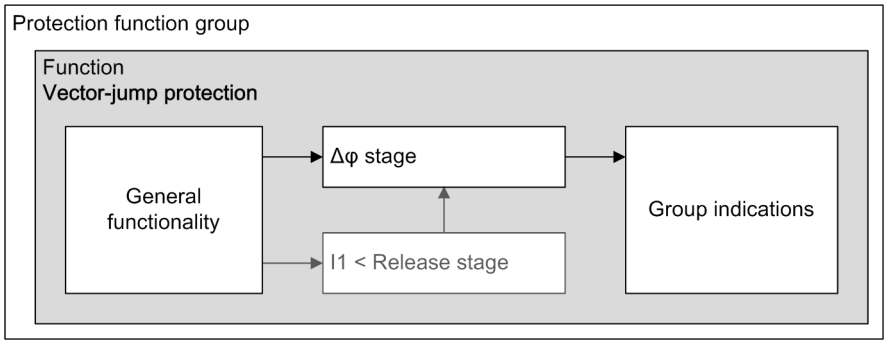
6.74 Vector-Jump Protection

6.74.1 Overview of Functions

The **Vector-jump protection** function:

- Is used for network decoupling of the power generating unit in case of a load loss
- Evaluates the phase-angle jump of the voltage phasors



6.74.2 Structure of the Function

The **Vector-jump protection** function can be used in the following function groups:

- Voltage-current 3-phase
- Voltage 3-phase
- Transformer side

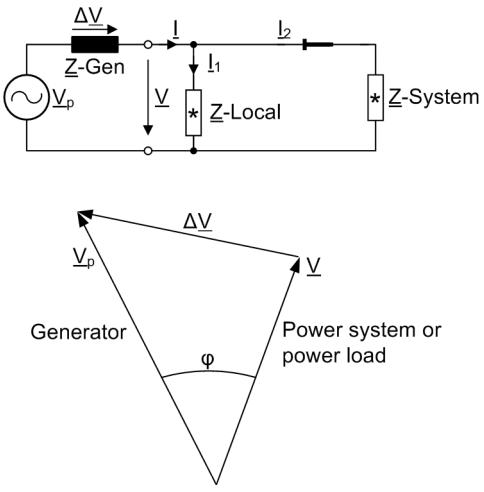
The **Vector-jump protection** function comes factory-set with a **Δφ** stage.
The following stages can operate simultaneously within the function:

- 1 **Δφ** stage
- 1 **I1 < Release** stage

[dw_VJP_structure, 1, en_US]

Figure 6-708 Structure/Embedding of the Function

6.74.3 General Functionality



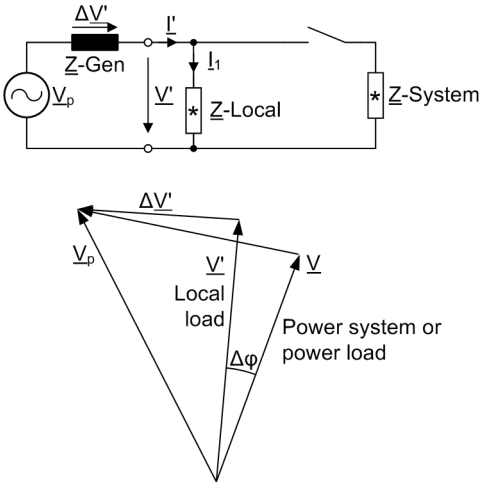
6.74.3.1 Description

Basic Principle of Vector-Jump Protection

The following 2 figures show the basic principle of the function **Vector-jump protection**.
The following figure shows the voltage vector of the steady state condition. The load current causes a voltage drop between the internal voltage V_p and the generator terminal voltage V.

If the load is switched off, the following situations occur:

- The current is reduced.
- A smaller voltage drop is caused.



[dw_load loss, 1, en_US]

Figure 6-709 Voltage Vector of the Steady State

The following figure shows the situations after the load is switched off:

- The terminal voltage V changes to V'.
- An additional phase-angle jump occurs.

A phase-angle jump occurs with load loss and is the evaluation criterion for the function **Vector-jump protection**. If the phase-angle differential exceeds a set threshold, the generator circuit breaker or the circuit breaker of the system switch opens. Therefore, the generator unit can be protected against unacceptable stress.

[dw_vector change, 1, en_US]

Figure 6-710 Vector Change after the Load Shedding

Table 6-35 Vector Description

Vector	Description
$\underline{V}_p$	Vector of the generator internal voltage (rotor voltage)
$\underline{V}$	Vector of the generator terminal voltage
$\Delta\underline{V}$	Vector of the voltage differential
$\underline{V}'$	Vector of the terminal voltage after the load shedding
$\Delta\underline{V}'$	Vector of the voltage differential after the load shedding

The following measures are applied to avoid unwanted tripping:

- Correction of steady-state deviations from rated frequency
- Frequency operating range limited to f_{rated} ± 3 Hz
- High measuring accuracy by using frequency-tracked measured values and evaluation of the positive-sequence phasor
- Enabling the minimum voltage for the function **Vector-jump protection**
- Blocking the function when the primary voltage is switched on or off as switching can lead to a phase-angle jump

Logic

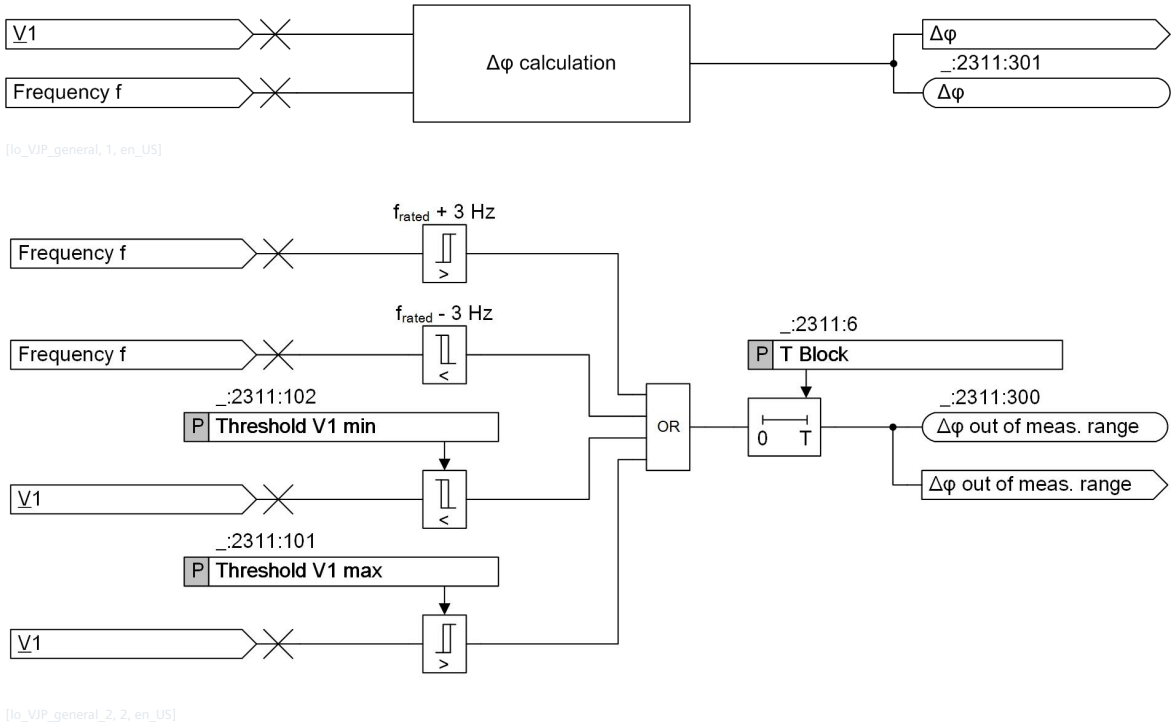


Figure 6-711 Logic Diagram of the General Functionality

Phase-Angle Calculation

The phase-angle differential is calculated at different time intervals (t-T, t-2T, t-3T[54]) from the vector of the positive-sequence voltage via a delta-interval measurement. With the current measured power frequency, the measuring errors of the angle measurement caused by frequency deviations are compensated.

Range

If the measured frequency or voltage is below the set threshold, the function **Vector-jump protection** is blocked.

The voltage and frequency bands have the following limits:

- The threshold of the voltage band is configurable.
- The frequency band ranges is fixed from f_{rated} - 3 Hz to f_{rated} + 3 Hz.

54 T = period or cycle time of the power system

Measurand

The general functionality calculates the phase-angle displacement Δφ and sends it to the **Δφ** stage. Δφ is used for comparison with the parameter **Threshold Δφ**. Δφ is displayed in the functional measured value and can be routed in a fault record and displayed in the fault log.

The functional measured values of Δφ in HMI are displayed differently in the following situations:

- If the function **Vector-jump protection** is inactive, the function value of Δφ is displayed as "---"
- If the function **Vector-jump protection** is active and has not picked up, the functional measured value of Δφ is displayed as 0.0°
- If the function **Vector-jump protection** is active and has picked up, the functional measured value of Δφ is displayed as a calculated value (for example, 12.0°) and remains unchanged until the next pickup of the function **Vector-jump protection**.

6.74.3.2 Application and Setting Notes

Parameter: Threshold V1 min

- Default setting **(_:2311:102) Threshold V1 min** = ***46.189 V***

With the parameter **Threshold V1 min**, you can define the minimum threshold of the voltage band.

The setting value is closed to the allowed lower limit of the voltage band. The default setting is 80 % of the rated positive-sequence voltage. The value of the rated positive-sequence voltage is 100 V/√3.

Parameter: Threshold V1 max

- Default setting **(_:2311:101) Threshold V1 max** = ***75.058 V***

With the parameter **Threshold V1 max**, you can define the maximum threshold of the voltage band.

The setting value is closed to the allowed higher limit of the voltage band. The default setting is 130 % of the rated positive-sequence voltage. The value of the rated positive-sequence voltage is 100 V/√3.

Parameter: T Block

- Default setting **(_:2311:6) T Block** = ***0.10 s***

With the parameter **T Block**, you set the dropout delay of the **Δφ** stage.

When voltages are connected or disconnected, the overfunction can be avoided with the timer **T Block**.

Siemens recommends to use the default setting of the parameter **T Block**. Keep in mind that the parameter **T Block** has always to be set to 2 cycles more than the measuring window for vector-jump measurement.

6.74.3.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting

6.74.4 Δφ Stage

6.74.4.1 Description

Logic

[lo_delta_phi_stage, 2, en_US]

Figure 6-712 Logic Diagram of the Δφ Stage

In the logic diagram, the **I1 < Release** stage is instantiated. You can find more information in chapter *6.74.5.1 Description*.

If the **I1 < Release** stage is not instantiated, the AND operation has no influence. The *Operate* indication is issued under the following conditions:

- The parameter **Operate & flt.rec. blocked** is set to ***no***.
- The operate delay expires.
- The phase-angle differential exceeds the parameter **Threshold Δφ**.

Measurand

The **Δφ** stage gets the measured value $\Delta\phi$ from the general functionality.

Pickup

The **Δφ** stage compares the value of the vector jump $\Delta\phi$ with the **Threshold Δφ**.

If the value of the **Threshold Δφ** is exceeded, the pickup delay starts.

The vector jump $\Delta\phi$ is stored in an RS flip-flop. Trippings can be delayed by the associated time delay.

Blocking the Stage

In the event of blocking, the picked up stage will be reset. The following blocking options are available for the stage:

- The parameter **Mode** is in the state *off*.
- The binary input signal *>Block stage* is active.
- The signal *Δφ out of meas. range* is active.

6.74.4.2 Application and Setting Notes

Parameter: Operate & flt.rec. blocked

- Default setting **(_:19261:2) Operate & flt.rec. blocked** = *no*

With the parameter **Operate & flt.rec. blocked**, you can block the operate indication, the fault recording, and the fault log. If you want the stage to have a warning indication only, set the parameter **Operate & flt.rec. blocked** to *yes*.

Parameter: Threshold Δφ

- Default setting **(_:19261:101) Threshold Δφ** = *10°*

With the parameter **Threshold Δφ**, you can set the pickup value of the **Δφ** stage.

The parameter value to be set for the vector jump depends on the supply and load conditions. Load changes cause a jump of the voltage vector. The value to be set must be established in accordance with the particular power system. An estimation can be done based on the system equivalent circuit in *Figure 6-710*. A network calculation considering the relevant source and load situations will be more precise.

If the setting for the parameter **Threshold Δφ** is too sensitive, every time loads are connected or disconnected, the protection function performs a network decoupling. Therefore, If no other calculated value is applicable to the setting of this parameter, Siemens recommends using the default setting.

Parameter: Operate delay

- Default setting **(_:19261:6) Operate delay** = *0.00 s*

With the parameter **Operate delay**, you can set the operate delay of the **Δφ** stage. For the tripping stage, set the operate delay between *0.00 s* and *60.00 s*.

Siemens recommends the default setting.

The following requirements can necessitate a change of the parameter **Operate delay** with respect to the default setting:

- The operate indication should be transmitted with delay to a programmable logic.
- There shall be enough time for an external blocking to take effect.

Parameter: T Reset

- Default setting **T Reset** = *5.00 s*

With the parameter **T Reset**, you can set the reset time for the *Pickup* indication stored in the RS flip-flop. When the timer **T Reset** expires, the protection function is reset automatically.

The reset time meets the following conditions:

- The reset time depends on the decoupling requirements
- The reset time must expire before the circuit breaker is reclosed

6.74.4.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
Stage Δφ 1				
_:19261:1	Stage Δφ 1:Mode		• off • on • test	off
_:19261:2	Stage Δφ 1:Operate & flt.rec. blocked		• no • yes	no
_:19261:101	Stage Δφ 1:Threshold Δφ		2.0° to 30.0°	10.0°
_:19261:6	Stage Δφ 1:Operate delay		0.00 s to 60.00 s	0.00 s

6.74.5 I1 < Release Stage

6.74.5.1 Description

Logic

[lo_undercurrent_release_stage, 1, en_US]

Figure 6-713 Logic Diagram of the I1 < Release Stage

The **I1 < Release** stage is an optional stage and is used to reduce the risk of overfunction.
The indication *Undercurrent release* is an additional safety criterion to avoid an unexpected trip. It indicates a load loss of the connected line to the system and the phase-angle criterion is released. If any load in the network is switched on or off, an unexpected trip can occur.

If the **I1 < Release** stage is not instantiated, the **Δφ** stage works without current-flow criterion. You can find more information in chapter *6.74.4.1 Description*.

If the positive-sequence current falls below the parameter **I< Threshold**, the message *Undercurrent release* is issued and is forwarded to the **Δφ** stage.

6.74.5.2 Application and Setting Notes

Parameter: I< Threshold

- Default setting **(_:101) I< Threshold** = ***0.100 A***

With the parameter **I< Threshold**, you can set the pickup value of the **I < Release** stage corresponding to the specific application. Consider that the current measuring point must be on the line side. The parameter **I< Threshold** depends on the load situation.

6.74.5.3 Settings

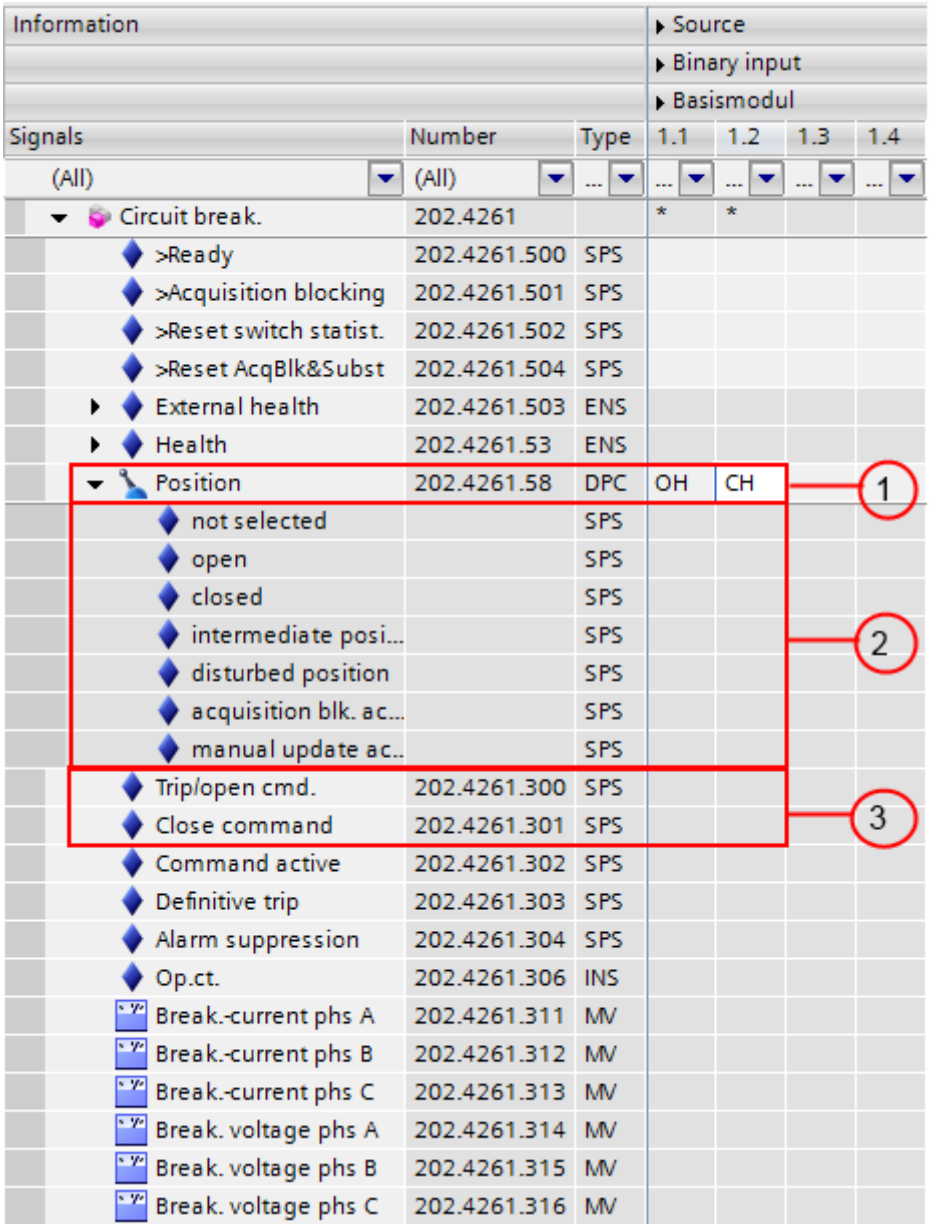
7.4	Control Functionality	1862
7.5	Synchronization Function	1890
7.6	User-Defined Function Block [Control]	1938
7.7	CFC-Chart Settings	1943
7.8	Tap Changers	1945
7.9	Voltage Controller	1959
7.10	Point-on-Wave Switching	2038



7.1 Introduction

7.1.1 Overview

The SIPROTEC 5 series of devices offers powerful command processing capability as well as additional functions that are needed when serving as bay controllers for the substation automation technology or when providing combi-protection. The object model for the devices is based on the IEC 61850 standard, making the SIPROTEC 5 series of devices ideally suited for use in systems employing the IEC 61850 communication protocol. In view of the function blocks necessary for the control functions, other logs are also used.

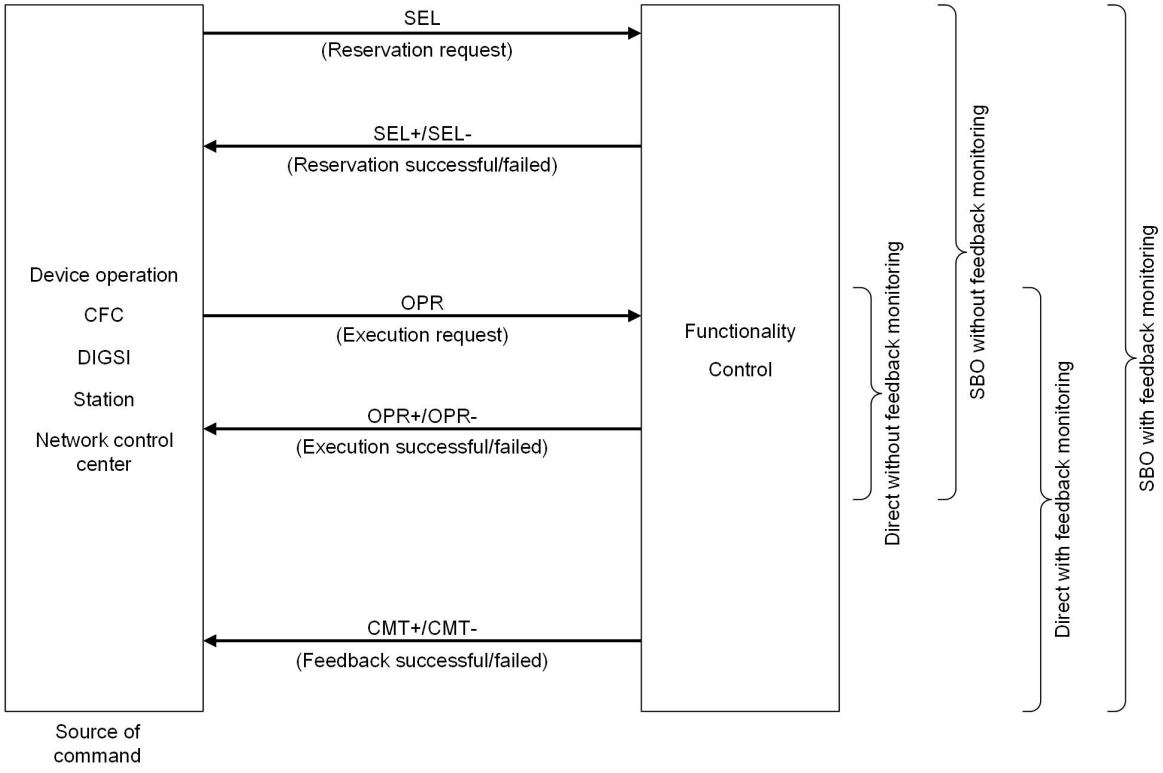
7.1.2 Concept of Controllables

The concept of so-called controllables is based on the data model described in IEC 61850. Controllables are objects that can be controlled, such as a switch with feedback. The model of a transformer tap changer, for example, contains controllables. The controllables are identifiable by their last letter **C** of the data type (for example, DPC = Double Point Controllable/Double Command with feedback or BSC = Binary-Controlled Step Position Indication / transformer tap command with feedback).

[sc_control, 1, en_US]

(1) Position (connect with binary inputs)
(2) Signalization of the current condition
(3) Command output (connect with relay)

The trip, opening, and the close commands are connected to the relays. For the trip command, a choice between saved and unsaved output is possible. The position is connected with 2 binary inputs (double-point indication). In addition, signals are available that display the current state of the switch (**not selected**, **off**, **on**, **intermediate position**, **disturbed position**). These signals can be queried in CFC, for example, in order to build interlocking conditions.



Control Models

You can set the operating mode of the controllables by selecting the control model.

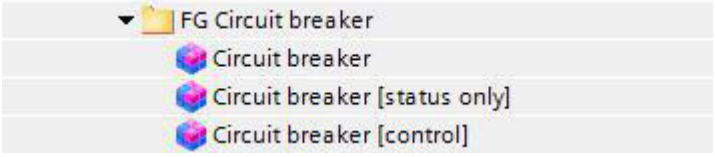
4 different control models are available:

- Direct without feedback monitoring (**`direct w. normal secur.`**)
- With reservation (SBO)[55] without feedback monitoring (**`SBO w. normal secur.`**)
- Direct with feedback monitoring (**`direct w. enh. security`**)
- With SBO with feedback monitoring (**`SBO w. enh. security`**)

The next figure shows the command sources, command types, and control models.

[dw_steuer, 2, en_US]

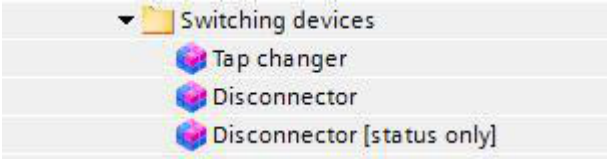
Figure 7-1 Command Sources, Command Types, and Control Models



The figure shows the control models (right) with the respective control mechanisms (center). The standard control model for a switching command in an IEC 61850 compliant system is **SBO with feedback monitoring** (**`SBO w. enh. security`**). This control model is the default setting for newly created switching devices.

55 SBO: Select Before Operate

7.2 Switching Devices



7.2.1 General Overview

You can find the following switching devices in the DIGSI 5 library in the function groups **Circuit breaker** and **Switching devices** (see following figures).

[sc_cb_ausw, 1, en_US]

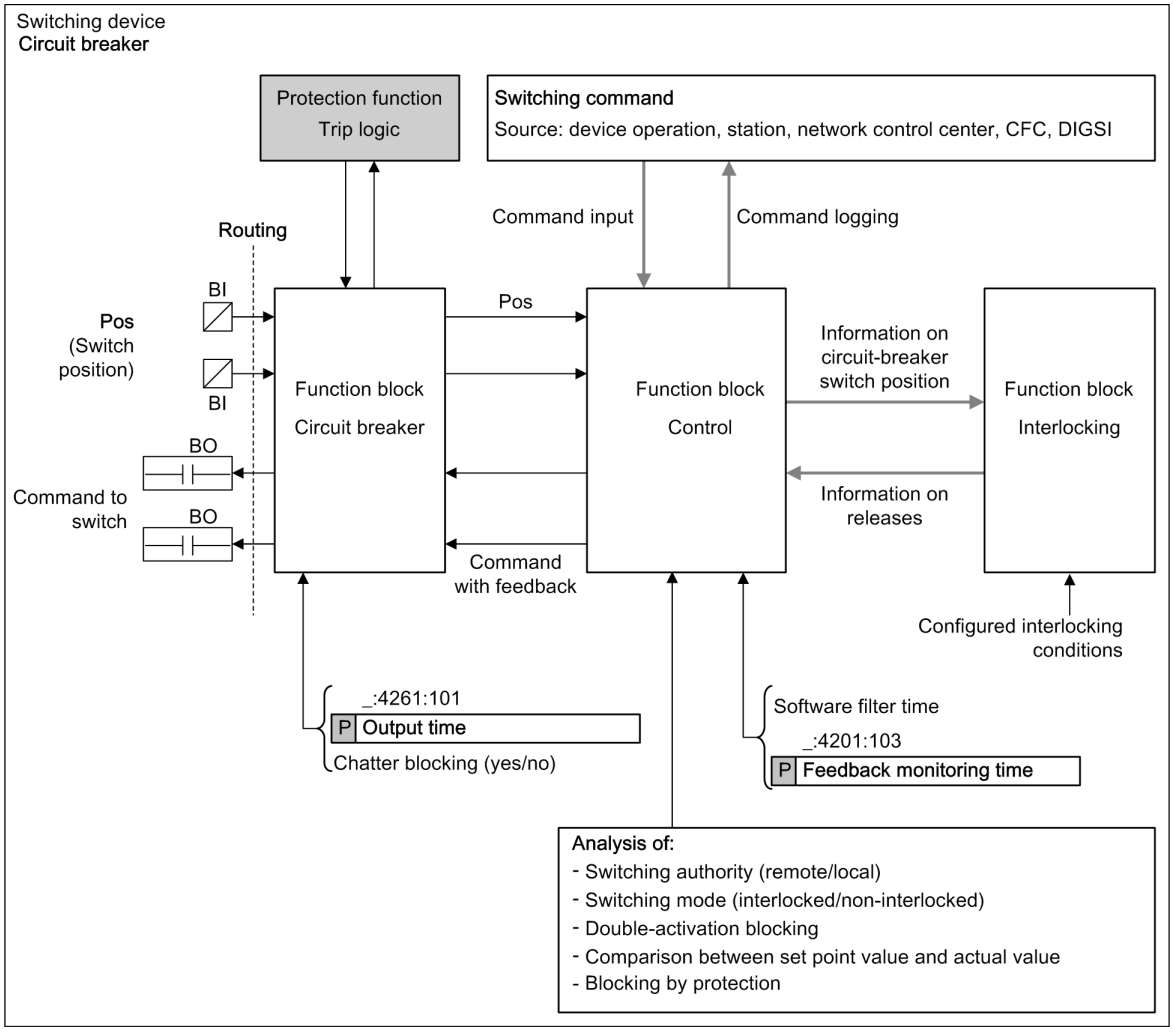
Figure 7-2 Selecting the Circuit-Breaker Switching Device Using the DIGSI Circuit-Breaker Function Group Menu

[scswausw, 1, en_US]

Figure 7-3 Selecting the Remaining Switching Devices Using the DIGSI Switching-Devices Menu

7.2.2 Switching Device Circuit Breaker

7.2.2.1 Structure of the Circuit-Breaker Switching Device



This chapter describes the control properties of the **Circuit-breaker** switching device.

The **Circuit-breaker** switching device contains the following function blocks that are needed for control:

- Function block **Circuit breaker**
- Function block **Control**
- Function block **Interlocking**

This corresponds to the logical nodes XCBR, CSWI, and CILO in IEC 61850.

In the case of protection devices or combined protection and control devices, additional functions can be contained in the **Circuit-breaker** switching device, for example, **Synchrocheck**, the **Automatic reclosing (AREC)**, the **Trip logic**, or **Manual On function**. However, these are not relevant for the control function. You can find the description of these functions in the chapter *Protection and Automatic Functions*. In addition, other functions can be initialized. You can find the description of these functions in the chapter *Protection Functions*.

[dw_breake, 1, en_US]

Figure 7-4 Control Function Blocks of the Circuit-Breaker Switching Device

The circuit breaker in DIGSI 5 is linked with the binary inputs that acquire the switch position via information routing. The circuit breaker in DIGSI 5 is also linked with the binary outputs that issue the switching commands.

The **Circuit-breaker** switching device is available in the following types:

- **3-pole circuit breaker [control only]**
  This switching device contains the function blocks **Control**, **Interlocking**, and **Circuit breaker** needed for control. The standard situation for the control function is that the SIPROTEC 5 device switches all 3 poles of the circuit breaker ***On*** or ***Off*** together. The **Synchronization function** can also be added.
- **3-pole circuit breaker**, **Circuit breaker [without current]**
  This switching device contains additional base function blocks for protection functions (for example, **Trip logic**, **Manual closure**, **Circuit-breaker test**).
- **1-pole circuit breaker**
  This switching device is intended for 1-pole tripping via the protection functions and contains the same base function blocks for protection as the **3-pole circuit breaker** switching device.
- **Circuit breaker [status only]**
  This switching device contains only the function block **Circuit breaker**. It is used to acquire the position of a switch, for example, from a neighboring bay. This object type can be used to model switches that can only be read but not controlled by the SIPROTEC 5 device.

NOTE

When setting the parameters of a device, you will find 2 circuit-breaker types in the DIGSI 5 library:

- **3-pole circuit breaker** or **1-pole circuit breaker**, depending on the device type selected (3-pole or 1-pole tripping)
- **Circuit breaker [status only]**

Function Blocks of the Circuit Breaker

Table 7-1 Function Blocks of the Circuit-Breaker Function Group

Function Block	Description	Parameter	Function
Circuit breaker	The Circuit-breaker function block in the SIPROTEC 5 device represents the physical switch.	**Output time**	The circuit breaker forms the switch position from the positions of the binary inputs and also outputs the command via the binary outputs.
Control	Command processing	**Control model** **SBO time-out** **Feedback monitoring time** **Check switching authority** **Check if pos. is reached** **Check double activat. blk.** **Check blk. by protection**	Command check, communication with the command source and with the function block **Circuit breaker**
Interlocking	Switchgear interlocking protection	Interlocking condition (deposited in CFC)	The functionality **Interlocking** generates the releases for switchgear interlocking protection.

For the setting values of the parameter, refer to *7.2.2.2 Application and Setting Notes*.

Additional Setting Options of the Circuit-Breaker Switching Element

The setting options of the circuit breaker are assigned to the function blocks on the basis of their relevance. Additional setting options of the circuit breakers that cannot be directly assigned to one of the 3 function blocks are nevertheless available:

Table 7-2 Setting Options of the Controllable **Cmd. with feedback** in the Function Block **Control** of the Circuit Breaker.

Properties	Function	To Be Found in
Software filtering time	Software filtering time for position detection	Position of the function block **Control** [56]
Retrigger filter (yes/no)	Switching retriggering of the filtering time on/off by changing the position	Position of the function block **Control** [56]
Message time before filtering (yes/no)	Consideration of the hardware filtering time for position-detection time stamp	Position of the function block **Control**[56]

56 First click **Position** and then click the **Details** key in the **Properties** window (below).

Properties	Function	To Be Found in
Suppress intermediate position (yes/no)	When activated, only the intermediate position is suppressed by the duration of the software filtering time.	Position of the function block **Control** 56
Treatment of spontaneous position changes (Gen. Software Filt./Spont. Software Filt.)	If you select the ***General software filter*** setting, the general settings for software filtering of spontaneous position changes and for position changes caused by a switching command apply. By selecting ***Spontaneous software filter***, a separate filtering is activated for spontaneous position changes.	Position of the function block **Control** 56
Spontaneous software filtering time	Software filtering time for spontaneous position changes	Position of the function block **Control** 56
Spontaneous retrigger filter (yes/no)	Switching on/off retriggering of the filtering time by spontaneous position change	Position of the function block **Control** 56
Spontaneous indication timestamp before filtering (yes/no)	Consideration of the hardware filtering time for position-detection time stamp in case of a spontaneous change	Position of the function block **Control** 56
Inhibit intermediate position for a spontaneous chng. (yes/no)	When activated, only the spontaneous change to the intermediate position is suppressed by the duration of the software filtering time.	Position of the function block **Control** 56

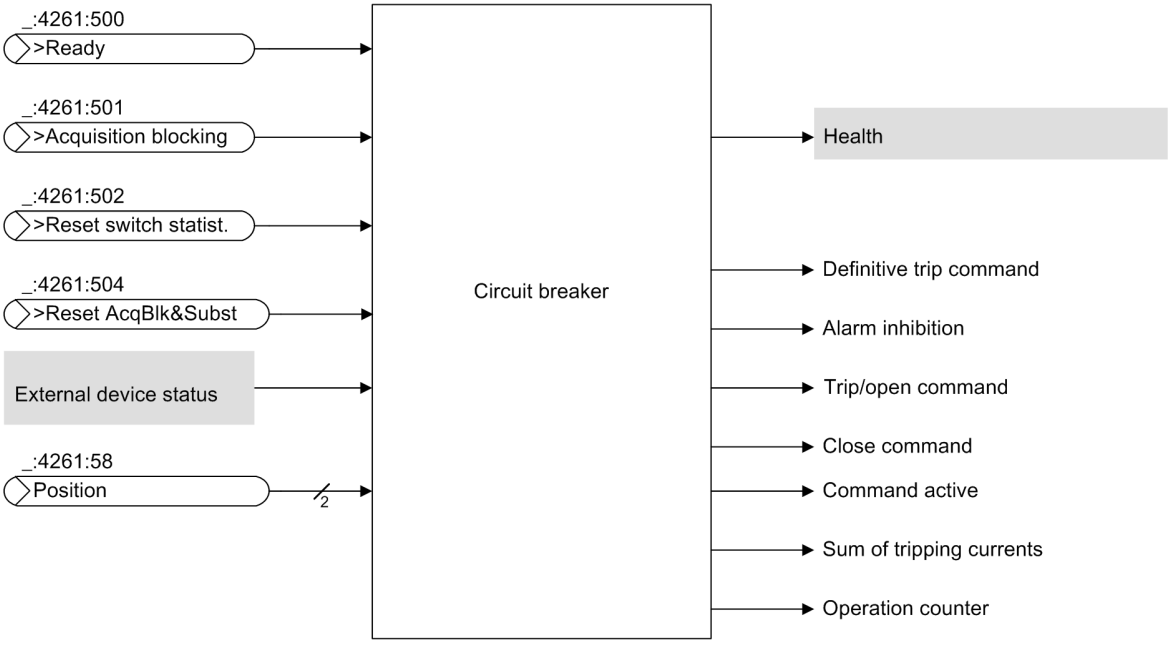
Properties	Function	To Be Found in
Chatter blocking (yes/no)	Switching chatter blocking on/off	Position of the function block **Circuit breaker**56

Table 7-4 Additional Settings in the Device Settings Having Effects on the Circuit Breaker

Properties	Function	To Be Found in
Number of permissible status changes	Chatter-blocking setting value: Once for the entire device	Device settings (to be found under Settings)
Chatter test time		
Number of chatter tests		
Chatter idle time		
Chatter check time		

The inputs and outputs as well as the setting options of the function blocks **Circuit breaker** and **Control** are described in the next section (refer to *7.2.2.3 Connection Variants of the Circuit Breaker*).



Interlocking

The function block **Interlocking** generates the releases for switchgear interlocking protection. The actual interlocking conditions are deposited in CFC. For more information on this, refer to the general chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*.

7.2.2.2 Application and Setting Notes

Circuit Breaker

The Circuit-breaker function block in the SIPROTEC 5 device represents the physical switch device. The task of the circuit breaker is to replicate the switch position from the status of the binary inputs.
The following figure shows the logical inputs and outputs of the **Circuit-breaker** function block.

[dw_func_ls, 2, en_US]

Figure 7-5 Logical Inputs and Outputs of the Circuit-Breaker Function Blocks

Table 7-5 and *Table 7-6* list the inputs and outputs with a description of their function and type. For inputs, the effect of **Quality = invalid** on the value of the signal is described.

EXAMPLE

If the signal **>Ready** has the **Quality = invalid**, then the value is set to **cleared**. In problematic operating states, the circuit breaker should signal that it is not ready for an **Off-On-Off cycle**.

Table 7-5 Inputs of the Circuit-Breaker Function Block

Signal Name	Description	Type	Default Value if Signal Quality = invalid
>Ready	The signal **>Ready** indicates that the OFF-ON-OFF cycle is possible with the circuit breaker. This signal is used for the AREC standby status.	SPS	Going
>Acquisition blocking	The binary input activates acquisition blocking. You can also set this binary input with an external toggle switch.	SPS	Unchanged
>Reset AcqBlk&Subst	Acquisition blocking and the substitution of the circuit breaker are reset with this input. If the input is activated, setting the acquisition blocking and the substitution is blocked.	SPS	Unchanged
>Reset switch statist.	Among other things, the binary input sets the operation counter for the switch to the value 0.	SPS	Unchanged

Signal Name	Description	Type	Default Value if Signal Quality = invalid
External health	The binary input **External health** reflects the circuit-breaker status (EHealth). This input will be set by the CFC using the BUILD_ENS block. In turn, BUILD_ENS can query binary inputs that represent the conditions ***OK***, ***Warning***, or ***Alarm*** (as a result of the function **Trip-circuit supervision**).	ENS	Unchanged
Position	The signal **Position** can be used to read the circuit-breaker position with double-point indication.	DPC	Unchanged

If the quality of the input signal assumes the status **Quality = invalid**, then the standby status (EHealth) of the **Circuit-breaker** function block is set to ***Warning***.

Table 7-6 Outputs of the Circuit-Breaker Function Block

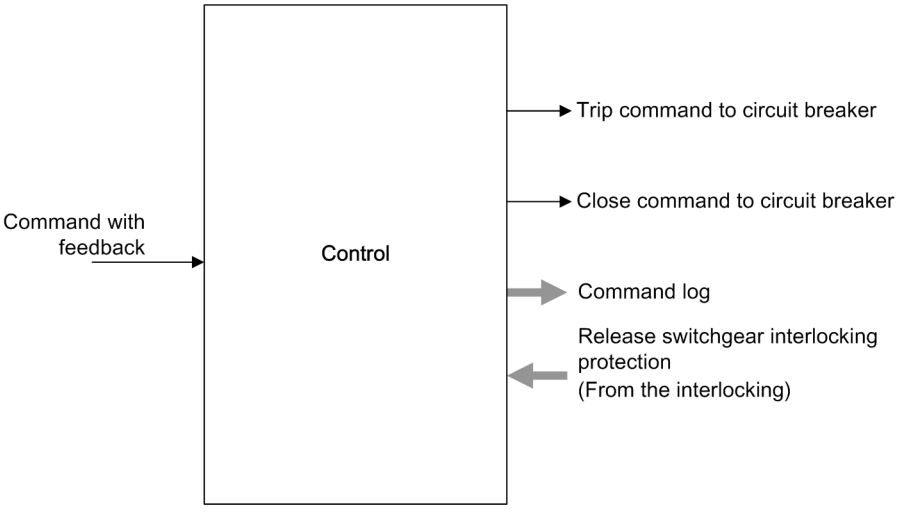
Signal Name	Description	Type
Definitive trip	Protection has finally been tripped.	SPS
Alarm suppression	The signaling contact for external alarm inhibition is suppressed during the runtime of automatic reclosing (optional) as well as during the command output of switching commands.	SPS
Op.ct.	The information counts the number of switching cycles of the circuit breaker.	INS
Trip/open cmd.	This logic output is responsible for the command output **Off**.	SPS
Close command	This logic output is responsible for the command output **On**.	SPS
Command active	The binary output **Command active** is responsible for signaling a running command (relay active or selected switching device (SEL)).	SPS
CB open hours	The statistical value counts the hours the circuit breaker is open.	INS
Operating hours	The statistical value counts the hours where at least one phase current is greater than the **Current thresh. CB open** parameter.	INS

Control

It is the task of the controls to execute command checks and establish communication between the command source and the circuit breaker. Using the control settings, you specify how the commands are to be processed (see also chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*).

Through the function SBO (Select Before Operate, reservation[57]), the switching device is reserved prior to the actual switching operation, thus it remains locked for additional commands. Feedback monitoring provides information about the initiator of the command while the command is in process, that means, informing whether or not the command was implemented successfully. These 2 options can be selected individually in the selection of the control model, so that 4 combinations in total are available (see the following table).

The control makes the following settings available (see next table).



Parameters	Default Setting	Possible Parameter Values
(_:4201:101) Control model	***SBO w. enh. security***[58]	***direct w. normal secur.*** ***SBO w. normal secur.*** ***direct w. enh. security*** ***SBO w. enh. security***
(_:4201:102) SBO time-out	***30.00 s***	0.01 s to 1800 s (Increment: 0.01 s)

57 In the IEC 61850 standard, reservation is described as **Select before Operate (SBO)**.

58 This default setting is the standard control model for a switching command in an IEC 61850-compliant system.

Parameters	Default Setting	Possible Parameter Values
(_:4201:103) Feedback monitoring time	1.00 s	0.01 s to 1800 s (Increment: 0.01 s)
(_:4201:104) Check switching authority	yes	no yes advanced
(_:4201:105) Check if pos. is reached	yes	no yes
(_:4201:106) Check double activat. blk.	yes	no yes
(_:4201:107) Check blk. by protection	yes	no yes

The following figure shows the logical inputs and outputs of the **Control** function block.

[dw_steue1, 1, en_US]

Figure 7-6 Logical Inputs and Outputs of the Control Function Block

Table 7-7 Control Function Block Input and Output

Signal Name	Description	Type	Value if Signal Quality=Invalid
Cmd. with feedback	With the **Cmd. with feedback** signal, the circuit-breaker position is accepted via the double-point indication of the **Circuit-breaker** function block and the command is issued.	Controllable (DPC) Unchanged	Unchanged

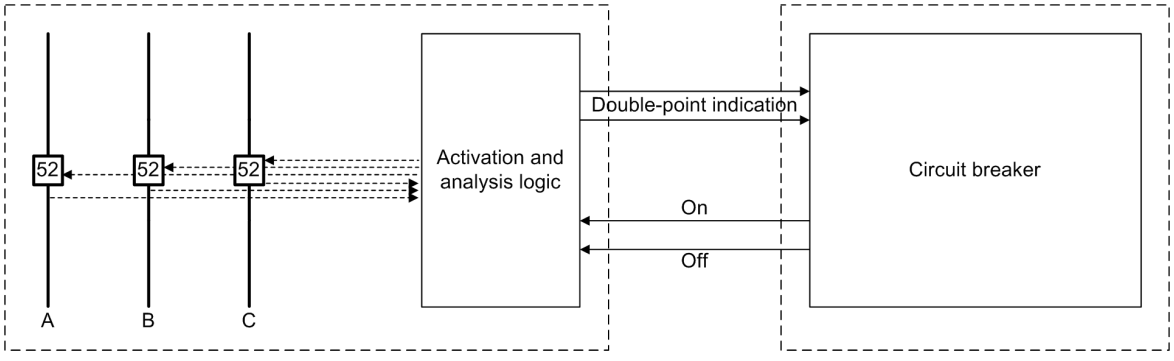
In the information routing of DIGSI 5, you may select a function key as a possible command source. In addition, it is displayed here if the command is activated by CFC. The logging is routed here.

7.2.2.3 Connection Variants of the Circuit Breaker

For each switching device, you can establish the number of poles (for example, 1-pole, 1.5-pole or 2-pole) that are switched with or without feedback. This results in the necessary amount of information to be processed, thus establishing the command type.

Whether the circuit breaker is triggered 1-, 1.5-, or 2-pole, depends on the design of the auxiliary and control-voltage system. In most cases, the activation of the opening coil of the circuit breaker is 1-pole.

Table 7-8 Meaning of the Abbreviations of the Connection Variants

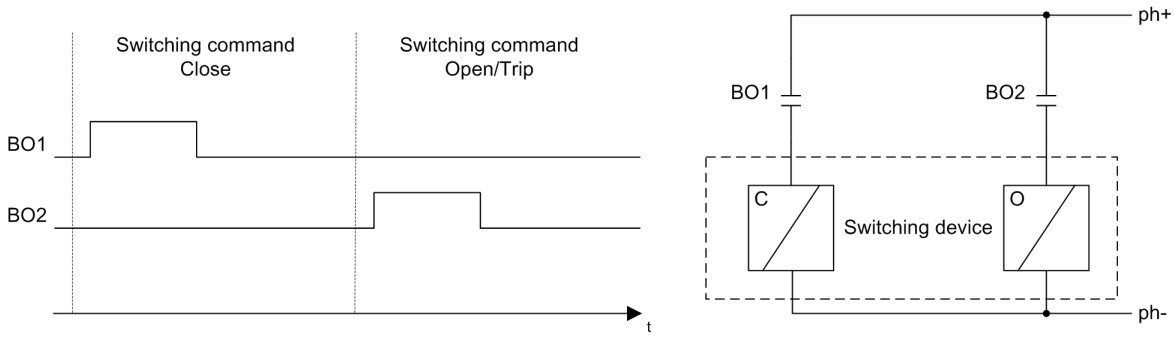


Abbreviation	Meaning of the Abbreviation of the Connection Variants
BO	Binary output
L+; L-	Control voltage
A	Trip command
Gnd	Close command

Table 7-9 Meaning of the Abbreviations in DIGSI

Abbreviation	Description of the Input in DIGSI
V	Unsaved trip command Click the right mouse button and enter **V**.
X	Close Command Click the right mouse button and enter **X** for the respective binary output.
OH	The switching-device feedback is in the position **OFF**, if there is voltage present at the routed binary input (H). Click the right mouse button and enter **OH**.
OL	The switching-device feedback is in the position **OFF**, if there is no voltage present at the routed binary input (L). Click the right mouse button and enter **OL**.
CH	The switching-device feedback is in the position **ON**, if there is voltage present at the routed binary input (H). Click the right mouse button and enter **CH**.
CL	The switching-device feedback is in the position **ON**, if there is no voltage present at the routed binary input (H). Click the right mouse button and enter **CL**.
TL	Trip command stored Click the right mouse button and enter **TL**.

Connection Variant: 3-Pole Circuit Breaker



This is the standard type for the control function. All 3 individual poles of the circuit breaker are triggered together by a double command.

[dw_3-pole_ls, 1, en_US]

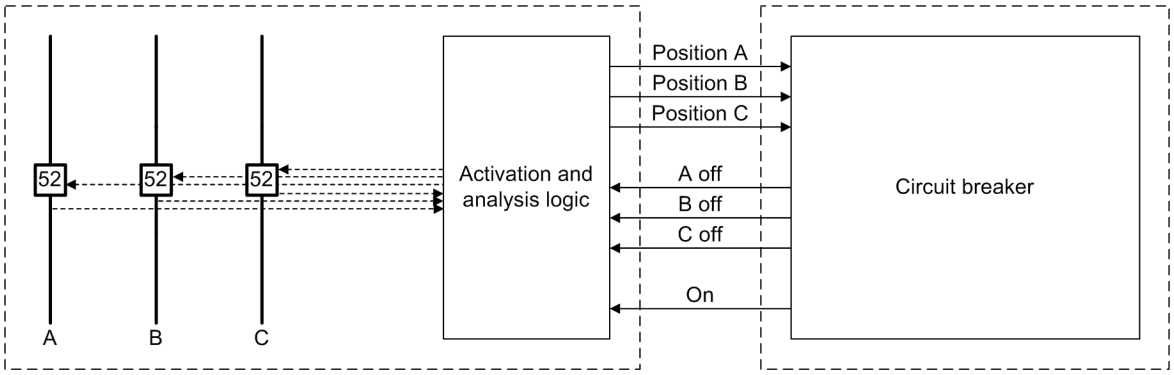
Figure 7-13 2-Pole Triggering, Routing in DIGSI

Connection Variant: 1-Pole Circuit Breaker

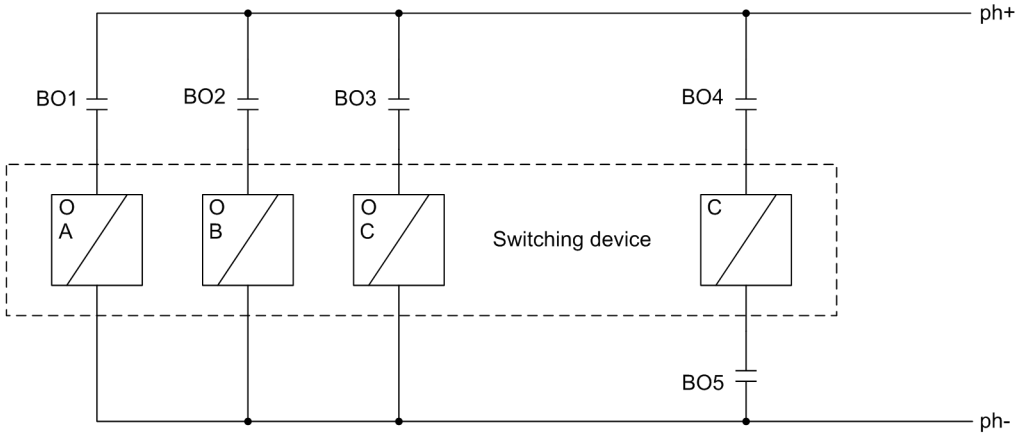


The 1-pole circuit breaker is used for separate activation and acquisition of the individual poles of a circuit breaker. It is intended for joint use by 1-pole protection and control functions.

NOTE

The wiring of the **Circuit-breaker** function group with binary inputs and binary outputs occurs 1 time per device.

The control function in this type switches all 3 poles on or off simultaneously.



The protection functions can switch off 1-pole. The close command is always 3-pole. Optionally only the open poles are closed.

[dw_1polls, 1, en_US]

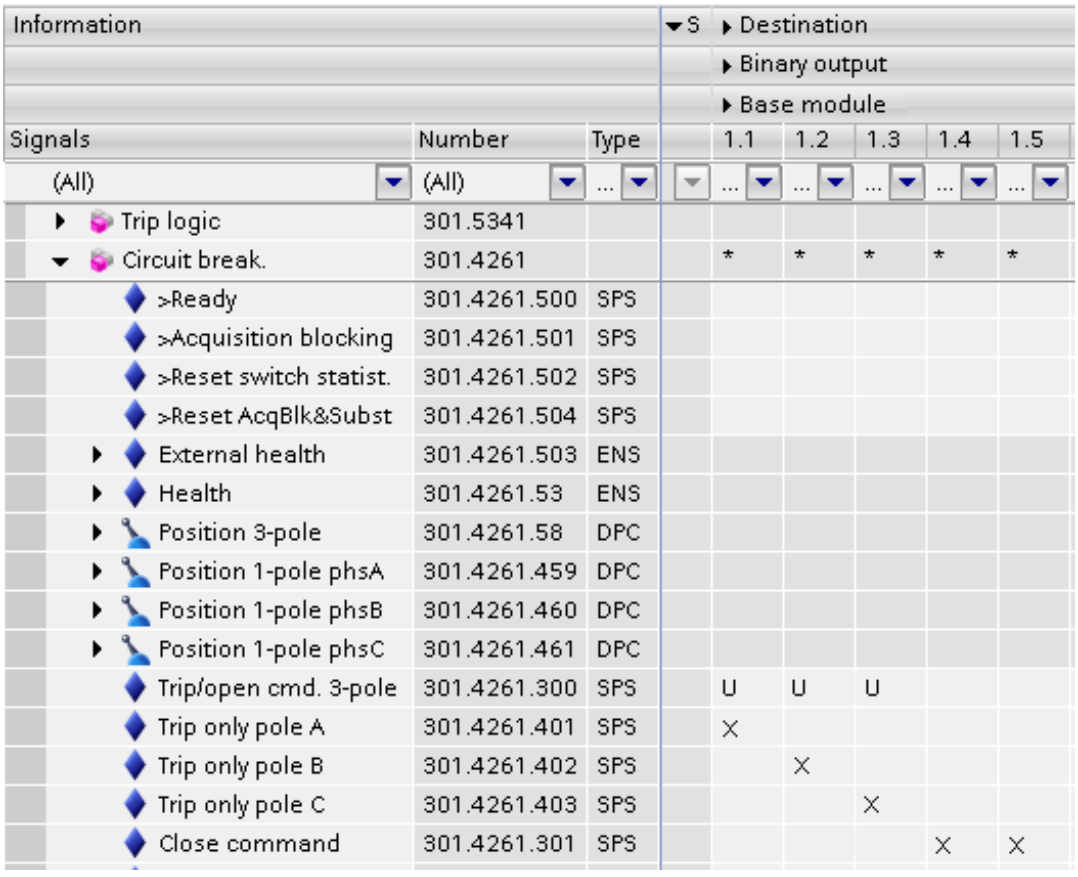


Figure 7-14 Circuit Breaker with 1-Pole Triggering

For the circuit breaker with 1-pole triggering, triggering takes place via one relay per phase for the trip command and via a 4th relay for the close command (see next figure).

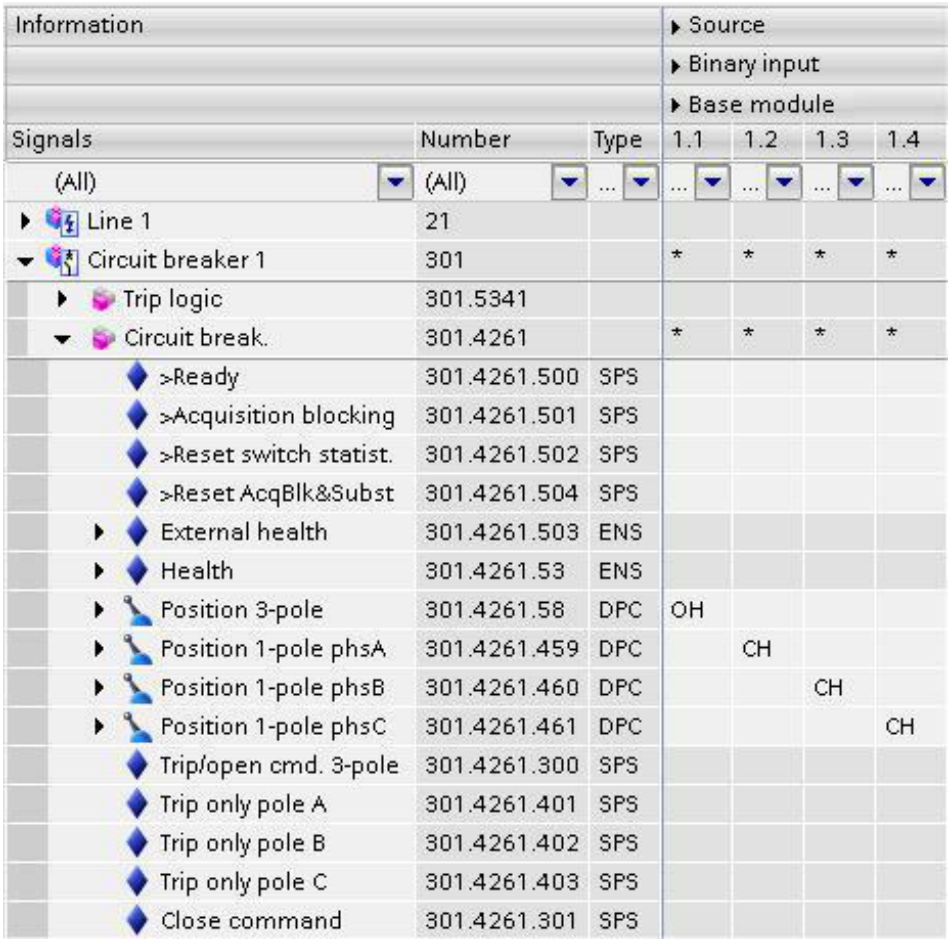
[sc_rang_1p_cb13pz, 1, en_US]

Figure 7-16 Routing in DIGSI

In the previous figure, the switch is connected 1-pole. The protection trip command is routed individually for the 3 phases (**`Trip only pole A`** to **`Trip only pole C`**). The protection trip command is routed for the 3 phases (**`Trip/open cmd. 3-pole`**). The control always switches off the 3 poles of the switch. In addition, the 3 **U** (Unlatched) routings of the trip command and open command are set to 3-pole. This routing is also used by protection functions that trip 3 poles. The close command is issued simultaneously for all 3 phases.



Example: Trip Command during Transition from 1-Pole to 3-Pole

During a transition from 1-pole to 3-pole tripping **`Trip only pole A`** remains active. When, for example informing an external AREC whether it is a 1-pole or 3-pole tripping, you can use the indication *`Trip logic:Trip indication:1-pole`* and *`Trip logic:Trip indication:3-pole`*.

Acquisition of the Circuit-Breaker Position

The binary inputs for feedback of the switch position are routed as shown in the previous figure (see also see *5.9.7.3 Acquisition of Circuit-Breaker Auxiliary Contacts and Further Information*).

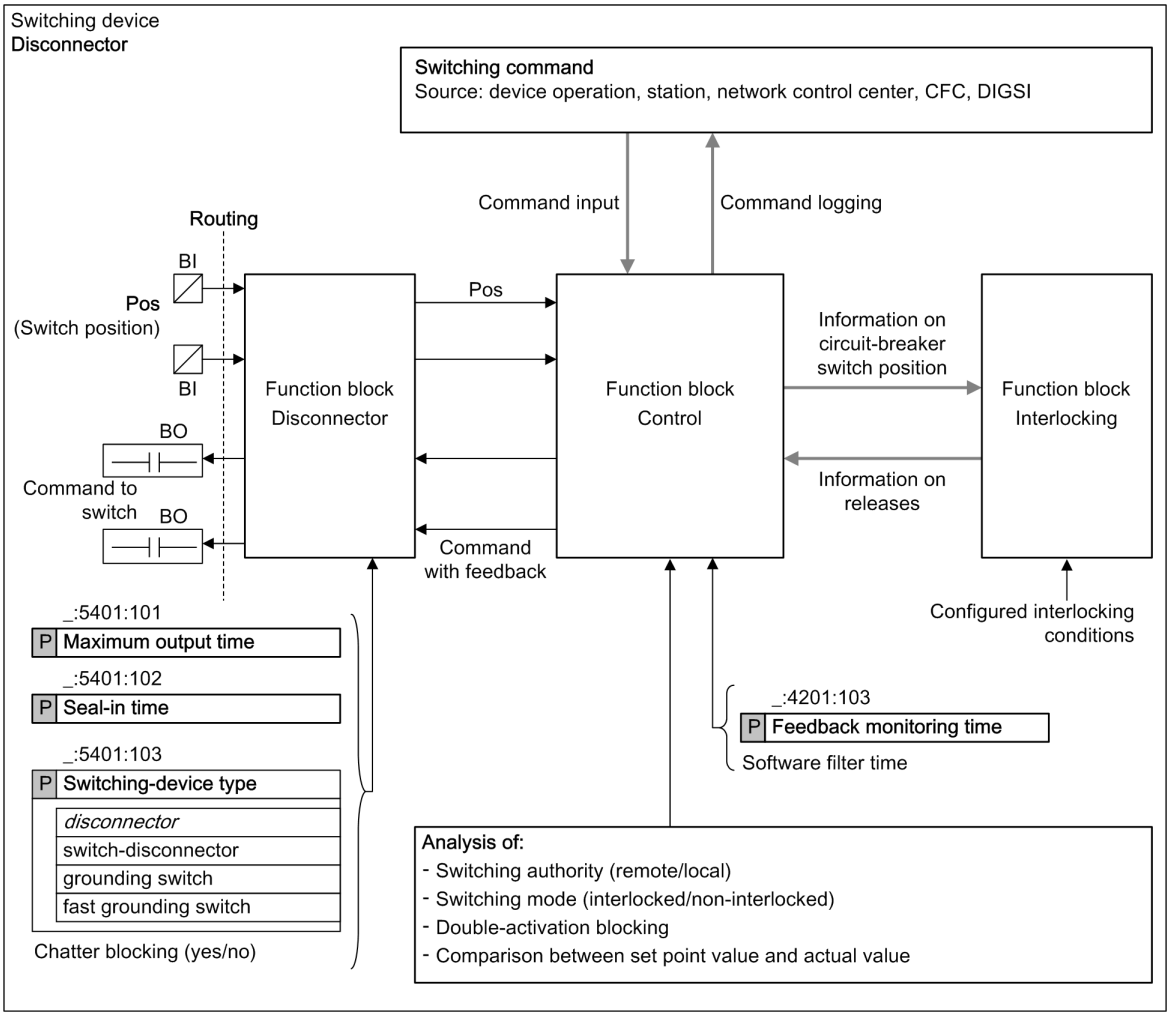
7.2.3 Disconnector Switching Device

7.2.3.1 Structure of the Disconnector Switching Device

Like the circuit breaker, the **Disconnector** switching device contains the following 3 function blocks:

- Function block **Disconnector**
- Function block **Control**
- Function block **Interlocking**



This corresponds to the logical nodes XSWI, CSWI, and CILO in IEC 61850.

NOTE

In contrast to the **Circuit-breaker** switching device, the **Disconnector** switching device cannot contain any additional functions because protection functions or synchronization can have no effect on the disconnector.

The following figure shows the structure of the **Disconnector** switching element:

[dw_discon, 2, en_US]

Figure 7-18 Control-Relevant Function Blocks of the Disconnector Switching Device

The **Disconnector** switching device behaves like the **Circuit-breaker** switching device. The only difference is the designation of the function block that the physical switch provides (disconnector instead of circuit breaker). Blocking by protection is not provided in the analysis of the **Control** function block.

The **Disconnector** switching device is available in the DIGSI 5 library in 2 different variants:

- **Disconnector with 3-pole connection**
  The device switches all 3 poles of the disconnector on or off simultaneously.
- **Disconnector without triggering (only status detection, no control)**
  This variant is rarely encountered. It is encountered with grounding switches that frequently cannot be controlled, but only provide their current position. In addition, the position of a disconnector in a neighboring bay can be acquired.

Function Blocks of the Disconnector

Table 7-10 Function Blocks of the Disconnector Function Group

Function Block	Description	Parameter	Function
Discon-nector	The disconnector represents the physical switch in the SIPROTEC 5 device.	**`Maximum output time`** **`Seal-in time`** **`Switching-device type`**	The disconnector replicates the switch position from the status of the binary inputs and also transmits the command via the binary outputs.
Control	Command processing	**`Control model`** **`SBO time-out`** **`Feedback monitoring time`** **`Check switching authority`** **`Check if pos. is reached`** **`Check double activat. blk.`**	Command checks, communication with the command source and with the function block **Disconnector**
Inter-locking	Switchgear interlocking protection	Interlocking condition (deposited in CFC)	The **Interlocking** functionality generates the releases for switchgear interlocking protection.

You can find the setting values of the parameter in *7.2.3.2 Application and Setting Notes*.

Additional Settings of Disconnector Switching Element

The settings of the disconnector are assigned to the function blocks on the basis of their relevance. Additional disconnector settings that cannot be directly assigned to one of the 3 function blocks and are identical to the circuit-breaker settings are available:

Table 7-11 Setting Options of the Controllable **`Command with Feedback`** in the **`Control`** Function Block of the Circuit Breaker

Characteristics	Function	To Be Found in
`Software filtering time`	Software filtering time for position detection	Position of the **Control**(1) function block
`Retrigger filter` (yes/no)	Switching retriggering of the filtering time on/off by changing the position	Position of the **Control**(1) function block
`Message time before filtering` (yes/no)	Consideration of the hardware filtering time for position-detection time stamp	Position of the **Control**(1) function block
`Suppress intermediate position` (yes/no)	When activated, only the intermediate position is suppressed by the duration of the software filtering time.	Position of the **Control**(1) function block

Characteristics	Function	To Be Found in
Spontaneous position changes filtered by (Gen. Software Filt./Spont. Software Filt.)	If the ***General software filter*** setting is selected, the general settings for software filtering of spontaneous position changes and for position changes caused by a switching command apply. By selecting ***Spontaneous software filter***, a separate filtering is activated for spontaneous position changes.	Position of the **Control**(1) function block
Spontaneous software filter time	Software filtering time for spontaneous position changes	Position of the **Control**(1) function block
Spontaneous retrigger filter (yes/no)	Switching on/off retriggering of the filtering time by spontaneous position change	Position of the **Control**(1) function block
Spontaneous indication timestamp before filtering (yes/no)	Consideration of the hardware filtering time for position-detection time stamp in case of a spontaneous change	Position of the **Control**(1) function block
Spontaneous suppress intermediate position (yes/no)	When activated, only the spontaneous change to the intermediate position is suppressed by the duration of the software filtering time.	Position of the **Control**(1) function block

(1) First click **Position** and then click the **Details** button in the **Properties** window (below).

Table 7-12 Setting Options of the Controllable **Position** in the Disconnector Function Block (Chatter Blocking)

Characteristics	Function	To Be Found in
Chatter blocking (yes/no)	Switching chatter blocking on/off	Position of the **Disconnector** (1) function block

(1) First click **Position** and then click the **Details** button in the **Properties** window (below).

Table 7-13 Additional Settings in the Device Settings with Effects on the Disconnector

Characteristics	Function	To Be Found in
Number of permissible state changes	Chatter-blocking setting value: Once for the entire device	Device settings (to be found under Settings)
Chatter test time		
Number of chatter tests		
Chatter dead time		
Chatter test time		

The inputs and outputs as well as the setting options of the **Disconnector switch** function block are described in *7.2.3.3 Trigger Variants of the Disconnector*. The **Control** function block is described identically as the **Circuit-breaker** function block, with the exception that the command check blocking is available through protection only with the circuit breaker.

You can find more information on this in *7.2.2.2 Application and Setting Notes*.

Interlocking

The **Interlocking** function block generates the releases for switchgear interlocking protection. The actual interlocking conditions are deposited in CFC. For more information on this, see the general chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*.

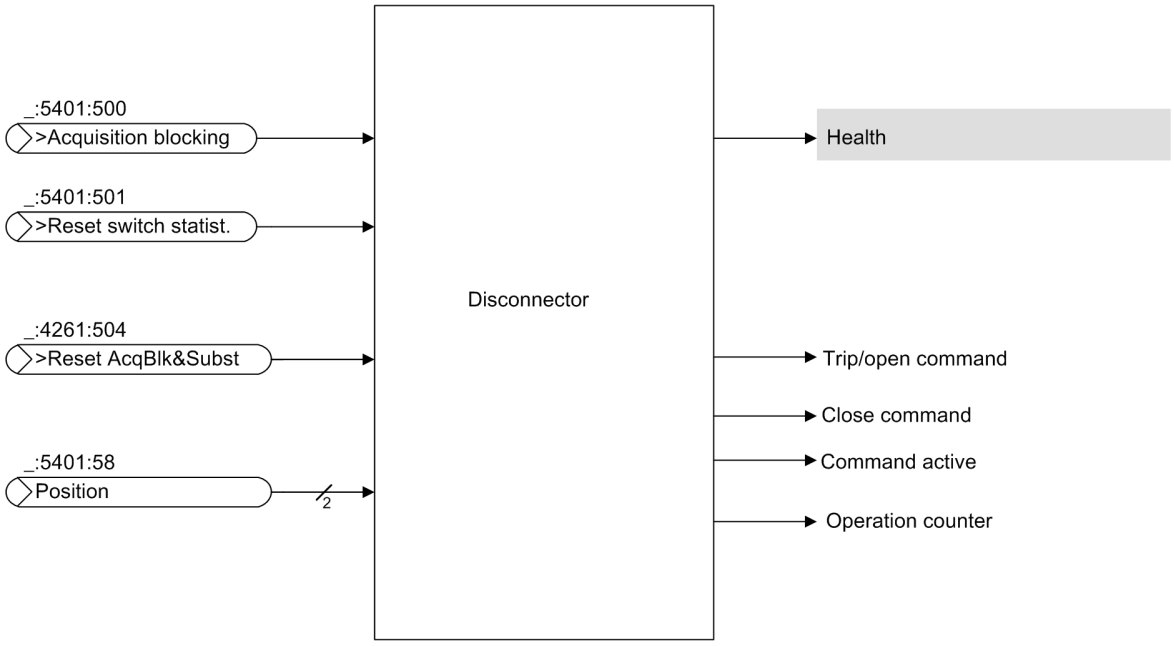
7.2.3.2 Application and Setting Notes

Disconnector

The disconnector represents the physical switch in the SIPROTEC 5 device. The task of the disconnector is to replicate the switch position from the status of the binary inputs.

The **Disconnector** function block is linked automatically via the information matrix with the binary inputs that register the switch position and with the binary outputs that issue the switching commands.

The **Disconnector** function block makes the following settings available (see next table).



Parameters	Default Setting	Possible Parameter Values
(_:5401:101) Maximum output time The **Maximum output time** specifies the duration of the output pulse created by the switching command.	***10.00 s***	0.02 s to 1800 s (Increment: 0.01 s)
(_:5401:102) Seal-in time If the target actuating position is not yet attained although feedback has already been received, the output time is extended by the **Seal-in time**. The Seal-in time is relevant for equipment that sends feedback before the switching operation is completely performed. The Seal-in time is only considered for control models with feedback monitoring.	***0.00 s***	0 s to 60 s
(_:5401:103) Switching-device type The **Switching-device type** specifies the type of the switching device.	***disconnector***	***switch-disconnector*** ***disconnector*** ***grounding switch*** ***fast grounding switch***

NOTE

The parameter **Switching-device type** is effective only on the IEC 61850 interface. This parameter is used to set the disconnector switching device type for communication via IEC 61850. It is a mandatory data object in the IEC 61850 standard.

The following figure shows the logical inputs and outputs of the **Disconnector** function block.

[dw_out_inp, 2, en_US]

Figure 7-19 Logical Inputs and Outputs of the Disconnector Function Block

Table 7-14 and *Table 7-15* list the inputs and outputs with a description of their function and type. For inputs, the effect of **Quality = invalid** on the value of the signal is described.

Table 7-14 Inputs of the Disconnector Function Block

Signal Name	Description	Type	Value if Signal Quality=Invalid
>Acquisition blocking	The binary input activates acquisition blocking. You can also set this binary input with an external toggle switch.	SPS	Unchanged
>Reset AcqBlk&Subst	Acquisition blocking and the substitution of the circuit breaker are reset with this input. If the input is activated, setting of the acquisition blocking and of the substitution is blocked.	SPS	Unchanged
>Reset switch statist.	The binary input sets the operation counter for the switch to the value 0.	SPS	Unchanged
Position	The binary input **Position** can be used to read the disconnector position with double-point indication.	DPC	Unchanged

If the quality of the input signal assumes the status **Quality = invalid**, then the standby status (Health) of the **Disconnector** function block is set to *warning*.

Table 7-15 Outputs of the Disconnector Function Block

Signal Name	Description	Type
Open command	This binary output is responsible for the command output **Off**.	SPS
Close command	This binary output is responsible for the command output **On**.	SPS

Signal Name	Description	Type
Command active	The binary output **Command active** is a running command for the signalization (command active or selected switching device). During Command active either an On or Off command is active.	SPS
Op.ct.	The information counts the number of disconnector switching cycles.	INS

Control

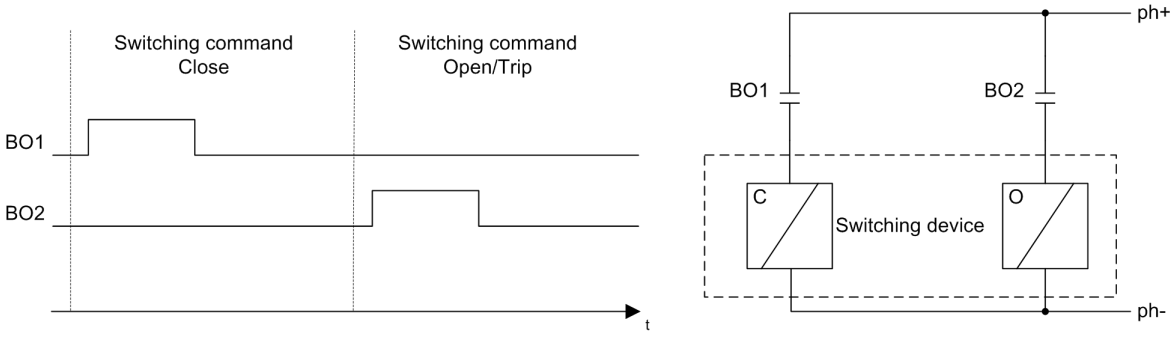
It is the task of the controls to execute command checks and establish communication between the command source and the disconnector. Using the control settings, you specify how the commands are to be processed (see also chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*).

Through the function SBO (Select Before Operate, reservation[59]), the switching device is reserved prior to the actual switching operation, thus it remains locked for additional commands. Feedback monitoring provides information about the initiator of the command while the command is in process, that means, informing whether or not the command was implemented successfully. These two options can be selected individually in the selection of the control model, so that 4 combinations in total are available (see the following table).

The control makes the following settings available (see next table).

Parameters	Default Setting	Possible Parameter Values
(_:4201:101) Control model	***SBO w. enh. security***[60]	***direct w. normal secur.*** ***SBO w. normal secur.*** ***direct w. enh. security*** ***SBO w. enh. security***
(_:4201:102) SBO time-out	***30.00 s***	-
(_:4201:103) Feedback monitoring time	***10.00 s***	-
(_:4201:104) Check switching authority	***yes***	***no*** ***yes*** ***advanced***
(_:4201:105) Check if pos. is reached	***yes***	***no*** ***yes***
(_:4201:106) Check double activat. blk.	***yes***	***no*** ***yes***

7.2.3.3 Trigger Variants of the Disconnector



The activation types are identical to those for the circuit breaker. The meaning of abbreviations can be found in *7.2.2.3 Connection Variants of the Circuit Breaker* and *7.2.2.3 Connection Variants of the Circuit Breaker*.

Whether the disconnector is triggered for 1-, 1.5-, or 2-phases depends on the design of the auxiliary and control voltage system.

59 In the IEC 61850 standard, Reservation is described as **Select before Operate (SBO)**.

60 This default setting is the standard control model for a switching command in an IEC 61850-compliant system.

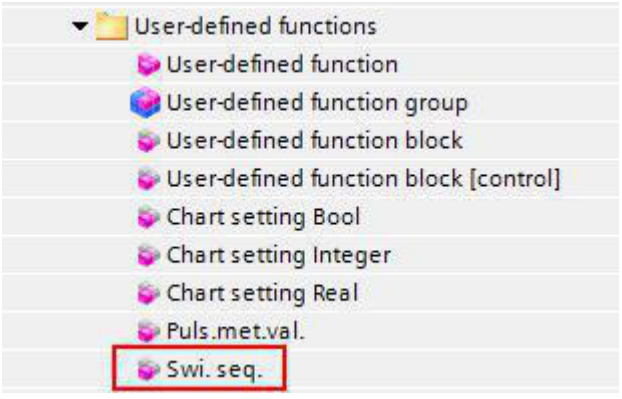
7.3 Switching Sequences



7.3.1 Overview of Functions

Switching sequences may be running inside the device that switch the switchgear automatically in a prespecified sequence.

A switching sequence consists of a special function block **Switching sequence** (Swi. seq.) from the DIGSI 5 Library and the project-specific list of the switching commands that are generated in the CFC.

7.3.2 Function Description

The function block **Switching sequence** is located in folder **User-defined functions** in the DIGSI 5 Library.

[sc_udeffb, 1, en_US]

Figure 7-26 Function Block **Switching Sequence** in the Library

These function blocks can be used in the information matrix on the highest level (level of the function groups) or in a user-defined function group.

One **Switching sequence** function block is used per switching sequence. The function block is the interface for controlling and monitoring the condition of the CFC switching sequence. The task of the function block is to verify the relative conditions for control commands, for example, switching authority, interlocking conditions, etc. You can connect the signals of the function block with the CFC chart. They start and stop the switching sequence and provide data about the status of the switching sequence (see *Figure 7-27*). The CFC chart is used to activate the switching device that must be switched. The CFC blocks define, among other things, the switching devices that must be switched.

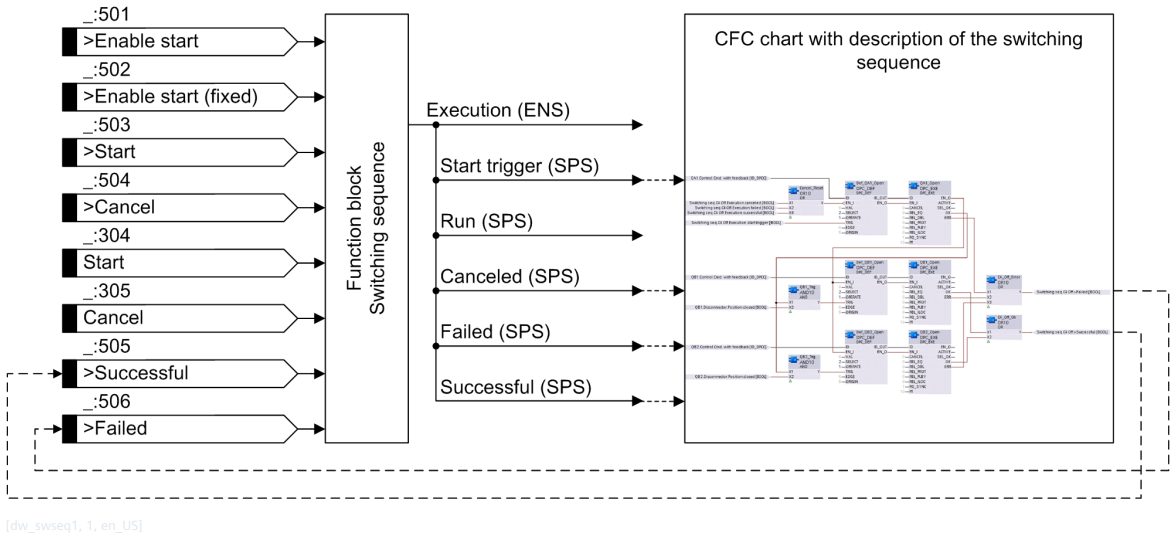


Figure 7-27 **Switching Sequence** Function Block

Starting and Canceling a Switching Sequence

One of the following methods can be used to start a switching sequence:

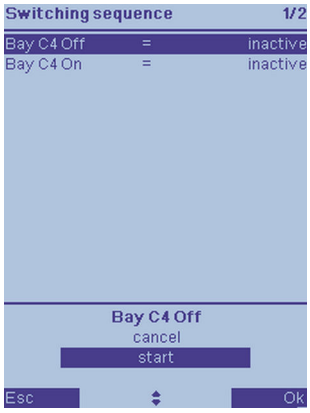
- On-site operation: menu or display page
- Input *>Start* during rising edge, for example, via binary input
- Controllable *Start* for the start via a communication protocol, for example, IEC 61850, T103, or DNP
- Input *>Start* via a function key
- Controllable *Start* via a function key

One of the following methods can be used to cancel a switching sequence:

- On-site operation: menu or display page
- Input *>Cancel* during rising edge, for example, via binary input
- Controllable *Cancel* for the cancelation via a communication protocol, for example, IEC 61850, T103, or DNP
- Input *>Cancel* via a function key
- Controllable *Cancel* via a function key

On-Site Operation

If at least one **Switching sequence** function block is used in the device, a new **Switching sequences** entry is shown in the first line of the **Control** menu. If this menu item is selected, an overview of all switching sequences and the current status will be displayed (see *Figure 7-28*, example with 2 switching sequences). You can start or cancel the switching sequences from this menu.



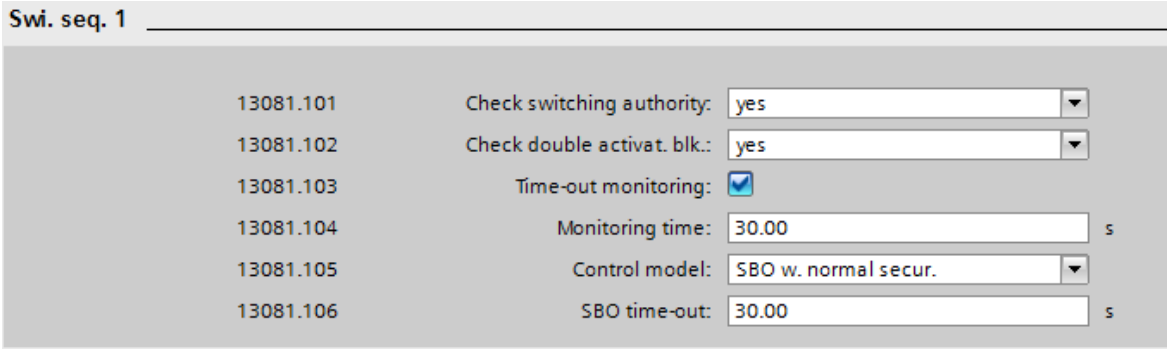


Figure 7-28
Overview of the Switching Sequences on the Device Display

7.3.3 Application and Setting Notes

The function block offers similar settings to the **Control** function block of a circuit breaker or disconnector (see chapter *7.2.1 General Overview*).

[sc_ccs4pa, 1, en_US]

Figure 7-29 Settings of the **Switching Sequence** Function Block

Parameter: **`Check switching authority`**

- Default setting **`(_:101) Check switching authority`** = ***`yes`***

With the **`Check switching authority`** parameter, you can determine whether the switching authority should be checked before the execution of the switching sequence.

Parameter: **`Check double activat. blk.`**

- Default setting **`(_:102) Check double activat. blk.`** = ***`yes`***

With the **`Check double activat. blk.`** parameter, you can determine whether the double activation of switching devices should be checked. The setting value ***`yes`*** indicates that a switching sequence will be started only if no switching commands for a circuit breaker and disconnector are active, provided that double-activation blocking was activated for those switching devices.

Parameter: **`Time-out monitoring`**

With the **`Time-out monitoring`** parameter, you can determine whether the feedback from the process should be evaluated. The feedback is gathered via the inputs *`>Successful`* and *`>Failed`*.

Parameter: **`Monitoring time`**

- Default setting **`(_:104) Monitoring time`** = ***`30.00 s`***

With the **`Monitoring time`** parameter, you can determine the duration of the monitoring time.

Parameter: **`Control model`**

- Default setting **`(_:105) Control model`** = ***`SBO w. normal secur.`***

With the **`Control model`** parameter, you select between ***`direct w. normal secur.`*** or ***`SBO w. normal secur.`*** to start the switching sequence.

It is not possible to set a control model for cancelation of the switching sequence. The control model ***`direct w. normal secur.`*** is always used to cancel the function.

Information

The **Switching sequence** function block provides the following data:

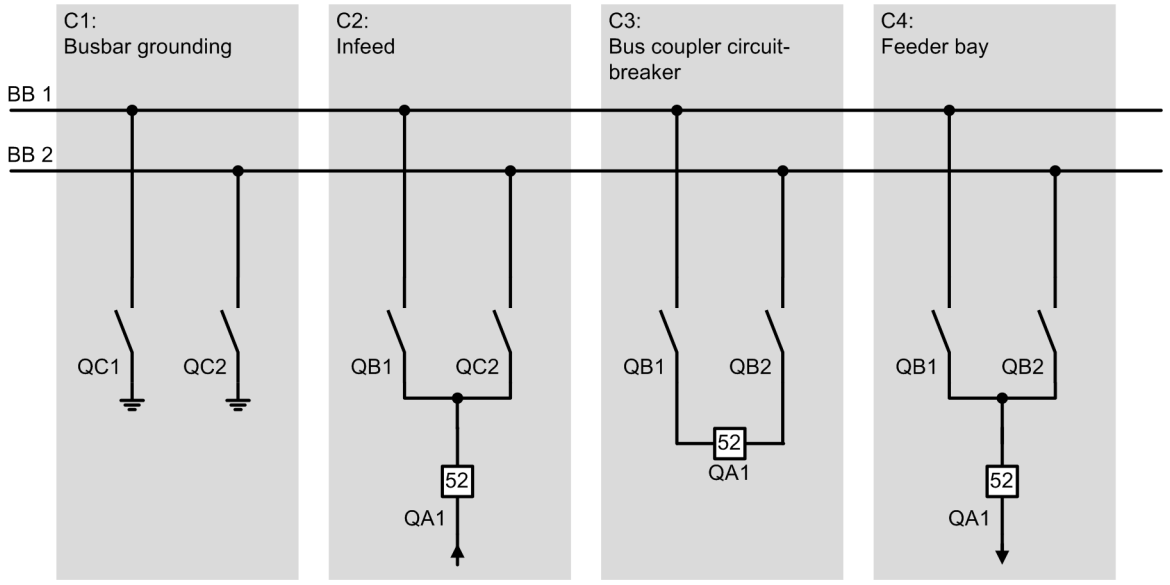
Swi. seq. 1	13081	
>Enable start	13081.501	SPS
>Enable start (fixed)	13081.502	SPS
>Start	13081.503	SPS
>Cancel	13081.504	SPS
>Successful	13081.505	SPS
>Failed	13081.506	SPS
Health	13081.53	ENS
Execution	13081.302	ENS
start trigger		SPS
running		SPS
canceled		SPS
failed		SPS
successful		SPS
Start	13081.304	SPC
Cancel	13081.305	SPC
Switching auth. station	13081.303	SPC

[sc_infof1, 1, en_US]

Figure 7-30 Data Provided by the **Switching Sequence** Function Block

In the **Switching sequence** function block, the interlocking is analog to the **Interlocking** function block and it is possible to use it in the switching sequence:

- *`>Enable start`*: Connection to interlocking conditions (CFC) for the start of the entire switching sequence. Not in effect in the **non-interlocked** switching mode.
- *`>Enable start (fixed)`*: Non-revocable interlocking conditions for the start of the entire switching sequence. In effect regardless of the switching mode.

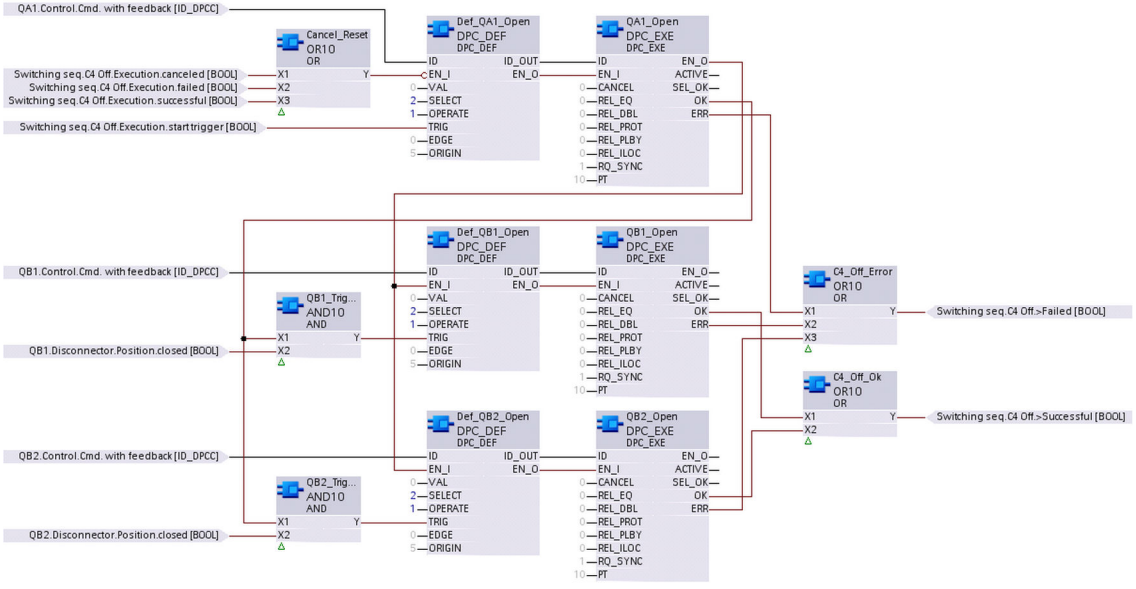


If the time-out monitoring is activated (parameter **`Time-out monitoring`**), the process feedback must take place via the inputs *`>Successful`* and *`>Failed`*. If the last switching command of the switching sequence was executed successfully, the input *`>Successful`* usually is set. To do this, connect the feedback of the last switching command from the CFC with this input of the function block during the device parameterization.

If a switching command fails, this feedback can be captured by the input *`>Failed`*. The active switching sequence will be ended immediately and does not have to wait for a time-out.

The indication *`Execution`* signals the current state of the switching sequence. The events *`running`*, *`canceled`*, *`failed`*, and *`successful`* are generated only while the time-out monitoring is activated. The event *`Start Trigger`* is used to start the switching sequence in the CFC chart.

Example for a Switching Sequence with CFC



The following figure shows a single-line diagram for a substation with 4 bays: Busbar grounding, infeed, bus-coupler circuit-breaker, and feeder bay.

[dw_bspunt, 1, en_US]

Figure 7-31 Example of a Substation

The switching sequence **C4 Off** (*Figure 7-32*) should switch off feeder bay C4. The circuit breaker is opened; followed by opening of one of the 2 busbar disconnectors.

[sc_ssc4as, 1, en_US]

Figure 7-32 CFC Switching Sequence **C4 Off**

Command Execution

As described in section *Starting and Canceling a Switching Sequence, Page 1856*, the display page or the **Control** menu can be used to start the switching sequence. The *Start Trigger* signal for indication *Execution* is used to recognize the start and initiates the switching sequence by pickup of **TRIG** in the DPC-DEF building block of circuit breaker QA1. Building blocks DPC-DEF and DPC-EXE are always used in pairs. The DEF building block controls the type and nature of the command

- **VAL** = Switching direction (0 = Off, 1 = On)
- **SELECT** = Select switching device (2 = Select with a value suitable for the preset control model ***SBO w. enh. security***)
- **OPERATE** = Switch switching device (1 = Switching device is switched on or off)

Using the connected DPC-EXE building block, the command checks can be deactivated (**REL_**...). In the application example, all inputs are set to 0 and therefore, all checks are activated.

After the open command of circuit breaker QA1 is acknowledged via the auxiliary contacts, the **OK** output of the CFC block DPC_EXE becomes active and triggers the next switching object. With the input **PT** the signal for the **OK** output is time-delayed (in the example by 10 ms) and creates a dead time between individual switching commands and the switching sequence. This dead time is important for the updating of the interlocking conditions.

If QB1 is closed, QB1 will be opened. If QB2 is closed, QB2 will be opened. In order to implement this logic, the **OK** output signal of QA1 is linked with the respective positions of circuit breakers QB1 and QB2 via the logical AND function. This signal serves as a trigger for the trip command of QB1 or QB2.

Because in this example the time-out monitoring is activated, the feedback about the successful or unsuccessful execution of the switching sequence must be parameterized. The **Switching sequence** function block provides the inputs *>Successful* and *>Failed*. In order to acknowledge the entire switching sequence positively, the OR operation of the **OK** outputs for the disconnectors QB1 and QB2 is sufficient. The feedback of all failed executions takes place via the OR operation of all **ERR** outputs of the switching devices. The benefit of such assessment is the fact that, in case of a failure, waiting for the time-out is not necessary, but the active switching sequence can be ended immediately.

In this example, the use of the **EN_I** input of building block DPC-DEF fulfills 2 tasks:

- Cancelation of the entire switching sequence
- Resetting of the outputs **OK** and **ERR** on building block DPC-EXE

By linking all **EN_I** inputs and **EN_O** outputs of building blocks DPC-DEF and DPC-EXE, the execution of the switching sequence can be controlled centrally since the value is transmitted between the building blocks. Only if input **EN_I** on the DPC-EXE is set to 1, a switching command is issued. If the input drops back to 0 while a command is being processed, this command will be canceled. With this behavior, cancelation of an entire switching sequence can be achieved. As recognition of a cancelation, the *canceled* signal of the indication *Execution* is used in the CFC chart and connected with the input **EN_I** of the first switching device, in this example, with the DPC-DEF building block of circuit breaker QA1.

Since the **OK** and **ERR** outputs of the DPC-EXE building block maintain their value until execution of the next command, it is necessary to reset the continuous output after each execution of the switching sequence for correct execution of the entire CFC switching sequence multiple times. In this case, the use of the **EN_I** input is also helpful. In the input drops back to 0, the **OK** and **ERR** outputs are also reset to 0. The triggers for ending the switching sequence are the events *failed* and *successful*. For this reason, in the above example, the signals *failed* and *successful* of the indication *Execution* were connected with **EN_I** of the DPC-DEF building block.

7.3.4 Settings

Addr.	Parameter	C	Setting Options	Default Setting
Swi. seq. #				
_:101	Swi. seq. #:Check switching authority		• no • yes • advanced	yes

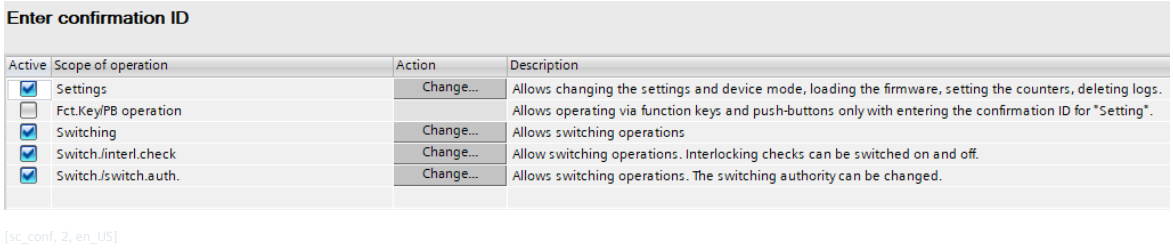
_:305	Swi. seq. #:Cancel	SPC	C

7.4 Control Functionality



7.4.1 Command Checks and Switchgear Interlocking Protection

Before switching commands can be issued by the SIPROTEC 5 device, several steps are used to check the command:

- Switching mode (interlocked/non-interlocked)
- Switching authority (local/DIGSI/station/remote)
- Switching direction (set=actual)
- Bay interlocking and substation interlocking
- 1-out-of-n check (double-activation blocking)
- Blocking by protection function

Confirmation IDs (with Inactive RBAC)

SIPROTEC 5 devices can operate using role-based access control (RBAC). If RBAC is active in the device, the authorizations to execute various actions are linked directly to the role concept.
If RBAC is inactive in the device, various actions are secured using the **confirmation IDs**. The following **confirmation IDs** from the **Safety** menu apply to the control functions:

[sc_conf, 2, en_US]

Figure 7-33 Confirmation IDs in DIGSI 5: Settings Menu

The following table identifies the meanings of the confirmation IDs:

Table 7-16 Relevant Confirmation IDs for Controls

Confirmation ID	Meaning	Description
Setting	Changing settings	The confirmation ID is requested before the device parameters can be changed.
Operation (function keys)	Process data access via function buttons	Access to process data is possible with the help of push-buttons and function buttons. The confirmation ID of **Set/operation** is requested.
Switching	General release for control of switching devices	The confirmation ID is usually not needed for bay controllers. In the case of protection devices, this confirmation ID can be used to safeguard control of switching devices.

Confirmation ID	Meaning	Description
Switch./interl.check	Switching non-interlocked	Switching mode: Release for switching without querying the interlocking conditions (***S1 operation***). The fixed interlocking conditions (for example, **>Enable opening(fixed)** and **>Enable closing (fixed)**) are still queried if this is set in the parameters. The confirmation ID is queried only for devices without a key switch; otherwise it is replaced with the key switch position.
Switch./switch.auth.	Release for switching authority **Local**	The confirmation ID is queried only for devices without a key switch; otherwise it is replaced with the key switch position.

The confirmation IDs are preset with the following values:

- Setting 222222
- Switching 333333
- Switch./interl.check 444444
- Switch./switch.auth. 666666

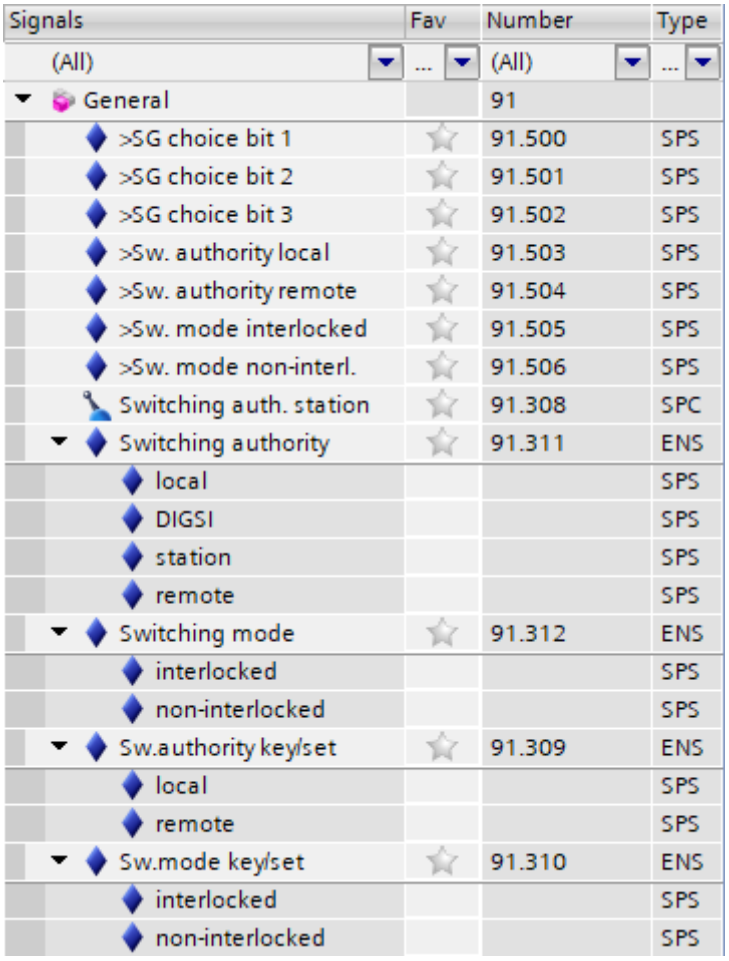
If you have configured a device with key switches, the confirmation IDs for non-interlocked switching and switching authority are not displayed or editable in DIGSI; the function is handled by the position of the key switch.

To increase security, change these codes with DIGSI.

Switching Mode (Interlocked/Non-Interlocked)

The switching mode determines whether or not the switchgear interlocking that has been configured in the CFC is checked before the command is output.

You can change the switching mode with the key switch **S1** (interlocking off/normal). For devices without a key switch, you can change the switching mode with a corresponding menu item on the display (after input of a confirmation ID). You can also set the switching mode for switching commands from the sources DIGSI, station or remote.



DANGER

If the switching mode = non-interlocked, the switchgear interlocking protection is shut off.

Erroneous switching operations can lead to severe or fatal injuries.

✧ Ensure manually that all checks have been implemented.

In addition, you can set the switching mode directly with a binary input or CFC. Use the **General** function block (see next figure).

Signals	Fav	Number	Type
(All)	...	(All)	...
General		91	
>SG choice bit 1		91.500	SPS
>SG choice bit 2		91.501	SPS

interlocked			SPS
non-interlocked			SPS

[sc_moscha, 1, en_US]

Figure 7-34 Switching Mode in Function Block General

The following table shows the effects of changing the switching mode to use command checks.

Table 7-17 Relationship Between Switching Mode and Command Checks

Command Check	Switching Mode	
	Interlocked	Non-Interlocked
Switching authority	Checked	Checked
Switching direction (set=actual)	Checked	Checked
Fixed interlocking conditions	Checked	Checked
Interlocking conditions	Checked	Not checked
1-out-of-n check (double-activation blocking)	Checked	Not checked
Blocking by protection function	Checked	Not checked

Switching Authority

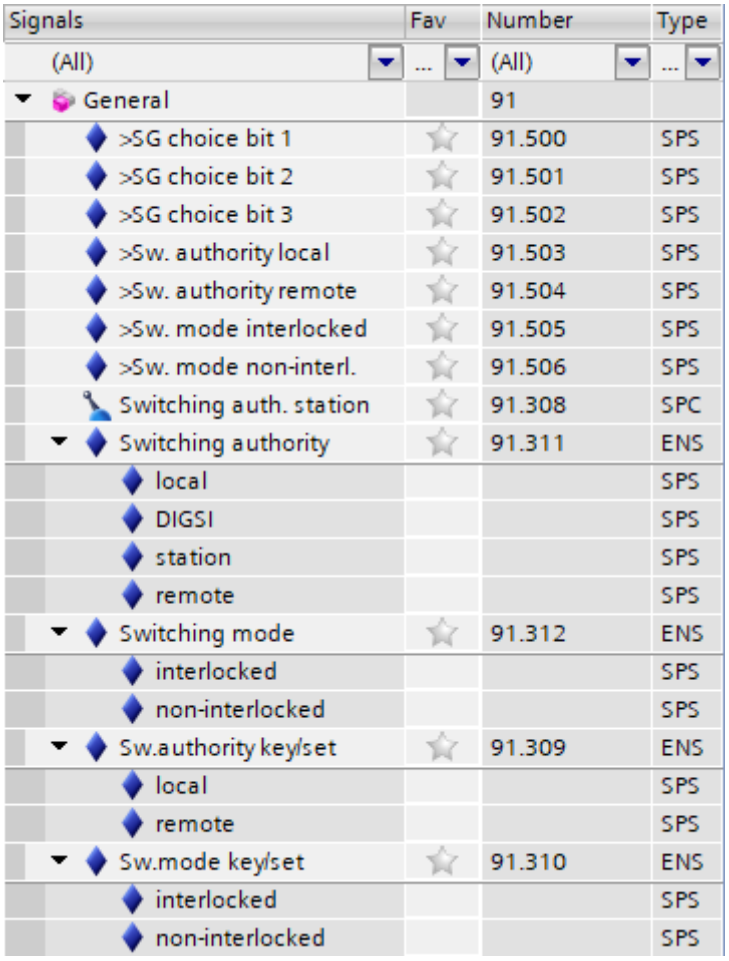
The switching authority determines which command source is allowed. The following command sources are possible:

- **Local**:

  A switching command from the local control (cause-of-error source **Local**) is possible only if the switching authority is set to **Local** and the device is capable of on-site operation. Setting the switching authority to **Local** is typically accomplished with key switch **S5** (Local/Remote). In this case, commands from all other sources are rejected. If the switching authority is set to **Local**, the setting cannot be changed **remotely**.

- **DIGSI**:

  A switching command from DIGSI (connected via USB or Ethernet, cause-of-error source **Maintenance**) is accepted only if the switching authority in the device is set to **Remote**. Once DIGSI has signed on the device for command output, no commands from other command sources or a different DIGSI PC will be executed.



- **Station**:

  This switching authority level can be activated via a parameter in the **General** function block. A switching command from the station level (cause-of-error source **Station** or **Automatic station**) is accepted if the switching authority is set to **Remote** and the controllable **Station switching authority** is set. This is accomplished by a command from the substation automation technology. Switching commands from the device or from outside the station (cause-of-error source **Local**, **Remote** or **Automatic remote**) are rejected.

  Full support of the switching-authority level is assured only when using the IEC 61850 protocol.

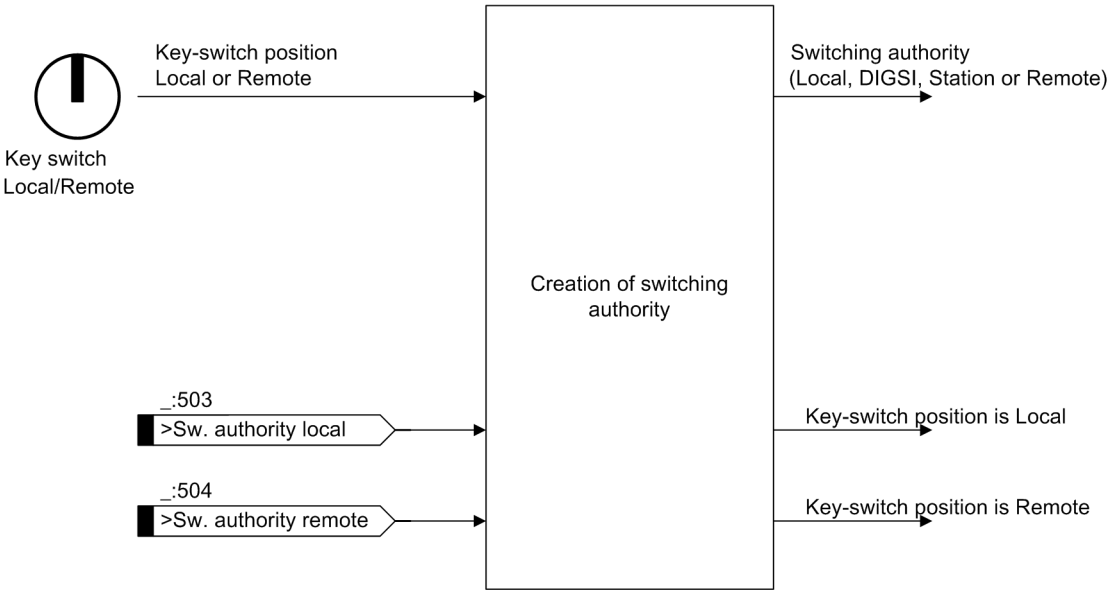
- **Remote**:

  This switching authority level stands from remote control directly from the network control center or (if the switching authority level **Station** is not activated) generally for **Remote** control. The cause-of-error source is **Automatic remote**. Commands from this level are accepted if the switching authority is set to **Remote** and the controllable **Station switching authority** is not set. Switching commands from the device or from the station (cause-of-error source **Local**, **Station** or **Automatic station**) are rejected.

[sc_moscha, 1, en_US]

Figure 7-35 Display of Switching Authority and Switching Mode in Information Routing (in Function Block General)

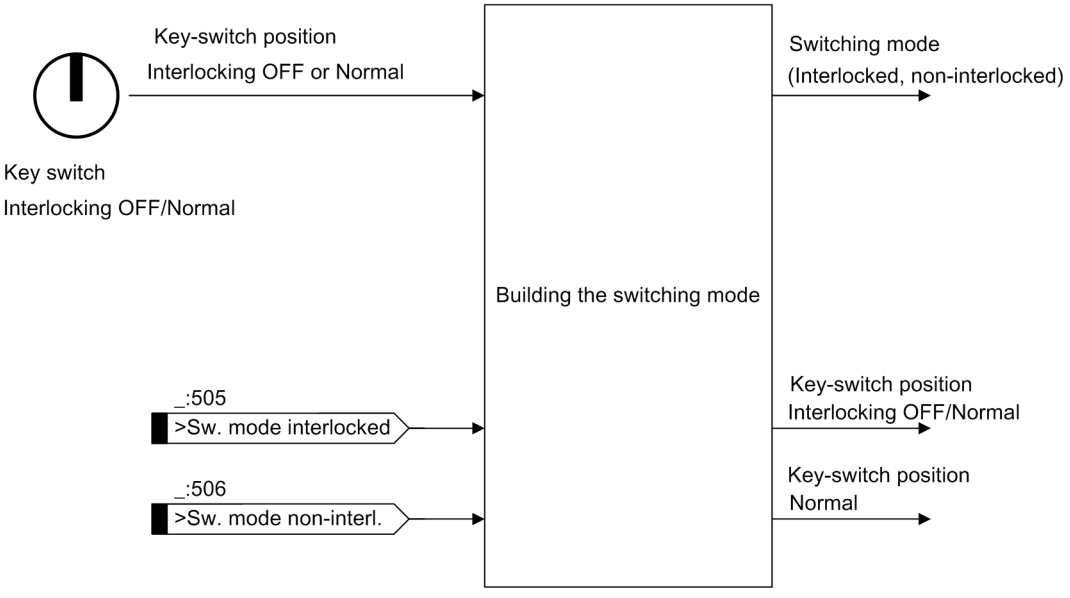
Sw. authority key/set and **Sw.mode key/set** indicate the current state of the key switch or parameter for switching authority or switching mode and provide this information for further processing in the CFC. In the CFC, for example, it is possible to set up an automatic routine to ensure that the switching authority is automatically set to ***Local*** when the key switch is set to ***non-interlocked***.



The following table shows the dependency of the switching mode on the key-switch position and the switching authority. In the case of switching commands from **Remote**, the information on whether switching is to be made to locked or unlocked is also sent. For this reason, the position of the key switch is irrelevant for the switching mode in these cases. The information in the table assumes that, in the case of **remote** switching commands or those from the **station**, the switching mode is *interlocked* in each case.

Table 7-18 Dependency of the Switching Mode on the Key-Switch Position and Switching Authority

	Switching Authority		
Key Switch for Switching Mode	**Local**	**Remote**	**Station**
Interlocked	Interlocked	Interlocked	Interlocked
Not interlocked	Non-interlocked	Interlocked	Interlocked

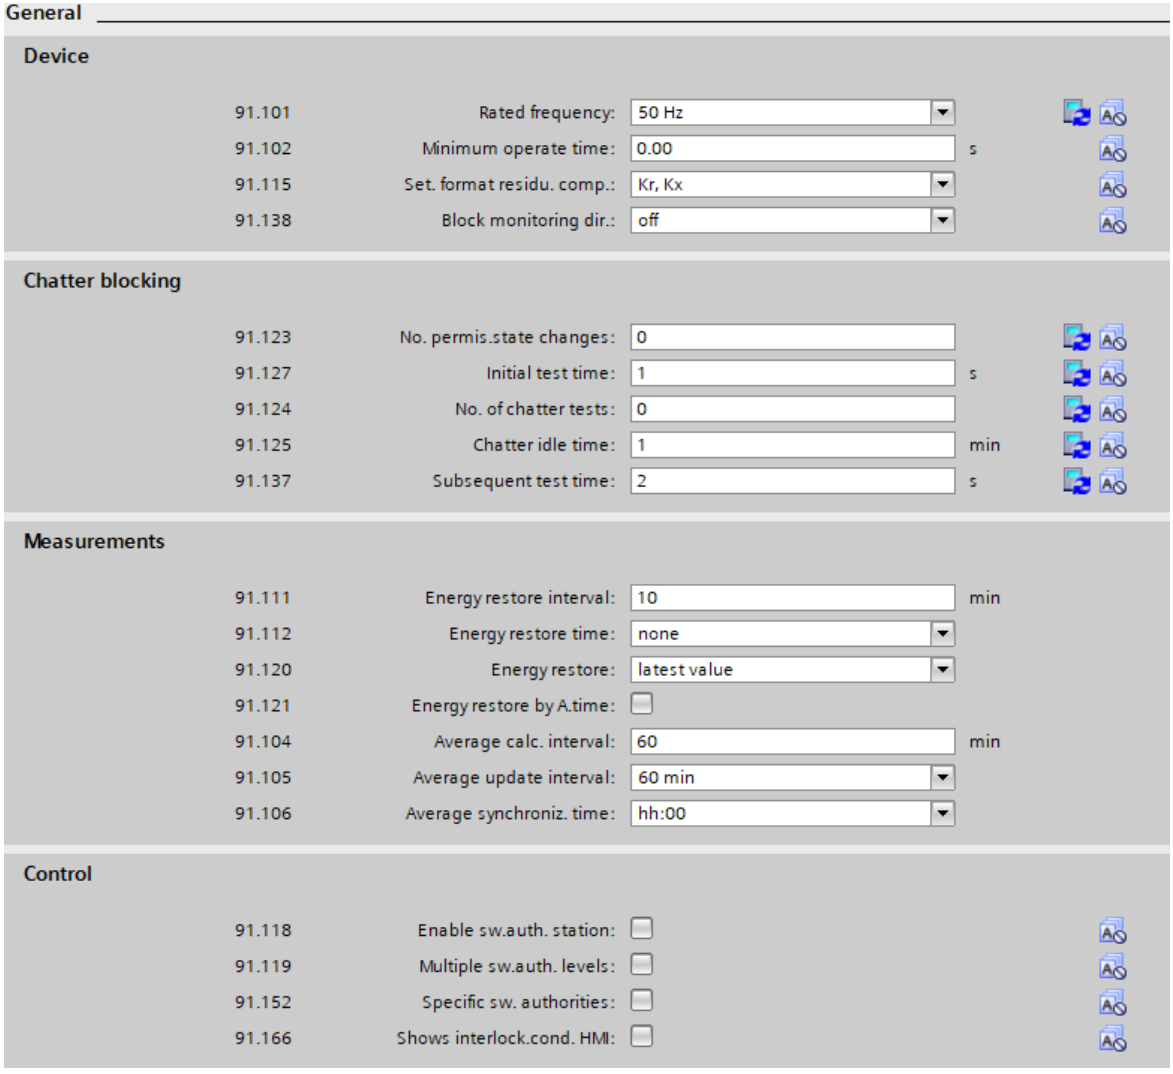


The signals shown in *Figure 7-35* in DIGSI 5 information routing have the following relationship:

- In terms of switching authority and switching mode, the respective key switch position serves as the input signal and the input signals in the matrix.
- The state of the switching authority and switching mode is indicated by corresponding output signals.
- The **Switching authority** and **Switching mode** functions link the input signals and in this way establish the output signals (see *Figure 7-36* and *Figure 7-37*).

[dw_authority, 1, en_US]

Figure 7-36 Establishing Switching Authority



[dw_modsch, 1, en_US]

Figure 7-37 Establishing Switching Mode

In the case of both functions, the input signals overwrite the state of the key switch. This allows external inputs to also set the switching authority or switching mode, if desired (for instance, by querying an external key switch).

The following additional settings are available for the switching authority:

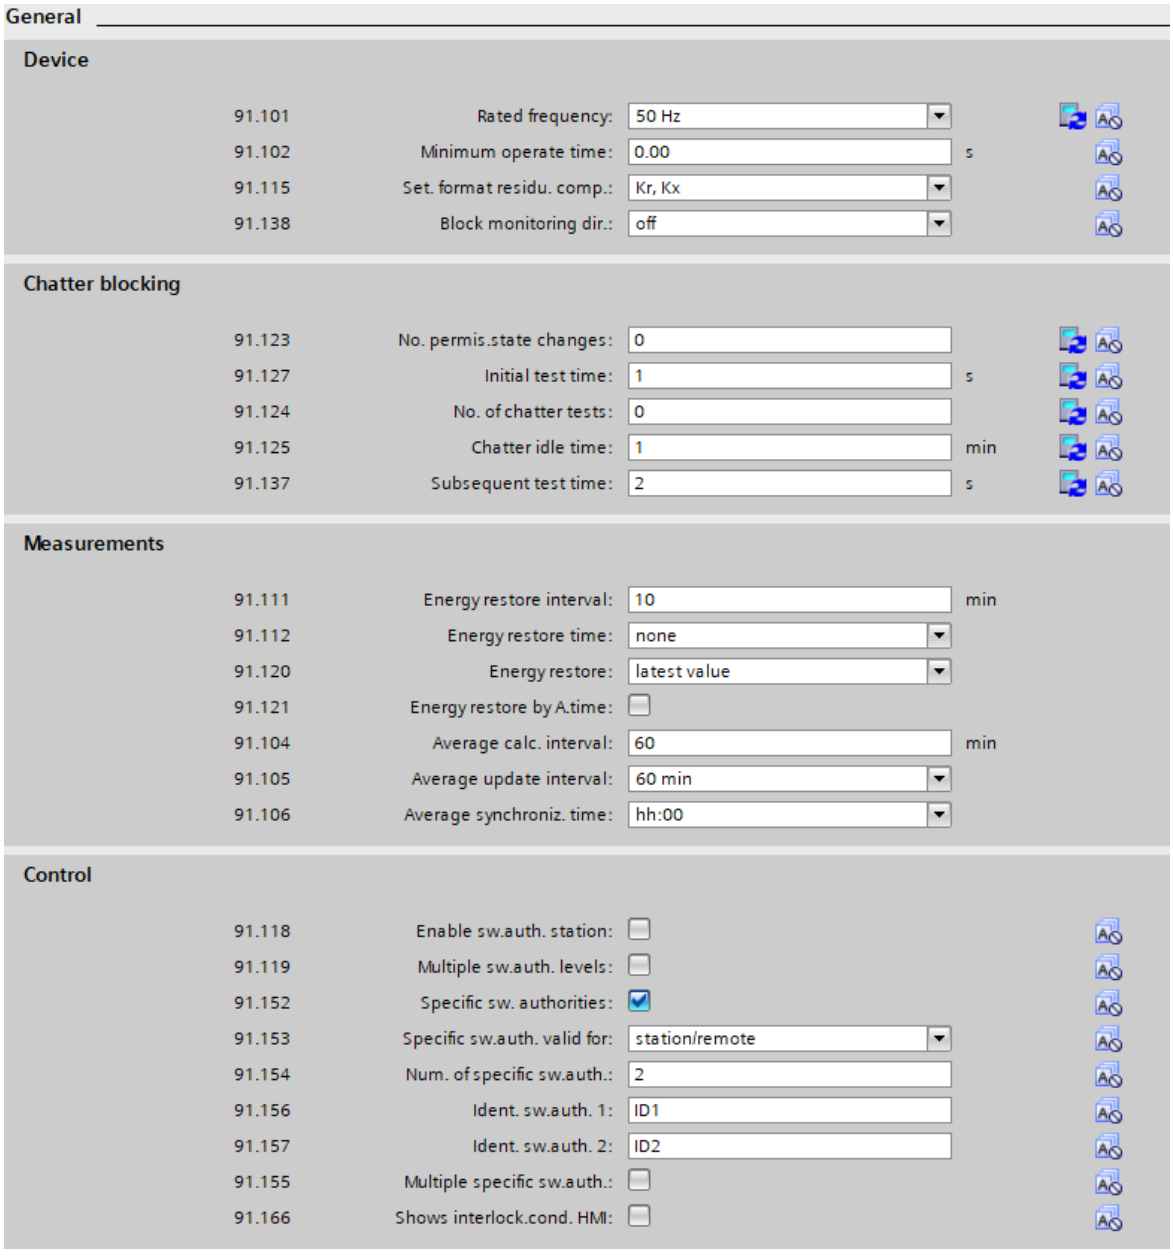
- **`Enable sw.auth. station`** (defined in IEC 61850 Edition 2):
  If you would like to use this switching authority, set the check mark **General/Control**.
- **`Multiple sw.auth. levels`**:
  This option permits switching commands from several command sources in the device if the switching authority **Remote** is selected. Subsequently, a distinction between these command sources can also be made. You can find more details in the following table. Activate this option by setting the check mark **General/Control**.
- **`Specific sw. authorities`**:
  You can enable additional options for the switching authority check. You can find more information about these options in *Specific Switching Authority, Page 1869*. By default, these are not used.
- **`Show int.lck.cond. on HMI`**:
  You can activate the parameter to show the status of interlocking conditions in the device. For additional information refer to *Specific Switching Authority, Page 1869*. By default, this parameter is inactive.

[sc_akt_hoh, 2, en_US]

Figure 7-38 How to Activate the Station Switching Authority and to Enable Several Switching-Authority Levels

Table 7-19 Effect on Switching Authority when Several Switching-Authority Levels Are Enabled with/ without Activation of the Station Switching Authority

Release Several Switching Authority Levels	Switching Authority in the Device	Status of DIGSI in the Device	Station Switching Authority Activated	State of the Station Switching Authority	Resulting Switching Authority
No	Local	–	–	–	Local
	Remote	Signed on	–	–	DIGSI
		Not signed on	No	–	Station and remote
			Yes	Set	Station
				Not set	Remote
Yes	Local	–	–	–	Local
	Remote	Signed on	–	–	DIGSI
		Not signed on	No	–	Local and station and remote
			Yes	Set	Local and station
				Not set	Local and station and remote



The following table shows the result of the switching-authority check, based on the set switching authority and the cause of the command. This overview represents a simplified normal case (no multiple command sources when using Station and Remote).

Table 7-20 Result of a Switching-Authority Check

Cause Source	Switching Authority			
	Local	DIGSI	Station	Remote
Local	Release	Blocked	Blocked	Blocked
Station	Blocked	Blocked	Release	Blocked
Remote	Blocked	Blocked	Blocked	Release
Local automatic operation	Release	Release	Release	Release
Station automatic operation	Blocked	Blocked	Release	Blocked
Remote automatic operation	Blocked	Blocked	Blocked	Release
DIGSI	Blocked	Release	Blocked	Blocked

Specific Switching Authority

Special switching authorities can be configured as extension of the switching-authority check. This makes it possible to differentiate the **Remote** command sources at the bay level. Switching authority can be routed to or revoked from different control centers that can, for example, belong to different companies. Thus, precisely one of these command sources can switch at a certain time. This function is based on extending the switching-authority check by verifying the identifier of the command source (field **Originator/orIdent** of switching command). In order to turn on the function, go to **General/Control** and set the check mark for the parameter **`Specific sw. authorities`**. More settings for the configuration of the identifiers and the behavior of the function as well as additional signals appear (see *Figure 7-40*). In order to permit an additional command source to switch, you must activate this specific switching authority. In order to do this, set the controllable **`Enable sw. auth. 1`** to **`Enable sw. auth. 5`**.

[sc_act additional options sw authority, 4, en_US]

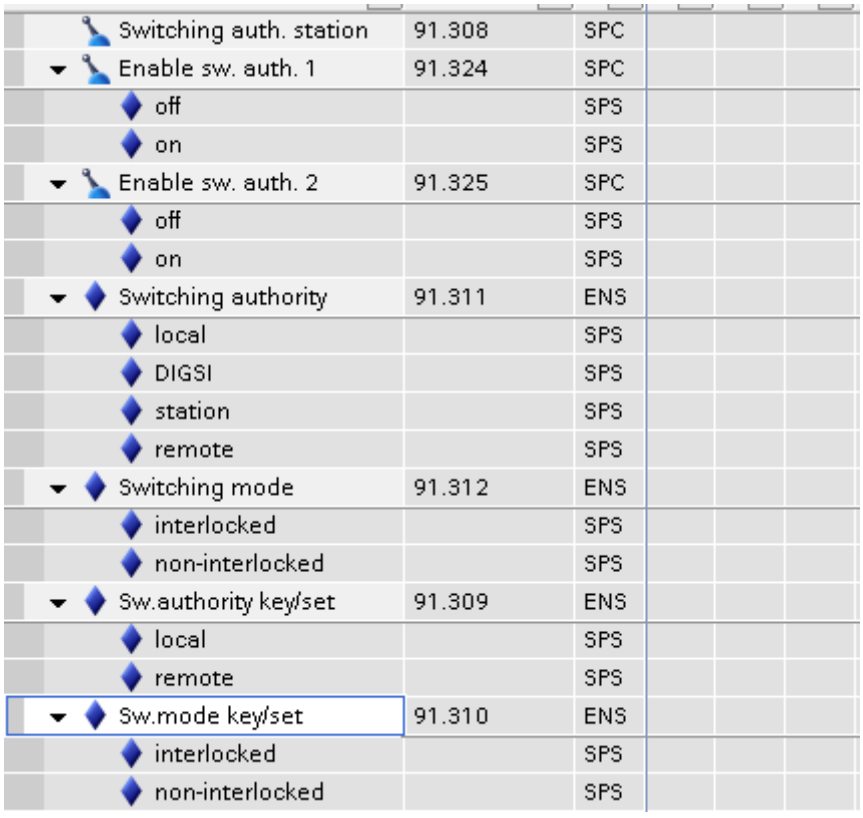
Figure 7-39 Activating Additional Options of the Switching Authority

The additional parameters allow you to set the following options:

- **`Specific sw.auth. valid for`** (for ***`station/remote`***, only ***`remote`*** or only ***`station`***):
  With this parameter, you determine for which command source the extended switching-authority check is used.

Table 7-21 Result Derived from the Combination of the Parameter Value **`Specific sw.auth. valid for`** and the Level of the Command Source (Field **`Originator/orCat`** of the Switching Command)

Command Source	`Specific sw.auth. valid for`		
	`station`	***`station/remote`***	***`remote`***
Local, local automatic	No check	No check	No check
Station, station automatic	Check	Check	No check



Command Source	Specific sw.auth. valid for		
	station	*station/remote*	*remote*
Remote, remote automatic	No check	Check	Check
DIGSI	No check	No check	No check

- **Num. of specific sw.auth.**:
  With this parameter, you determine how many specific switching authorities are available. This determines the number of parameters **Identifier switching authority** as well as the controllable **Active. Sw. auth.**.
- **Identifier switching authority 1** to **Identifier switching authority 5**:
  The number of names that appear corresponds to the number set in the previous parameter. You can select the names as you wish, 1 to 64 characters are allowed. The command check verifies whether these titles correspond with those sent by the command source. This applies to the switching commands as well as to the activation of a specific switching authority. The requirement for this is the system interface IEC 61850. The field **Originator/orIdent** is used.
- **Multiple specific sw.auth.** ensures the simultaneous validity of the various command sources. The following table shows how to determine the resulting specific switching authority when activating the command sources of Remote or Station. If this parameter is activated, all parameterized command sources get permissible automatically (see last row in the table) and they cannot be deactivated via the controllable **Enable sw. auth. 1** to **Enable sw. auth. 5**. Otherwise, the enabled command source with the lowest number has always the highest priority and prevails against the other numbers.

Table 7-22 Determining Switching Authority if Multiple Command Sources Are Available

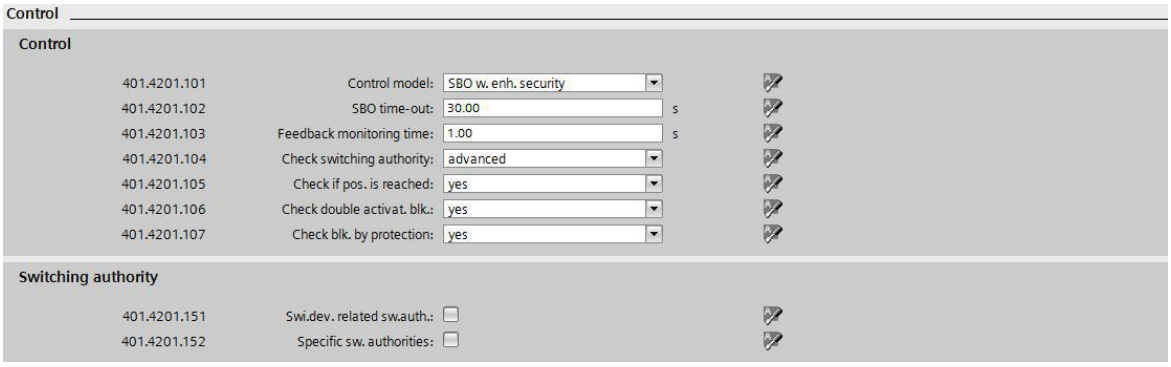
Multiple specific sw.auth.	Enable sw. auth. 1	Enable sw. auth. 2	Enable sw. auth. 3	Enable sw. auth. 4	Enable sw. auth. 5	Resulting Specific Switching Authority
No	On	*	*	*	*	Switch. auth. 1
No	Off	On	*	*	*	Switch. auth. 2
No	Off	Off	On	*	*	Switch. auth. 3
No	Off	Off	Off	On	*	Switch. auth. 4
No	Off	Off	Off	Off	On	Switch. auth. 5
No	Off	Off	Off	Off	Off	None
Yes	On	On	On	On	On	All

The * symbol in the previous table refers to any value.

[sc_sw authority and mode in info routing, 1, en_US]

Figure 7-40 Display of Switching Authority and Switching Mode in the Information Routing (in Function Block General), Example of 2 Activated Remote Switching Authorities

Individual Switching Authority and Switching Mode for the Switching Devices

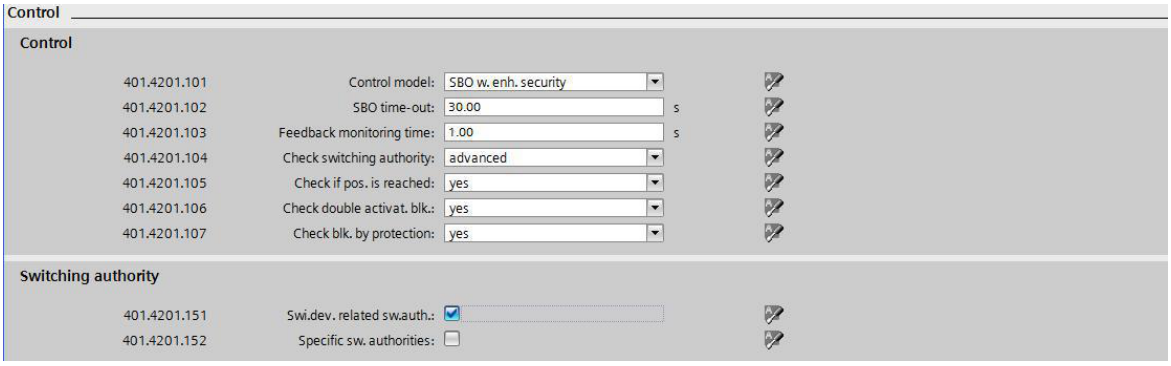


In a standard case, the functionalities switching authority, switching mode, and specific switching authority as described in the previous sections, are applicable to the entire bay unit and, therefore, are valid for all switching devices that are controlled by this bay unit. In addition, you can configure an individual switching authority and specific switching authority as well as individual switching modes for single switching devices. Therefore, individual switching devices can accept various switching authorities and switching modes simultaneously.

This is offered for the following function groups and function blocks:

- **Circuit-breaker** function group
- **Disconnector** function group
- **Transformer tap changer** function group
- **Switching sequence** function block

This allows to select individual settings for each switching device. This is useful if, for example, switching devices of different utilities are managed within a single bay.



In order to activate this option, go to the function block **Control** of a switching device and set the parameter **`Check switching authority`** to ***`advanced`***. An additional table containing initially 2 parameters is displayed.

[sc_add parameters sw authority sw device, 1, en_US]

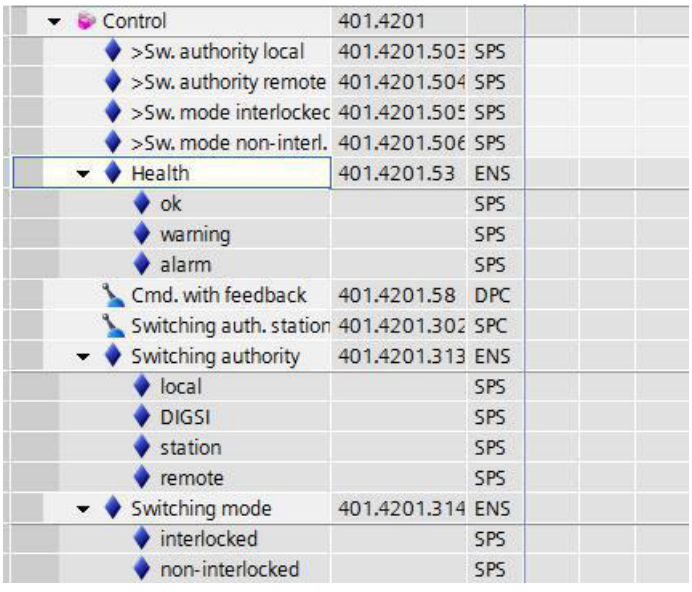


Figure 7-41 Additional Parameters for Switching Authorities in the Parameters of a Switching Device

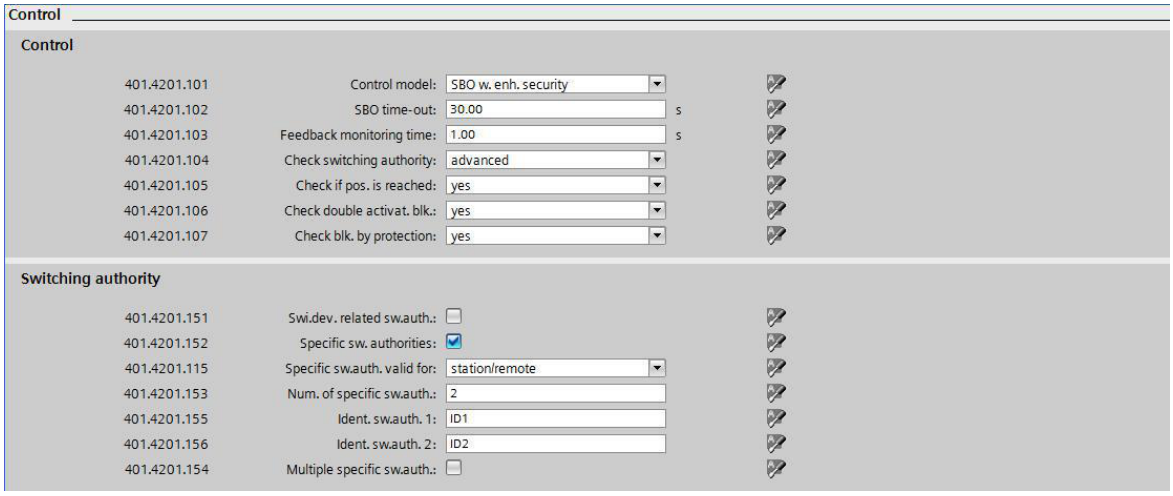
When activating the parameter **Swi.dev. related sw.auth.**, an individual switching authority as well as an individual switching mode for this switching device are configured. Additional signals are displayed in the **Control** function block of the corresponding switching device.

[sc_extended parameters sw authority sw device, 1, en_US]

Figure 7-42 Expanded Parameters for the Switching Authority in the Switching Device

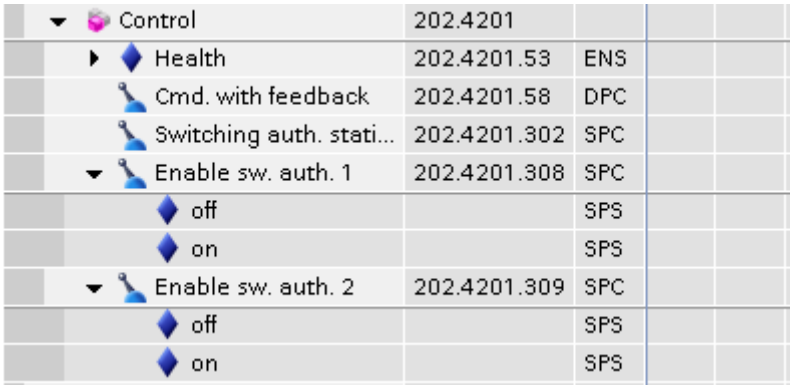


[sc_switching auth sw mode changeable, 1, en_US]

Figure 7-43 Individually Modifiable Switching Authority and Switching Mode for Switching Devices

The new input signals that are displayed allow you to set the individual switching authority and switching mode for the switching devices. For this switching device, these inputs overwrite the central switching

authority and the switching mode. The outputs *Switching authority* and *Switching mode* indicate the states only for this switching device.



When activating **Specific sw. authorities**, an individual specific switching authority for this switching device is configured. Additional parameters are displayed.

[sc_parameters FB control all additional options, 1, en_US]

Figure 7-44 Parameters of the FB Control with All Additional Options

The functionality of the specific switching authority for the individual switching device and the significance of the additional parameters is identical to the operating mode of the central specific switching authority. Additional signals are displayed in the **Control** function block.

[sc_specific sw authority changeable per sw device, 1, en_US]

Figure 7-45 Specific Switching Authority, Modifiable for Each Switching Device

Switching Direction (Set = Actual)

With this check, you avoid switching a switching device into a state that has already been achieved. For instance, before a trip command is issued to a circuit breaker, its current position is determined. If this circuit breaker is already in the ***Off*** position, no command is issued. This is logged accordingly.

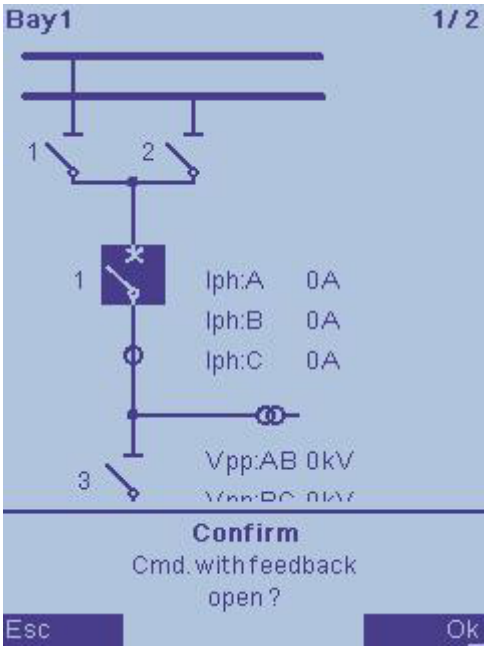
Switchgear Interlocking Protection

Switchgear interlocking protection means avoiding maloperation by checking the bay and substation interlocking and thus preventing equipment damage and personal injury. The interlocking conditions are always system-specific and for this reason are stored as CFC charts in the devices.

SIPROTEC 5 devices recognize 2 different types of interlocking conditions:

- Normal interlocking conditions:
  These can be revoked by changing the switching mode to **non-interlocked**.

- Non-revocable (fixed) interlocking conditions:
  These are still checked even if the switching mode is set to **non-interlocked**.
  Application: Replacing mechanical interlocking, for example, that prevent actuation of a medium-voltage switch.



Each of the 2 categories has 2 release signals (for the ***On*** and ***Off*** switching directions) that represent the result of the interlocking plan, so that interlocking is in effect during the command check (see the figure below). The default setting for all release signals is ***TRUE***, so that no switchgear interlocking checks take place if no CFC charts have been prepared.

Information			Source							
			Binary input							
			Base module							
Signals	Number	Type	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8
(All)	(All)	...	...	...	...	...	...	...	...	...
Circuit breaker 1	201									
Trip logic	201.5341									
Circuit break.	201.4261									
Manual close	201.6541									
Control	201.4201									
Interlocking	201.4231									
>Enable opening	201.4231.500	SPS								
>Enable closing	201.4231.501	SPS								
>Enable opening (fixed)	201.4231.502	SPS								
>Enable closing (fixed)	201.4231.503	SPS								
Health	201.4231.53	ENS								

[sc_verrie, 1, en_US]

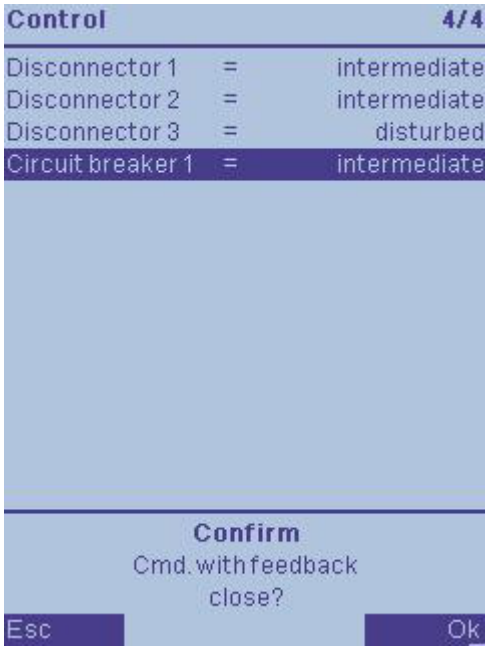


Figure 7-46 Interlocking Signals in Function Block Interlocking

By default, the status of interlocking conditions is not visible in the device, see the following figure.

[sc_HMI_WO_Position, 1, en_US]

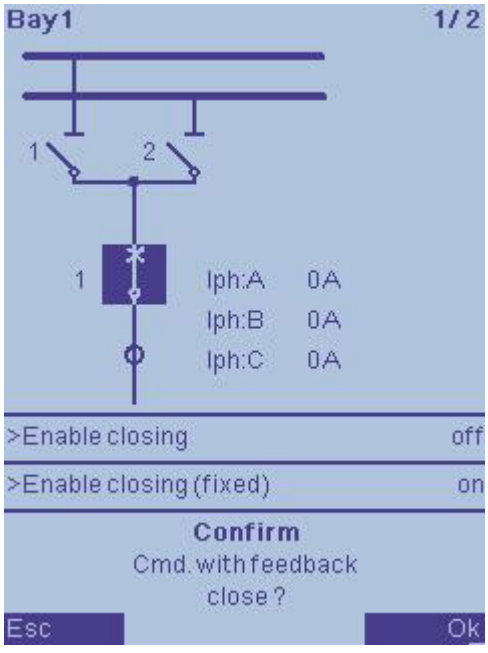

Figure 7-47 The Status of Interlocking Conditions is not Visible in the Control Display

[sc_HMI_WO_Position2, 1, en_US]

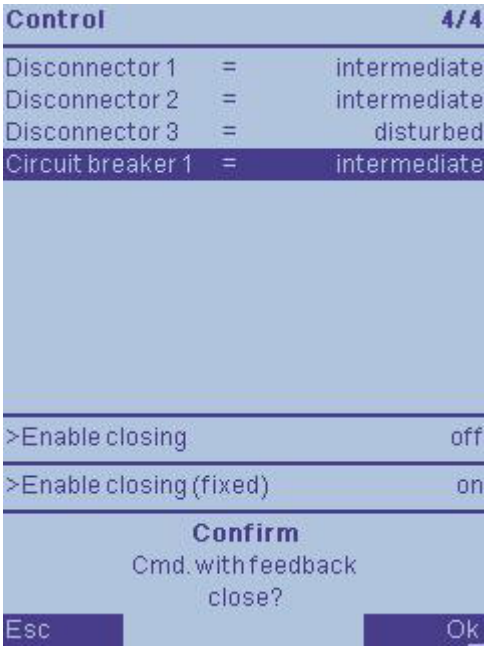

Figure 7-48 The Status of Interlocking Conditions is not Visible in the Control Menu

But, if you activate the parameter **`Show int.lck.cond. on HMI`** by navigating to **Settings** > **Device settings** > **General** > **Control** in DIGSI 5, you can get the status of interlocking conditions in the device.

[sc_HMI_W_Position, 1, en_US]

Figure 7-49 The Status of Interlocking Conditions is Visible in the Control Display

[sc_HMI_W_Position2, 1, en_US]

Figure 7-50 The Status of Interlocking Conditions is Visible in the Control Menu

EXAMPLE

For Interlocking

For the making direction of the circuit breaker QA in bay E01 (see the figure below), it is necessary to check whether the disconnectors QB1, QB2, and QB9 are in the defined position, that is, either **`On`** or ***`Off`***. Opening the circuit breaker QA should be possible at any time.

The interlocking equations are: QA_On = ((QB1 = On) or (QB1 = Off)) and ((QB2 = On) or (QB2 = Off)) and ((QB9 = On) or (QB9 = Off)). There is no condition for opening.

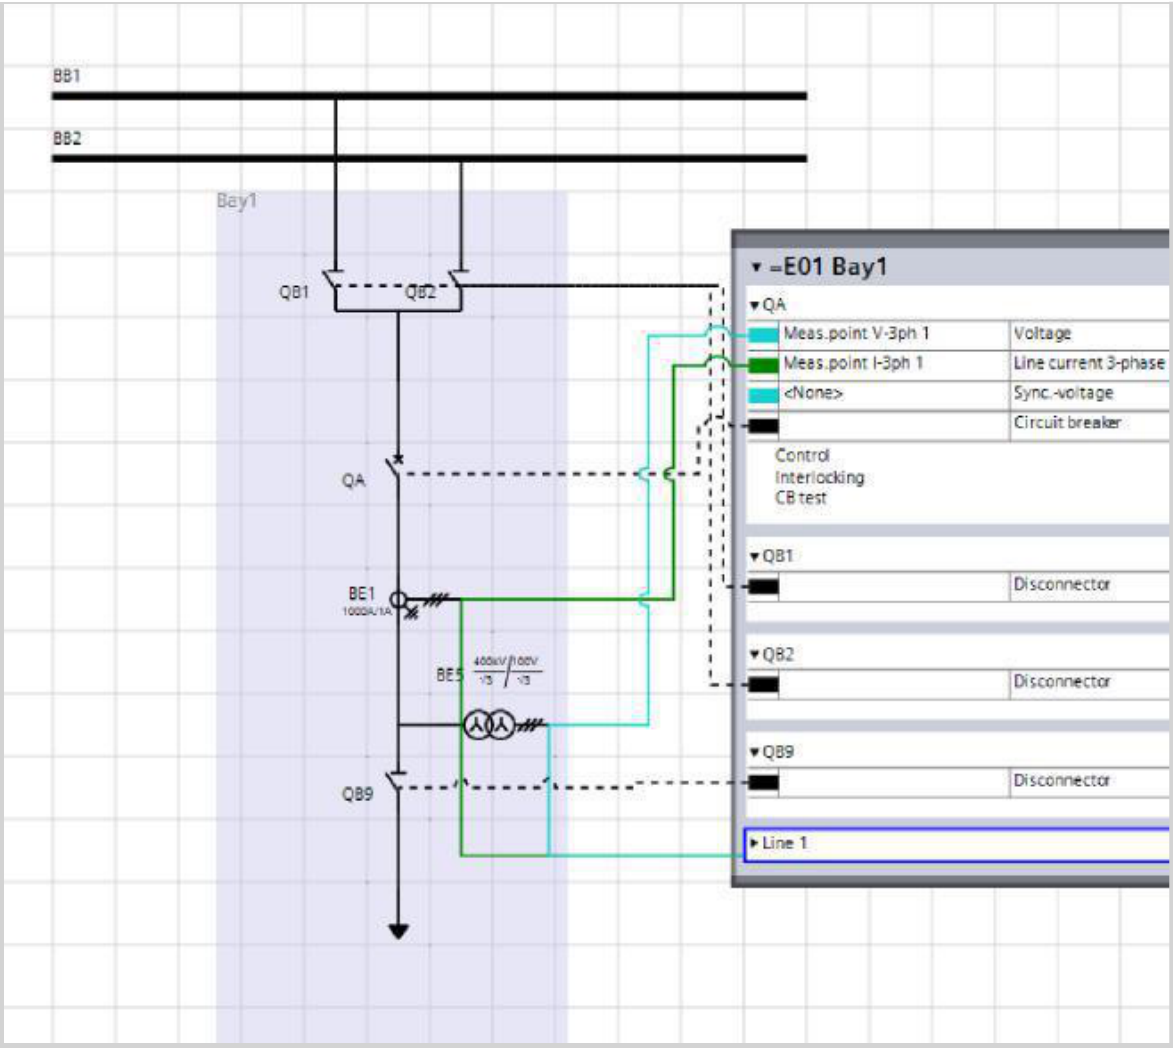

Figure 7-51 Feeder Bay for a Double Busbar System

The CFC chart that is required to implement the interlocking equation is shown in the next figure.

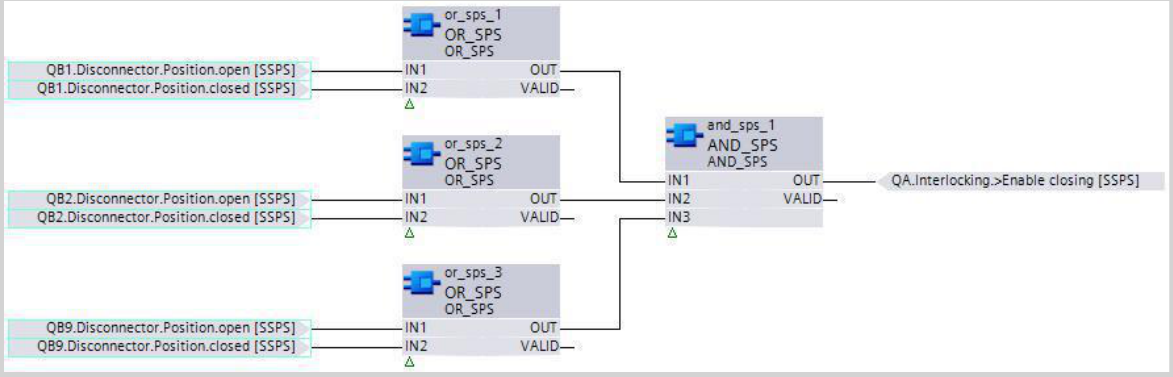

Figure 7-52 Interlocking Chart for Bay Interlocking

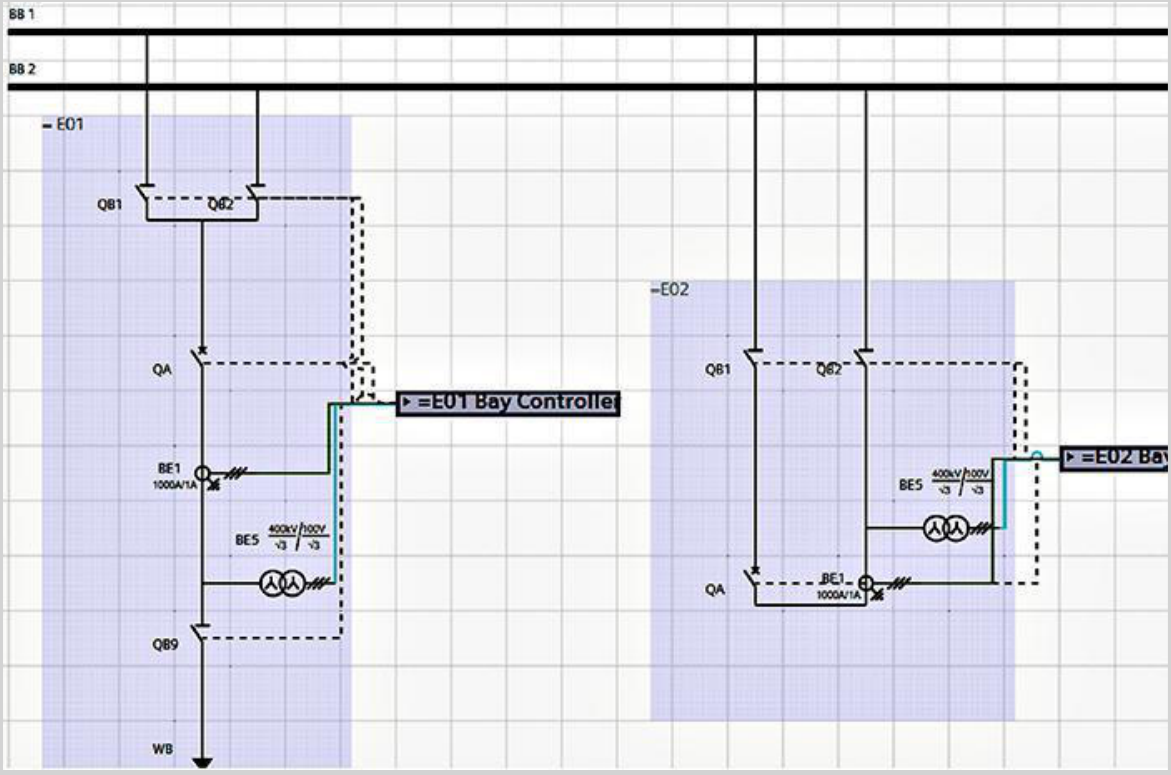

Since the **Disconnector** function block provides the defined position ***On*** or ***Off***, the exclusive OR gate XOR is not necessary for the linkage. A simple OR suffices.

As can be seen in the CFC chart, the result of the check is connected to the **>Release on signal** in the **Interlocking** function block in the **Circuit breaker QA** function group (see *Figure 7-52*).

EXAMPLE

For System Interlocking

This example considers the feeder = E01 from the previous example (bay interlocking) and additionally the coupler bay = E02 (see the figure below).

[sc_system, 1, en_US]

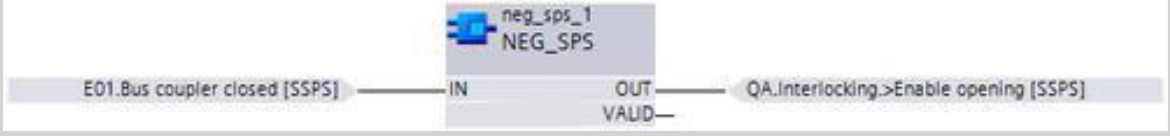

Figure 7-53 System with Feeder and Coupler Bays

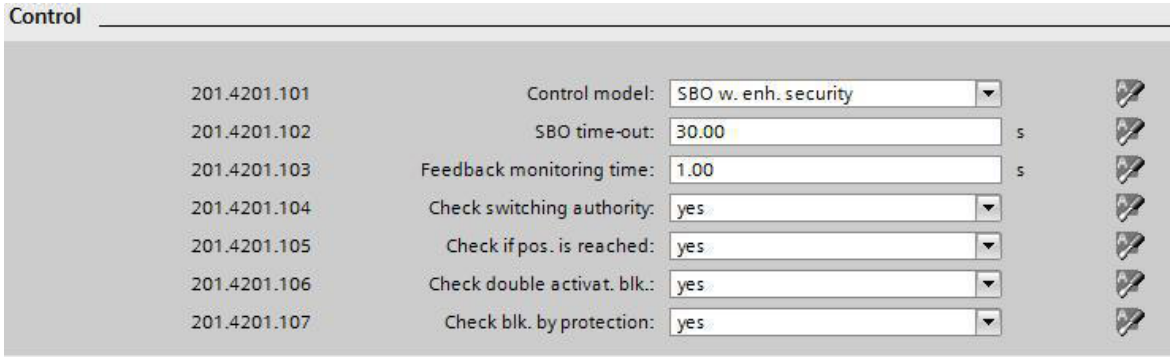
The circuit breaker QA in coupler bay = E02 will be considered next. As the multibay interlocking condition, you must provide the bus-coupler circuit-breaker command block at the end:

If the 2 busbars in bay = E01 are connected, that is, if the 2 disconnectors QB1 and QB2 in bay =E01 are closed, the circuit breaker QA in bay = E02 is not allowed to be switched off. Accordingly, bay = E01 in the CFC of the device generates the indication *Bus coupler closed* from the positions of the switches QB1 and QB2 and, using IEC 61850-GOOSE, transmits it to bay = E02 in the device. You must then store the following interlocking condition in bay = E02:

QA_Off = NOT (= E01/Bus coupler closed)

In the CFC chart for the bus coupler device = E02, you must create the following CFC chart (see the figure below).



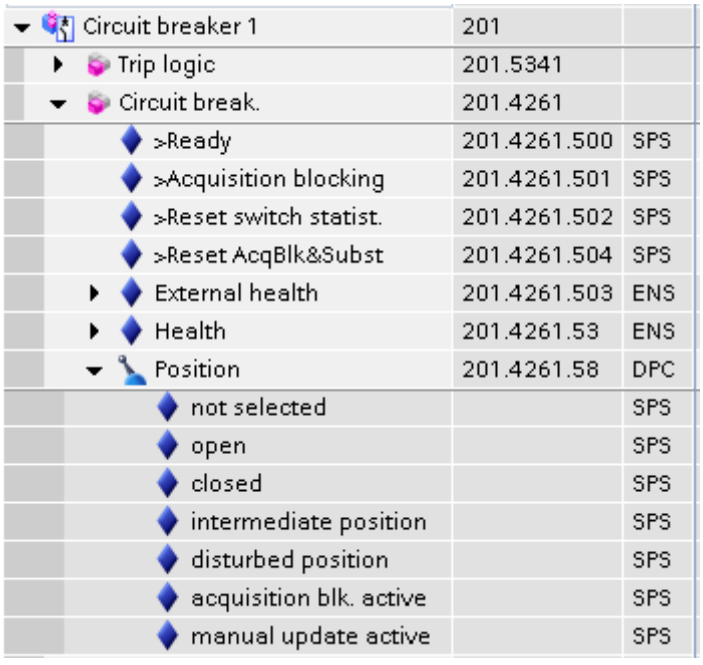
[sc_planve, 1, en_US]

Figure 7-54 Interlocking Chart for System Interlocking

1-Out-of-n Check (Double-Activation Blocking)

The double-activation blocking prevents 2 commands from being executed in the device simultaneously. You can set the device-internal check for each switching device as a parameter in the **Control** function block.

The default setting is ***Yes***, that is, double-activation blocking is active (see the figure below).



[sc_double, 1, en_US]

Figure 7-55 Activating the Double-Activation Blocking

With SIPROTEC 5, it is also possible to achieve multibay double-activation blocking.

In this case, send the signal **`not selected`** to other devices for analysis using IEC 61850-GOOSE. This signal is available under **Position** in every **Circuit breaker** or **Disconnector** function block in the switching device function groups (see figure below).

[sc_notselected, 1, en_US]

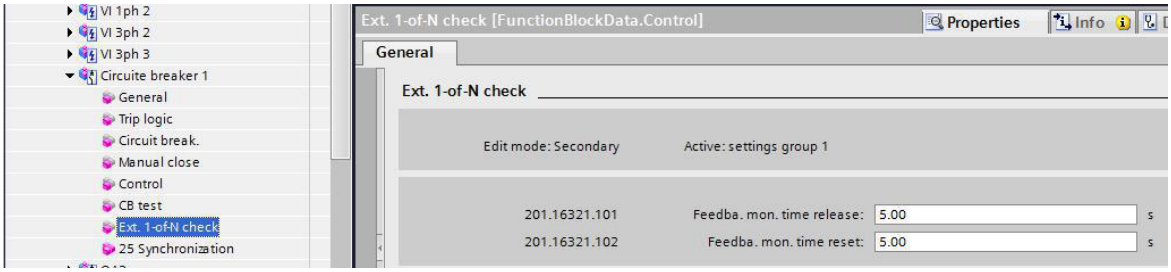


Figure 7-56 Signal *`not selected`* in the Circuit-Breaker Function Block

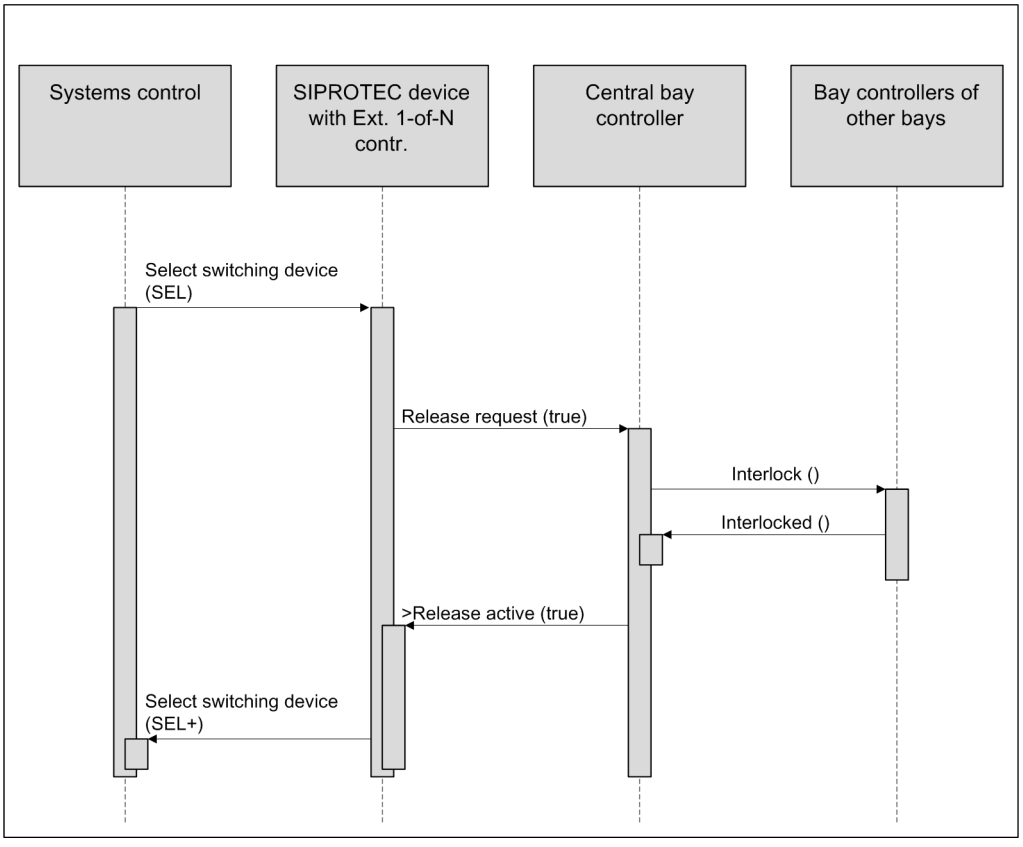
The signal is then queried in the CFC interlocking conditions for the associated switching devices and is used to generate the release signal (for example, **`>Release on`**).

External 1-of-N Check (Cross-Bay Double-Activation Blocking)

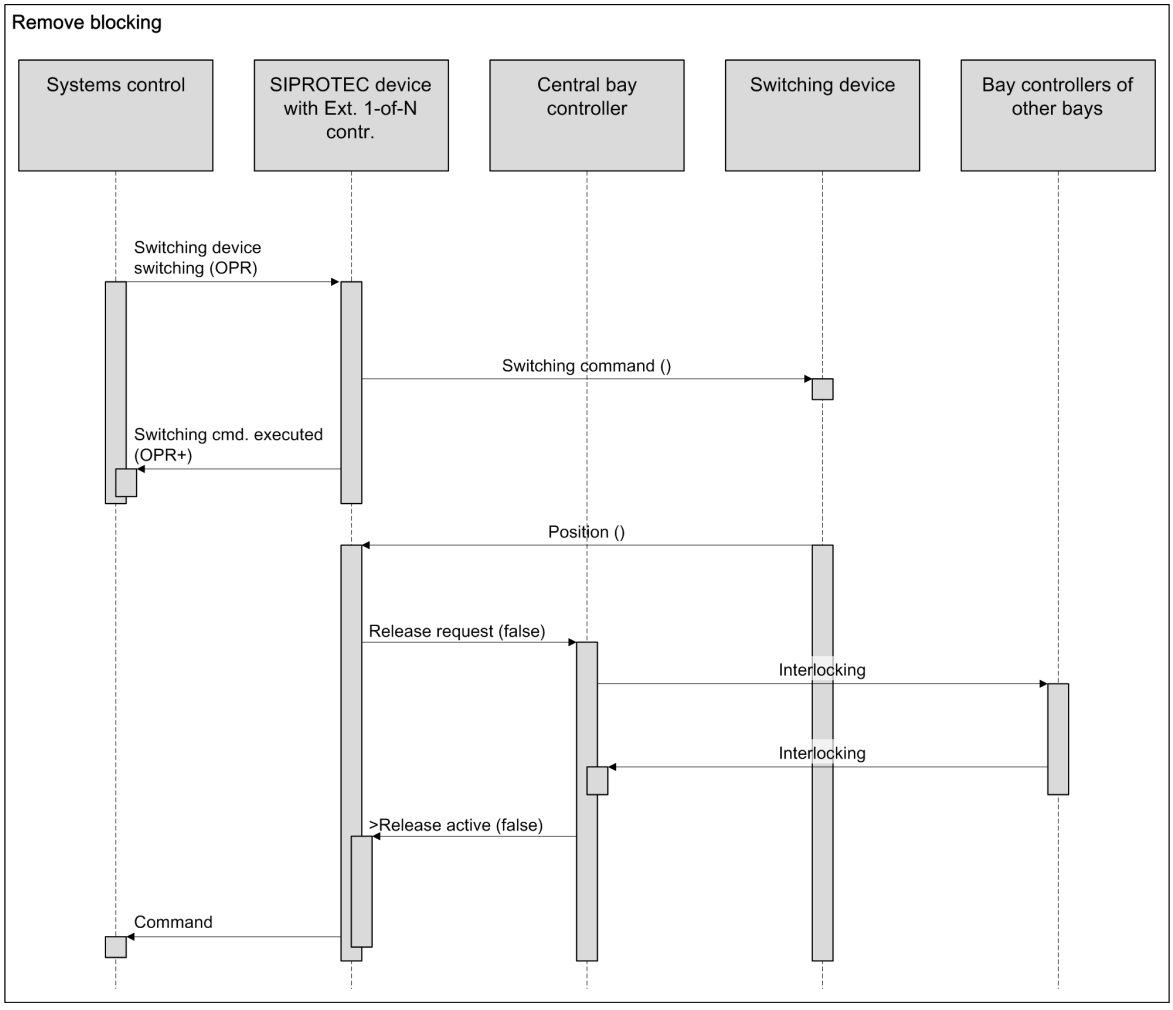
The function block **Ext. 1-of-N check** offers another option to implement a cross-bay 1-out-of-n check. You can select this function block in the FG **Circuit breaker** – **Control** in the DIGSI library. This function makes it possible to interlock other switching devices across all bays before the allocation of the switching device takes place in its own assigned bay or before the switching operation can be executed.



You can use the function block **Ext. 1-of-N check** in the **Circuit breaker** and **Disconnector** function groups. In order to use the function, a control model **with feedback monitoring** must be configured in the circuit-breaker control.

[sc_library properties info routing ext 1-out-of-n control, 1, en_US]

Figure 7-57 Command Execution



If the external 1-of-N check is instantiated, the output ***Release request*** prompts a central bay controller before executing a switching command. This bay controller must permit the switching operation (see the following figure). If the allocated switching devices were locked in another bay, the release is issued. Only when the release was issued via the input ***>Release active*** is the allocation (**`Control model`**: ***`SBO w. enh. security`***) or the switching command (**`Control model`**: ***`direct w. enh. security`***) executed and confirmed. The central bay controller is parameterized to reject a 2nd switching request.

[dw_set blocking, 1, en_US]

Figure 7-58 Setting the Blocking

Once the switch position has been reached, interlocking of the switching devices is canceled via the output ***Release request***. The switching command is completed and acknowledged with CMT (see the following figure) only when interlocking termination has been acknowledged positively via the input ***>Release active***.

[dw_remove blocking, 2, en_US]

Figure 7-59 Terminating the Blocking

User I/O Objects of the External 1-of-N Check Function Block

Name	I/O	Description	Range
Release request	O	This output remains active from the time of the switching prompt until the new position is reached.	true/false
>Release active	I	If this input is set, the switching device is released for switching operation. As long as this input is set, this switching device is blocked for additional switching operations.	true/false

Blocking by Protection Function

- Default setting **(_:107) Check blk. by protection** = ***yes***

In devices with protection and control functions, Siemens recommends that no switching commands can be issued while protection functions have picked up.

The default setting for blocking by the protection function is therefore ***yes***. If necessary, you can disable this blocking. You can find the settings on the same page as the double-activation blocking (see *Figure 7-55*).

NOTE

Remember, for instance, that pickup of the thermal overload protection can create a fault as well and thus prevent switching commands.

NOTE

The command check **Blocking by protection function** is only available for controlling circuit breakers, because in this case a unique relationship with protection functions has been configured. In disconnectors, this relationship is not always unique, precisely with regard to the 1 1/2 circuit-breaker layout, and it must be mapped for each system using CFC charts.

To carry out the command check **Blocking by protection function** for disconnectors, use the following indications (if present) in your interlocking conditions:

- Group indication: **`Pickup`** (Function group **Transformer**)
- Circuit-breaker failure protection: **`Pickup`** (**Circuit-breaker failure protection**)

7.4.2 Command Logging

All commands in the sequence are logged. The command log contains:

- Date and time
- Name of the switching device (or function group)
- Reason for the transmission (SEL = Selected, OPR = Operate, CMT = Command execution end, SPN = Spontaneous)
- Status or switching direction

EXAMPLE

The following example illustrates control of a circuit breaker QA1 for various cases.

- Successful command output
- Interrupted command
- Command interrupted by switchgear interlocking
- Command ended due to missing feedback
- Spontaneous change of switch position without command output

The following figures indicate command logging for various scenarios of the standard control model SBO with feedback monitoring.

7.5 Synchronization Function

7.5.1 Overview of Functions

The 1-channel **Synchronization function** (ANSI 25) checks whether the activation is permissible without a risk to the stability of the system when interconnecting 2 parts of an electrical power system.
Typical applications are as follows:

- Synchronization of a line and a busbar
- Synchronization of 2 busbars via a cross-coupling
- Synchronization of a generator and a busbar

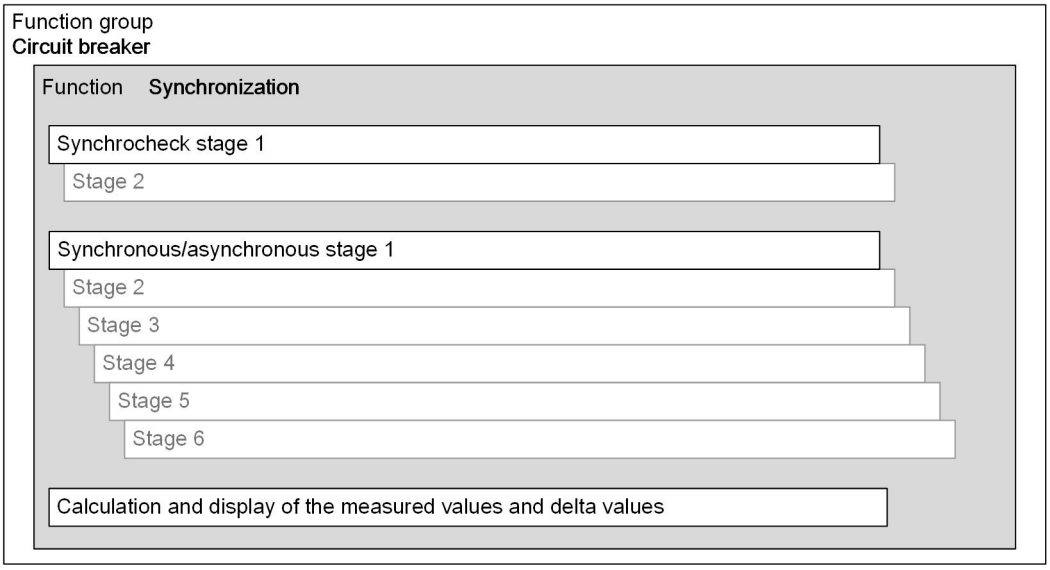
A power transformer between the 2 measuring points can also be taken into consideration.
The following operating modes are covered:

- Synchrocheck
- Switching synchronous power systems
- Switching asynchronous power systems
- Switching to dead line/busbar

7.5.2 Structure of the Function

The function **Synchronization** is used in the function group **Circuit-breaker**.
The following stage types can be used within the function:

- Synchrocheck stage
- Synchronous/asynchronous stage



NOTE

Siemens recommends using the synchronization functions for the following powers of the plant:

- 1-channel synchronization function for a plant with a power of < 10 MVA
- 1.5-channel paralleling function for a plant with a power of < 100 MVA
- 2-channel paralleling function for a plant with a power of ≥ 100 MVA

For a 1-channel synchronization function, the probability for a correct switching or for erroneous switching is identical. With the 1.5-channel paralleling function, you can achieve much greater reliability. In this function, a 2-out-of-2 decision has already been made, but only one channel switches. You can achieve the best reliability with the 2-channel paralleling function. In this function, there is also a 2-out-of-2 decision, but both channels are part of the close-command creation. The SIPROTEC 5 device 7VE85 with a 1.5- or 2-channel paralleling function is suitable for plants with a higher power (≥ 10 MVA).

The stage types **Synchrocheck** and **Synchronous/Asynchronous (Sychr./Asycr.)** are preconfigured at the factory.
In addition, the stage type **Extended delta-f options** are available in the function library. This has not been preconfigured.
You can operate a maximum of 2 stages of the stage type **Synchrocheck** or 6 stages of the **Synchronous/asynchronous** in parallel.
As soon as the function is available in the device, the functional measured values are calculated and displayed.

[dw_synfn1-01, 2, en_US]

Figure 7-69 Structure/Embedding of the Function

7.5.3 Connection and Definition

Connection

You can find examples for the synchronization of line and busbar in the following 2 figures. *Figure 7-72* shows an example for the synchronization of 2 busbars via bus coupler.

The synchronization function uses 2 voltages to check the connecting conditions: a voltage of the reference side 1 (V1) as well as a voltage to be used as a reference on side 2 (V2). The reference voltage of side 1 is designated in the synchronization function as V1[61].

This is always the voltage of the measuring point that is connected to the **Sync. voltage 1** interface of the Circuit-breaker function group. The voltage to be set as reference is designated with V2[61]. This is always the voltage of the measuring point that is connected to the **Sync. voltage 2** interface of the **Circuit-breaker** function group. The assignment of the measuring points to the interfaces of the **Circuit-breaker** function group can be configured, see *2.1 Embedding of Functions in the Device*.

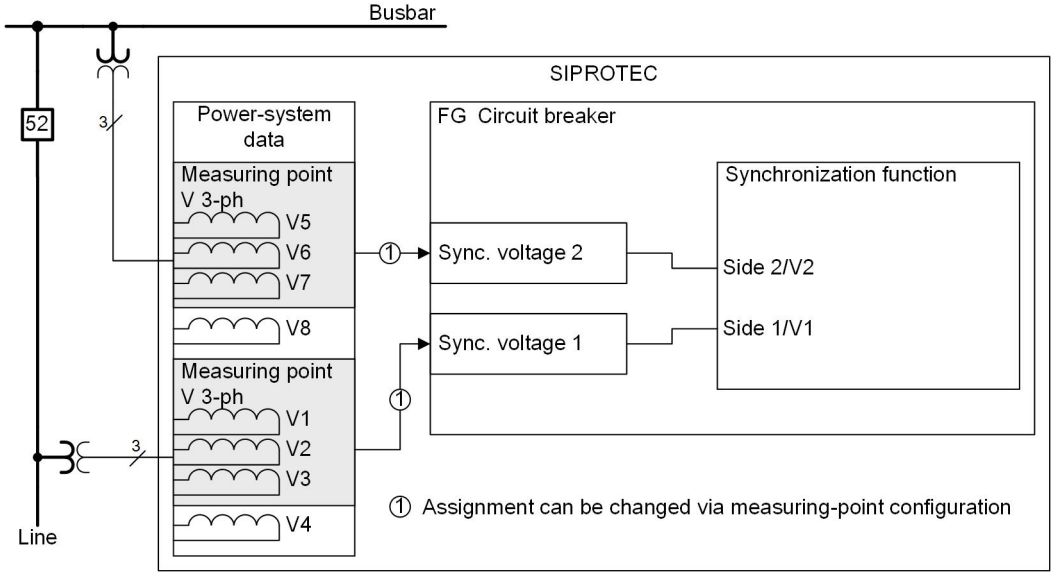
The selection of the voltages used for the synchronization depends on the device connection to the primary system:

- Connection of the primary system via 4 voltage inputs and hence use of a 1-phase and a 3-phase measuring point (*Figure 7-70* and *Figure 7-72*):

  The voltage connected to the 1-phase measuring point is definitive here. If. for example, this is the phase-to-ground voltage V_A, the voltage V_A is also used by the other side of the 3-phase measuring point.

- Connection of the primary system via 6 voltage inputs and hence use of two 3-phase measuring points (*Figure 7-71*):

  The phase-to-phase voltage V_{AB} of both sides is always used for the test.



You can connect both the phase-to-ground voltages and the phase-to-phase voltages to the device. The possible interface connections are listed in the Appendix.

61 Do not confuse the designations V1 and V2 with the numbering of the voltage inputs V1 to V4 (*Figure 7-70*) and V1 to V8 (*Figure 7-71*).

[dw_syns03-01, 2, en_US]

Figure 7-72 Synchronization of 2 Busbars via Cross-Coupling, Connection via 4 Voltage Inputs

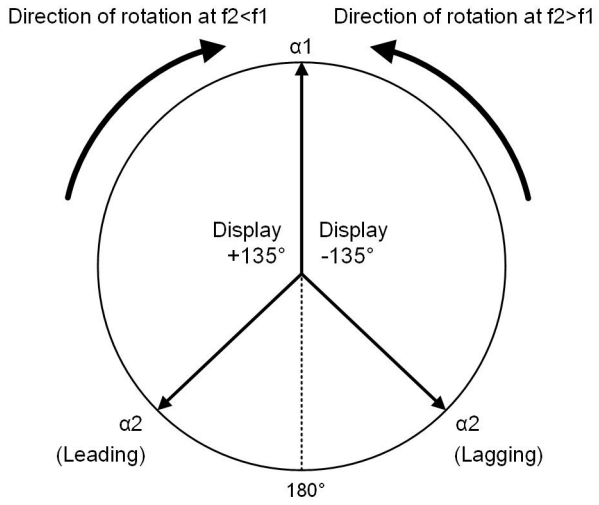
Definition of the Variables

The definition of the variables is important for understanding the following implementation. The reference side 1 indicates the function with 1. This yields the reference values voltageV1, frequencyf1, and phase angle α1. The side to be synchronized indicates the function with 2. The electrical variables of side 2 are then the voltageV2, frequencyf2, and phase angle α2.

When forming the differential variables, the function is oriented to the definition of the absolute measuring error (Δ x = measured value – real value). The reference value and hence the real value is side 1. This results in the following calculation specifications:

Differential voltage dV = V2 – V1

A positive sign means that the voltage V2 is greater than the voltage V1. In other cases, the sign is negative.



Differential frequency df = f2 – f1

A positive result means that according to the example from *Figure 7-70* the busbar frequency is greater than the line frequency.

Phase-angle difference dα = α2 – α1

The representation is limited to ±180°. A positive result means that α2 **leads** by a maximum of 180°. In the case of a negative value, α2 **lags** by a maximum of 180°. *Figure 7-73* shows the circumstances. The phase angle α1 was added to the zero axis as a reference system.

If asynchronous systems are present and the frequency f2 is greater than f1, the angle dα then changes from the negative value to 0 and then to the positive value. As shown in *Figure 7-73*, the direction of rotation is counterclockwise (mathematically positive). At f2 < f1, the direction of rotation is clockwise.

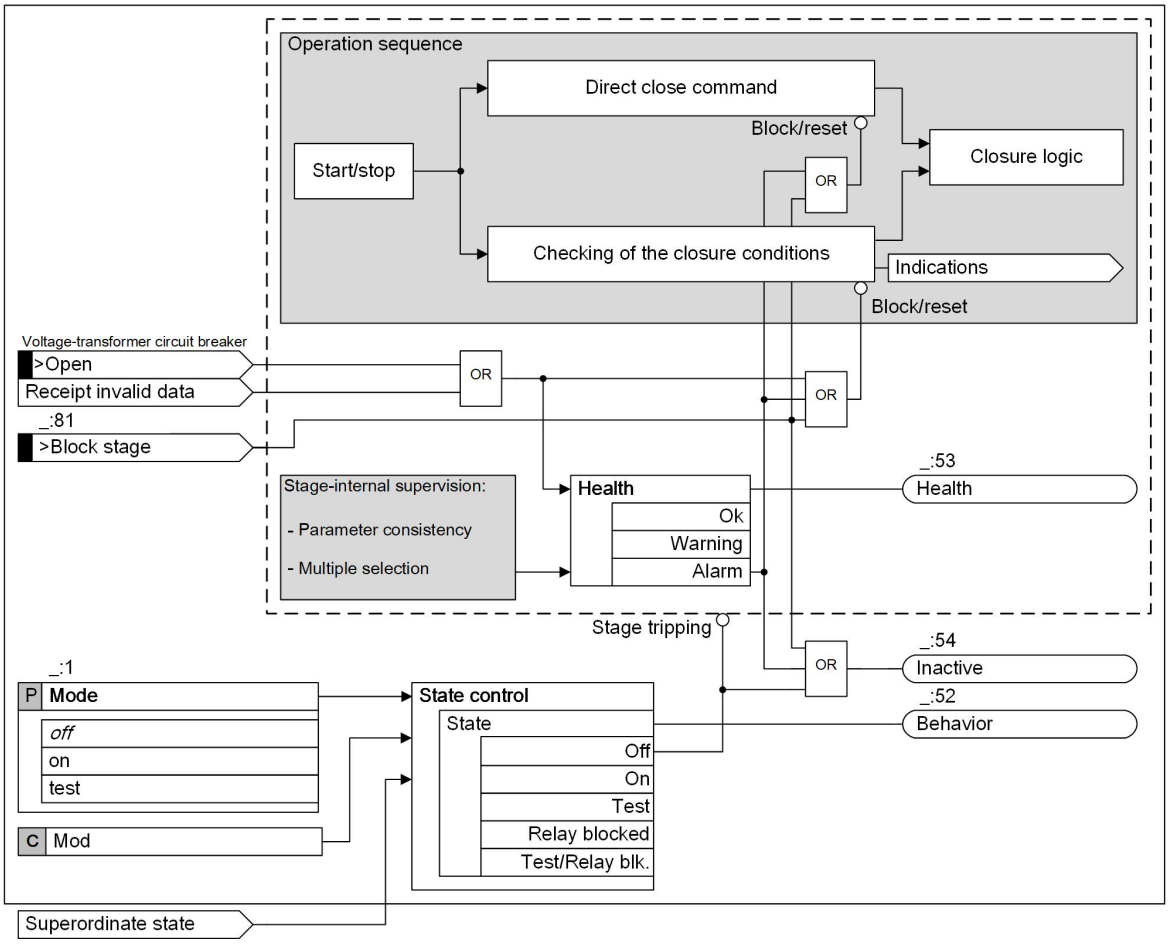
[dw_synp_04, 2, en_US]

Figure 7-73 Phase-Angle Difference Representation dα

Only positive values are permissible for the setting parameters. Inequalities are used to characterize the setting parameters uniquely. The representation is explained with the example of differential voltage. 2 setting values are necessary to allow unbalanced settings.

The inequality V2 > V1 yields a positive value for dV. The associated parameter is **`Max. voltage diff. V2>V1`**. For the 2nd setting parameter **`Max. voltage diff. V2<V1`**, the inequality V2 < V1 applies. It corresponds to a negative dV.

The procedure is the same for the differential frequency and differential phase angle.



7.5.4 General Functionality

7.5.4.1 Description

Overview of a Synchronization Stage (Sync Stage)

A synchronization stage can be integrated in the following blocks (see *Figure 7-74*):

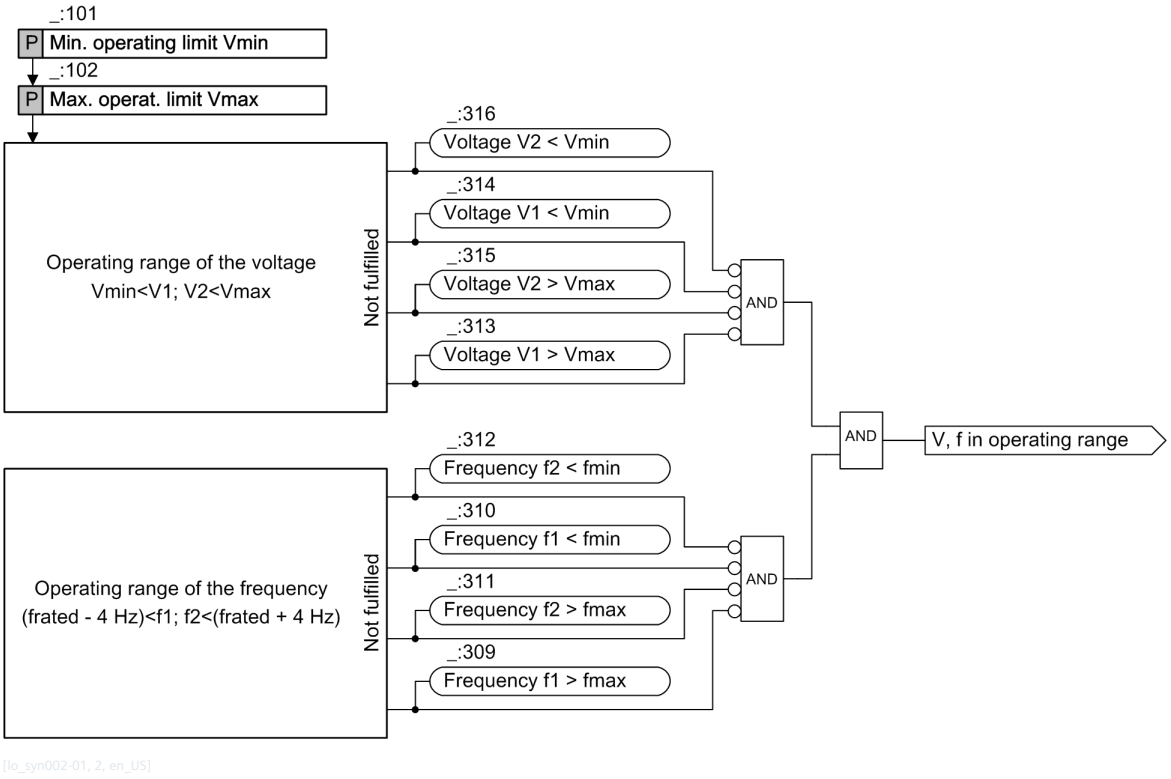
- Stage control with mode, state control, standby, and blocking (description in this chapter)
- Supervision (description in this chapter)
- Functional sequence for issuing the closing release (see *7.5.6 Sequence of Functions*)

[lo_syn001-01, 6, en_US]

Figure 7-74 Overview of the Stage Logic

Stage Control

The normal stage control is used for a synchronization stage (see *Figure 7-74*).



Note the following special features:

- For control via IEC 61850, a parameterized function Synchrocheck is only executed if the service parameter **Synchrocheck** is set to ***true***. The function control also provides the service parameter **Interlock-Check**. If the service parameter **Synchrocheck** is set to ***false***, switching is not synchronized. Siemens recommends checking the desired behavior for control from remote via IEC 61850 before the commissioning.
- As soon as there is a synchronization function available in the device, the measured values are calculated and displayed. One stage must be activated for calculating all Delta settings. It is not necessary to start the stage for this purpose.
- If all synchronization stages are deactivated within the function, closure via the control will no longer be possible, as none of the stages can generate a closing release. If the synchronization function is deleted, the circuit breaker is no longer regarded as subject to compulsory synchronization. In this case, it is possible to activate via the control without synchronization.
- If more than one synchronization stage is activated, the **>Selection** signal must be active for exactly one stage, so that it can be activated via the controls.

You can block the entire synchronization stage via the binary signal **>Block stage**. A started process is completed and the entire stage reset after blocking. The stage must be restarted to initiate a new switching

procedure. The blocking only affects the test process for the closing conditions. The measured values are still calculated and displayed.

Operating Range

[lo_syn002-01, 2, en_US]

Figure 7-75 Logic of the Operating Ranges

The operating range of the synchronization function is defined by the configurable voltage limits **`Min. operating limit Vmin`** and **`Max. operat. limit Vmax`**, as well as by the specified frequency band f_{rated} ±4 Hz.

If one or both voltages are outside the permitted operating range when the measurement is started or a voltage leaves the range, this is displayed via corresponding indications **`Frequency f1 > fmax`**, **`Frequency f1 < fmin`**, **`Voltage V1 > Vmax`**, **`Voltage V1 < Vmin`**, etc. The closing conditions are then not checked.

Supervision

The supervisions listed below are executed in a function-specific manner. If one of the supervisions picks up, the indication *`Health`* goes to ***`Warning`***. The stage is indicated as **`Inactive`**. A closing release or direct close command is not possible in this case.

- For consistency of settings of specific parameters
  Definite threshold-value settings are checked after a parameter change. If there is an inconsistency, the error message **`Setting error`** is issued.
- For multiple selection of the stage at the start time of the synchronization
  If there is a simultaneous selection of multiple closed synchronization stages at the start time, the error message **`Multiple selection`** is issued.

Measuring-Voltage Failure

If a voltage-transformer fault (measuring-voltage failure) is recorded via the binary input signal **`>Open`** of one of the voltage-measuring points, then the closing conditions of the synchronization stage are no longer

tested. This means that a release of the closure based on the measurement is no longer possible. The readiness of the stage turns to ***Warning***. Direct close command is still possible.

The device-internal supervision function measuring-voltage failure detection (Fuse Failure Monitor) does not have any effect on the synchronization stage.

Functional Measured Values

The functional measured values for the Synchronization function are displayed in their own primary, secondary, and percentage measured value windows. Voltage measurements are always displayed as ph-ph voltages, even if the associated measuring point records phase-to-ground voltages. The functional measured values are determined and displayed as soon as the device is functional. The difference values are calculated as soon as the stage is activated.

Table 7-24 Protection-Specific Values of the Synchronization

Values		Primary	Secondary	% Referenced to
V_1	Reference voltage V_1	kV	V	Rated operating voltage of the primary values
V_2	Voltage to be synchronized V_2	kV	V	Rated operating voltage of the primary values
f_1	Frequency of the voltage V_1	Hz	Hz	Rated frequency
f_2	Frequency of the voltage V_2	Hz	Hz	Rated frequency
dV	Voltage difference V_2–V_1	kV	V	–
df	Frequency difference f_2–f_1	Hz	Hz	–
dα	Angle difference α_2–α_1	°	–	–

Multiple Synchronization Points

The synchronization function can only be used within a Circuit-breaker function group. It always operates on the circuit breaker that is linked to the Circuit-breaker function group. The reference to the circuit breaker is therefore unique. If you wish to switch several circuit breakers (synchronization points) with the device, you must create several Circuit-breaker function groups.

Different Synchronization Conditions per Synchronization Point

Within the synchronization function, you can operate maximum 2 stages of the stage type **Synchrocheck** and maximum 6 stages of the type **Synchronous/asynchronous** in parallel. All setting parameters for a synchronization point are included in each synchronization stage.

If you have to synchronize with different synchronization conditions (parameter settings), several synchronization stages are used for a synchronization point/circuit breaker. In this case, you must define which of the synchronization stages is currently active via the binary signal **>Selection** (synchronization stage x). The closing conditions are checked if the respective stage is activated via the **>Selection** binary signal and the stage is activated.

The fault indication **Multiple selection** is issued upon simultaneous selection of different synchronization stages. If several synchronization stages are activated and the input signal **>Selection** (synchronization stage x) is missing at the starting time, a valid selection is awaited during the supervision time **Max.durat. sync.process**. If this does not come, the process is terminated.

Different Voltage-Transformer Ratios from Both Sides of the Electrical Power System

The synchronization function automatically takes different transformation ratios of the voltage measuring points into account on both sides of the power system. Set the parameter **Voltage adjustment** in the synchronization function for the following cases:

- Without a power transformer between the voltage measuring points of the circuit breaker to be synchronized, if the rated primary voltages are different on both sides of the electrical power system.
- With a power transformer between the voltage measuring points of the circuit breaker to be synchronized, if the transfer ratios of the rated primary voltages on the voltage transformer are different on both sides of the electrical power system.

For more information about the parameter **Voltage adjustment**, refer to *7.5.4.2 Application and Setting Notes*, *Parameter: **Voltage adjustment**, Page 1901*.

Synchronization via a Transformer

There are systems in which a power transformer is located between the voltage measuring points of the circuit breaker to be synchronized. The device automatically considers the different voltage stages by setting the rated primary voltages of the power transformer from 2 sides of the electrical power system. A phase displacement must be taken into account based on the transformer vector group via the parameter **Angle adjust. (transform.)**.

The parameter is defined as -Δα = –(α2 – α1).

To calculate the delta variables Δα and ΔU, the voltage of side 2 is converted to that of side 1 using the settings of the 2 parameters **Angle adjust. (transform.)** and **Voltage adjustment**.

The displayed voltage V2 in the device display is the voltage from the power-transformer side, which is close to the point to be synchronized, and not the measured voltage of the voltage transformer of side 2.

For more information, refer to *7.5.4.2 Application and Setting Notes*.

Different Connection Types on Both Sides

If both the measuring points used by the synchronization functions record different voltages of the 3-phase system, the calculation of the phase-angle difference is automatically considered.

EXAMPLE:

The 1-phase measuring point connected with **Sync-voltage 1** records the phase-to-phase voltage V_{AB}. The 1-phase measuring point connected with **Sync-voltage 2** records V_A. In this case the phase angle between V_{AB} and V_A takes into consideration the delta variable Δα during calculation.

This automation guarantees that several voltage sources can be switched between during running operation, each of which records different voltages.

7.5.4.2 Application and Setting Notes

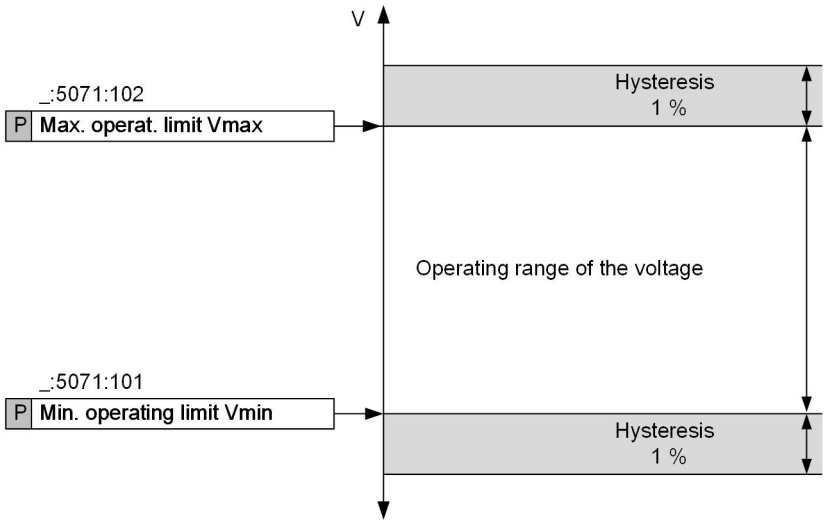
Stage-Type Selection

The following 2 types of stages are available:

Stage Type	Application
Synchrocheck stage	Select this type of stage to issue, for example, an additional release during a manual reclosing for safety reasons. With this type, the variables ΔV, Δf, and Δα are checked before connecting the 2 parts of the power system.
Synchronous/asynchronous stage	Select this type of stage if it is necessary to differentiate between synchronous and asynchronous systems, depending on the switch position. If galvanically coupled systems are switched in parallel, synchronous systems are present. A typical characteristic of synchronous systems is equality of frequency (Δf ≈ 0). In this state, the conditions Δα and ΔV are checked. If the systems are galvanically isolated, asynchronous systems can be present. At the same time, compliance with the voltage difference ΔV and frequency difference Δf conditions is checked. The time of the direct close command is calculated taking into account the angle difference Δα and the make time of the circuit breaker. The time of the direct close command is calculated such that the voltages are equal at the moment the circuit-breaker poles come into contact (ΔV ≈ 0, Δα ≈ 0).

Configuration of the Voltages V1 (Reference Side) and V2

The voltages V1 and V2 are established via the connection of the measuring points to the interface of the function groups (refer to chapter *7.5.3 Connection and Definition*). The measuring point connected to the interface **Voltage** is the reference side 1 with the reference voltage V1. The measuring point connected to the interface **Sync. voltage** is the side 2 with V2. The definition of the Delta parameters that can be derived from this is also described in chapter *7.5.3 Connection and Definition*.



Parameter: `Min. operating limit Vmin`, `Max. operat. limit Vmax`

- Recommended setting value `(_:5071:101) Min. operating limit Vmin` = *90 V*
- Recommended setting value `(_:5071:102) Max. operat. limit Vmax` = *110 V*

The values define the voltage operating range of the synchronization stage. A normal setting is approx. ±10 % of the rated voltage.

NOTE

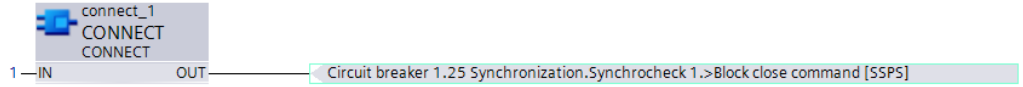
All voltages connected according to the parameterized measuring-point connection type are subjected to the appropriate Vmin/Vmax test. Therefore, connected phase-to-ground voltages are multiplied by √3, since the threshold values must be set with reference to the rated voltage (phase-to-phase voltage).

[lo_hyster-01, 2, en_US]

If the Synchronization function is started within the hysteresis, no switching is performed as a result of the minimum and maximum operating limit (parameters **Min. operating limit Vmin** and **Max. operat. limit Vmax**). If the Synchronization function is started within the voltage operating range and the voltage exceeds the minimum or maximum operating limit during the synchronization process, selecting can occur in the area of the hysteresis.

Parameter: Max.durat. sync.process

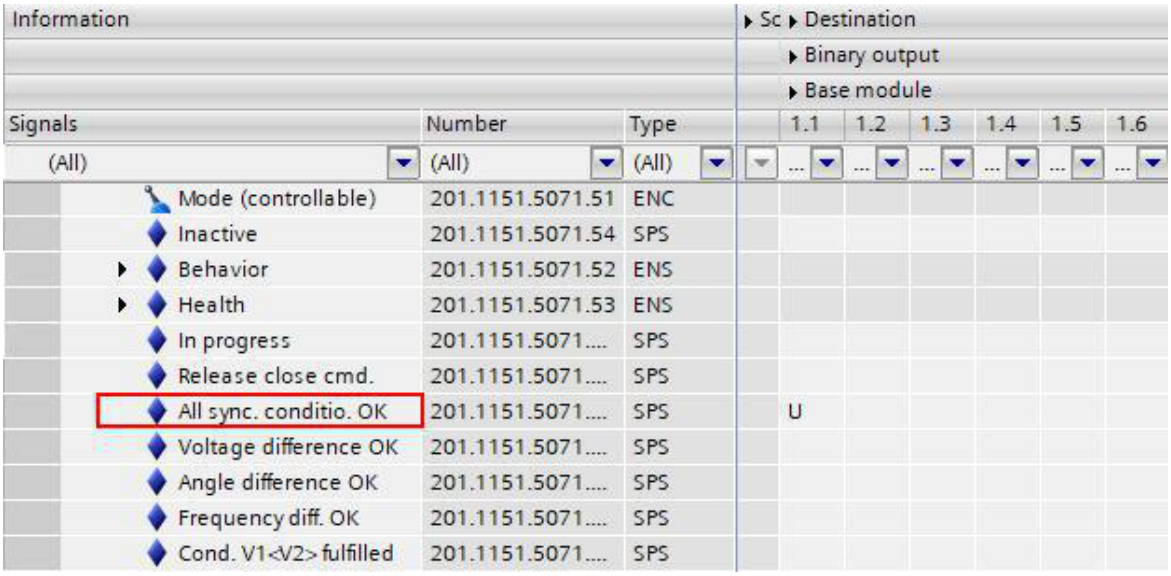
- Default setting **(_:5071:110) Max.durat. sync.process** = ***30 s***



The parameterized conditions must be fulfilled within this time. If the conditions are not fulfilled, no further closing release takes place and the synchronization stage is stopped. If this time is set to ∞, conditions are checked until they are fulfilled. This is also the default setting. Observe the operating conditions when defining the time limitation. This must be defined specifically for each system. If 0 or 0.01 s is set, then all conditions are checked once at the starting time. Thereafter the process is stopped immediately.

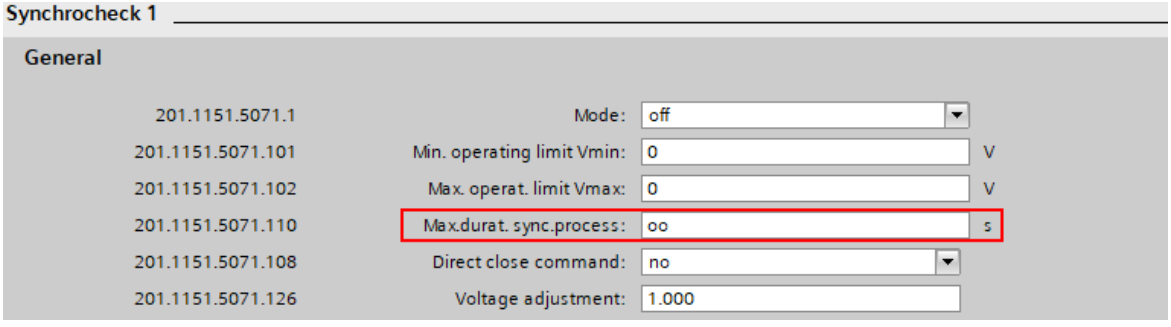
If the closure release is assigned, the synchronization is terminated. If the synchrocheck is to continuously display the switching conditions, without issuing a direct close command at synchronization, proceed as follows:

EXAMPLE:



For Continuous Checking of the Switching Conditions without Issuing a Direct Close Command

With the aid of the following CFC chart you can set the input *>Block stage* of the corresponding synchrocheck stage permanently:



[sc_sync_CFC, 3, en_US]

If you route the indication *All sync. conditio. OK* to the corresponding binary output, you receive a separate release of the closure for an external synchronization unit.

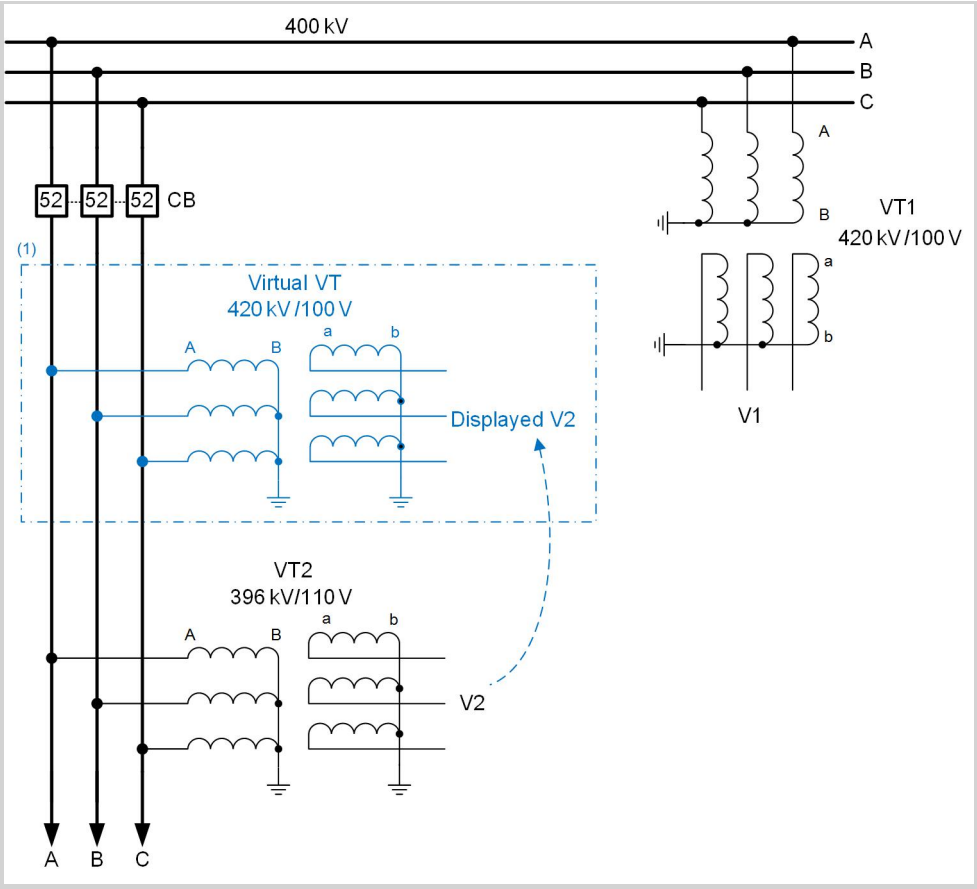
[sc_sync_routing, 2, en_US]

If you wish to permanently report each occasion on which synchronization conditions are reached following the start of synchronization, you set the parameter **`Max.durat. sync.process`** to ∞.

[sc_sync_setting, 2, en_US]

Parameter: `Voltage adjustment`

- Default setting **`(_:5071:126) Voltage adjustment`** = ***`1.00`***



The parameter can be used for correction of amplitude errors, for example, due to indirect measurement (for example, transformer tap changer).

To apply a transformer between measuring points, the **`Voltage adjustment`** parameter is not needed. The transformer ratios are set for the measuring points and the function will take them into account automatically.

To apply a transformer between the voltage measuring points, the transformer ratio does not have to be taken into account. When you set the parameter **`Voltage adjustment`**, the transformer ratio is automatically taken into account. In the following, you can find 2 examples for the setting of the parameter **`Voltage adjustment`**:

Example 1:

In the electrical power system, no power transformer exists between the voltage measuring points of the circuit breaker to be synchronized. The rated primary voltages of 2 sides of the electrical power system are different.

[dw_example w.o. power transformer, 1, en_US]

Figure 7-76 Example: the Electrical Power System without a Power Transformer

(1) The virtual VT does not exist in the primary voltage system. It is just a virtual voltage transformer to show the displayed V2 on the device display. The virtual VT has the same transformer ratio as VT1.

The displayed V2 is a processed voltage from VT2.

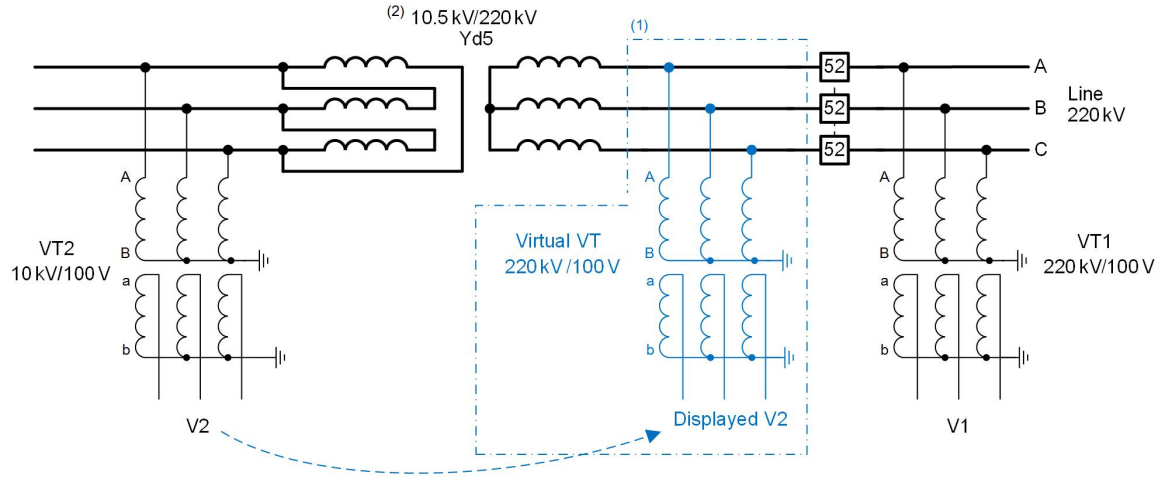
$$\text{Voltage adjustment} = \frac{V2_{\text{rated prim.}}}{V1_{\text{rated prim.}}} = \frac{396\ \text{kV}}{420\ \text{kV}} \approx 0.94$$

[fo_ex1_V adjustment, 1, en_US]

With:

$V2_{\text{rated prim.}}$	Rated primary voltage of VT2
$V1_{\text{rated prim.}}$	Rated primary voltage of VT1

For this example, the displayed voltage V2 on the device display is from the virtual VT, not from VT2.



The primary voltages, secondary voltages, and percentage values of the measured values are shown in the following table.

Table 7-25 Primary Voltage, Secondary Voltage, and Percentage Value

Measured Value	Primary Voltage	Secondary Voltage	Percentage Value
V1	400 kV	$\frac{400\,\text{kV}}{420\,\text{kV}/100\,\text{V}} \approx 95.238\,\text{V}$	$\frac{400\,\text{kV}}{420\,\text{kV}} \cdot 100\,\% \approx 95.238\,\%$
V2	400 kV	$\frac{400\,\text{kV}}{396\,\text{kV}/110\,\text{V}} \approx 111.111\,\text{V}$	$\frac{400\,\text{kV}}{396\,\text{kV}} \cdot 100\,\% \approx 101.01\,\%$
Displayed V2	400 kV	$\frac{400\,\text{kV}}{420\,\text{kV}/100\,\text{V}} \approx 95.238\,\text{V}$	$\frac{400\,\text{kV}}{420\,\text{kV}} \cdot 100\,\% \approx 95.238\,\%$

Example 2:

In the electrical power system, a power transformer is located between the voltage measuring points of the circuit breaker to be synchronized. The power transformer ratio differs from the ratio between the rated primary voltages of the voltage transformers of 2 sides of the electrical power system.

[dw_example w. power transformer, 1, en_US]

Figure 7-77 Example: the Electrical Power System with a Power Transformer

(1) The virtual VT does not exist in the primary voltage system. It is just a virtual voltage transformer to show the displayed V2 on the device display. The virtual VT has the same transformer ratio as VT1.

The displayed V2 is a processed voltage from VT2.

(2) This ratio is not the rated transformer ratio on the transformer name plate. This ratio is an actual ratio which considers the tap-changer scenarios when the **Tap changer** function is not used in the device. The rated transformer ratio is 220 kV/10 kV.

$$\text{Voltage adjustment} = \frac{V2_{\text{rated prim.}}}{V1_{\text{rated prim.}}} \cdot R_{PT} = \frac{10\,\text{kV}}{220\,\text{kV}} \cdot \frac{220\,\text{kV}}{10.5\,\text{kV}} \approx 0.95$$

[fo_ex2_V adjustment, 1, en_US]

With:

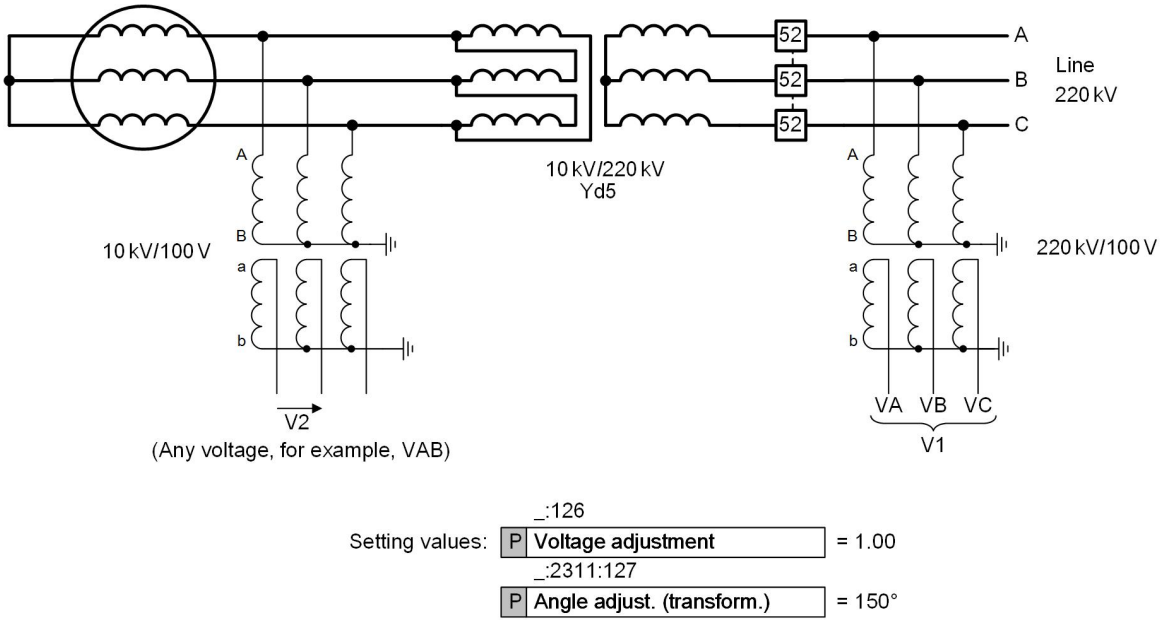
$V2_{\text{rated prim.}}$	Rated primary voltage of VT2
$V1_{\text{rated prim.}}$	Rated primary voltage of VT1
R_{PT}	Transformer ratio of the power transformer

For this example, the displayed voltage V2 on the device display is from the virtual VT, not from VT2.

The primary voltages, secondary voltages, and percentage values of the measured values are shown in the following table.

Table 7-26 Primary Voltage, Secondary Voltage, and Percentage Value

Measured Value	Primary Voltage	Secondary Voltage	Percentage Value
V1	220 kV	$\frac{220\,\text{kV}}{220\,\text{kV}/110\,\text{V}} = 110\,\text{V}$	$\frac{220\,\text{kV}}{220\,\text{kV}} \cdot 100\,\% = 100\,\%$
V2	10.5 kV	$\frac{10.5\,\text{kV}}{10\,\text{kV}/100\,\text{V}} = 105\,\text{V}$	$\frac{10.5\,\text{kV}}{10\,\text{kV}} \cdot 100\,\% = 105\,\%$
Displayed V2	220 kV	$\frac{220\,\text{kV}}{220\,\text{kV}/110\,\text{V}} = 110\,\text{V}$	$\frac{220\,\text{kV}}{220\,\text{kV}} \cdot 100\,\% = 100\,\%$



Parameter: **`Angle adjust. (transform.)`**

- Default setting **`(_:2311:127) Angle adjust. (transform.)`** = *0* °

The parameter can be applied under the following conditions:

- 1. Phase-angle rotation by power transformer between the measuring points
- 2. Correction of phase-angle errors

1. Phase-angle rotation by power transformer between the measuring points:

[dw_transformer between the measuring points, 2, en_US]

Figure 7-78 Transformer between the Measuring Points

If there is a power transformer between the voltage transformers of the circuit breaker to be synchronized, you then have to correct the phase-angle rotation for a vector group deviating from 0. *Figure 7-78* shows such an application. The **`Angle adjust. (transform.)`** parameter is used to save the phase-angle rotation.

The transformer vector group is defined from the upper-voltage side to the undervoltage side. If the reference voltage transformer V1 is connected on the upper-voltage side of the transformer (as in *Figure 7-78*), enter the phase-angle rotation directly according to the vector group. A vector-group figure of 5, for example, means an angular rotation of 5 · 30° = 150°. Set this value for the **`Angle adjust. (transform.)`** parameter.

If the voltage connection V1 is on the undervoltage side due to the system, you then have to apply the extension angle with 360°. A transformer with vector group 5 yields an angular adjustment of 360° – (5 · 30°) = 210°.

2. Correction of phase-angle errors:

You can correct a phase-angle error between the voltage transformers in increments. Ascertain a possible correction value during commissioning.

Parameter: CB make time

- Default setting **(_:5041:113) CB make time** = ***0.060 s***

If you are to interconnect under asynchronous system conditions with the device as well, the make time of the circuit breaker must be taken into account. The device uses this to calculate the time of the direct close command, so that the voltages are in phase at the moment of closure of the switch poles. Note that apart from the operating time of the switch, this also includes the pickup time of an auxiliary relay that may be upstream. You can determine the make time using the protection device (see commissioning notes in *11.23 Primary and Secondary Testing of the Synchronization Function*).

This parameter only occurs for the stage type **Synchronous/asynchronous**.

7.5.4.3 Settings

Addr.	Parameter	C	Setting Options	Default Setting
General

7.5.5 Dynamic Measuring-Point Switching

Dynamic measuring-point switching provides the capability to connect the voltages used in the Synchrocheck function to various measuring points. In this way, for example, it is possible to use the correct voltage on the basis of the switch position on the switching devices. If more than 1 measuring point is connected to *V sync1* or *V sync2*, you must create the **`V sync select.`** function block in the function group **Circuit breaker**.

Selection of the desired voltage measuring points (*V sync1* and *V sync2*) for the function group **Circuit breaker** is controlled via Continuous Function Chart.

Example

Figure 7-79 shows an example of a synchrocheck in a breaker-and-a-half arrangement. If circuit breaker QA2 is to be closed, the reference voltages must be selected from several possible measuring points. This selection of measuring points is dependent on the switch positions of all circuit breakers and disconnectors.

[dwdynmsu-140212-01.tif, 1, en_US]

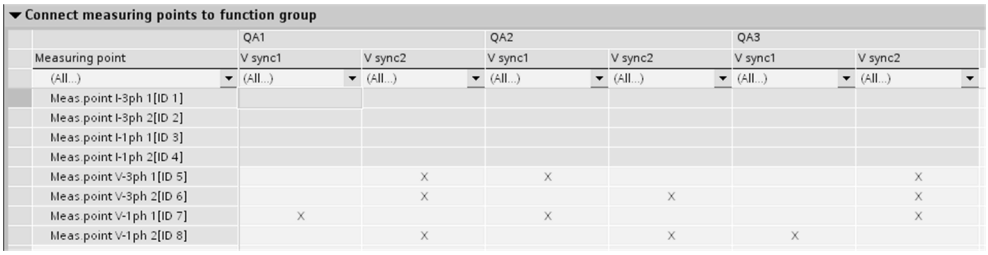

Figure 7-79 Synchronization in a Breaker-and-a-Half Arrangement

Each synchronization function requires 2 comparison voltages. For the circuit breaker QA2 located in the middle, there are 2 options for each side (V_{sync1} and V_{sync2}). The selection of synchronization voltages for each side depends on the position of the circuit breaker and the disconnectors.

For circuit breakers QA1 and QA3, the busbar voltage (V_{sync1}) is available for one side, and 3 voltages (V_{sync2}) are available for the other side.

Connecting Measuring Points to Circuit-Breaker Function Group

The following figure shows the connection of the function group **Circuit breaker** with several measuring points in DIGSI. The ID of each measuring point appears in parentheses after the name.

[scdynms2-211212-01.tif, 1, en_US]

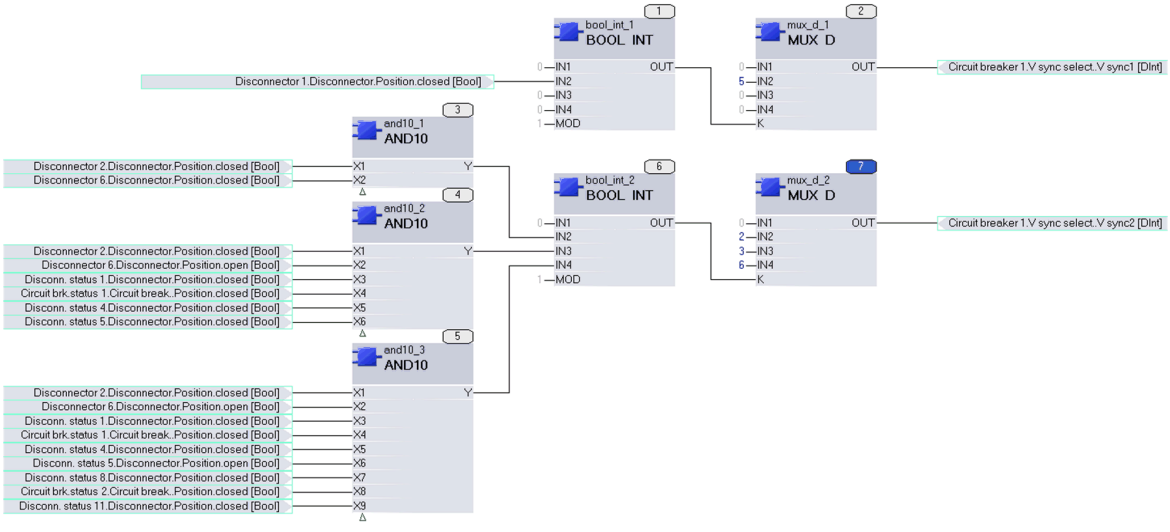

Figure 7-80 Connecting the Measuring Points with the Function Group Circuit-Breaker

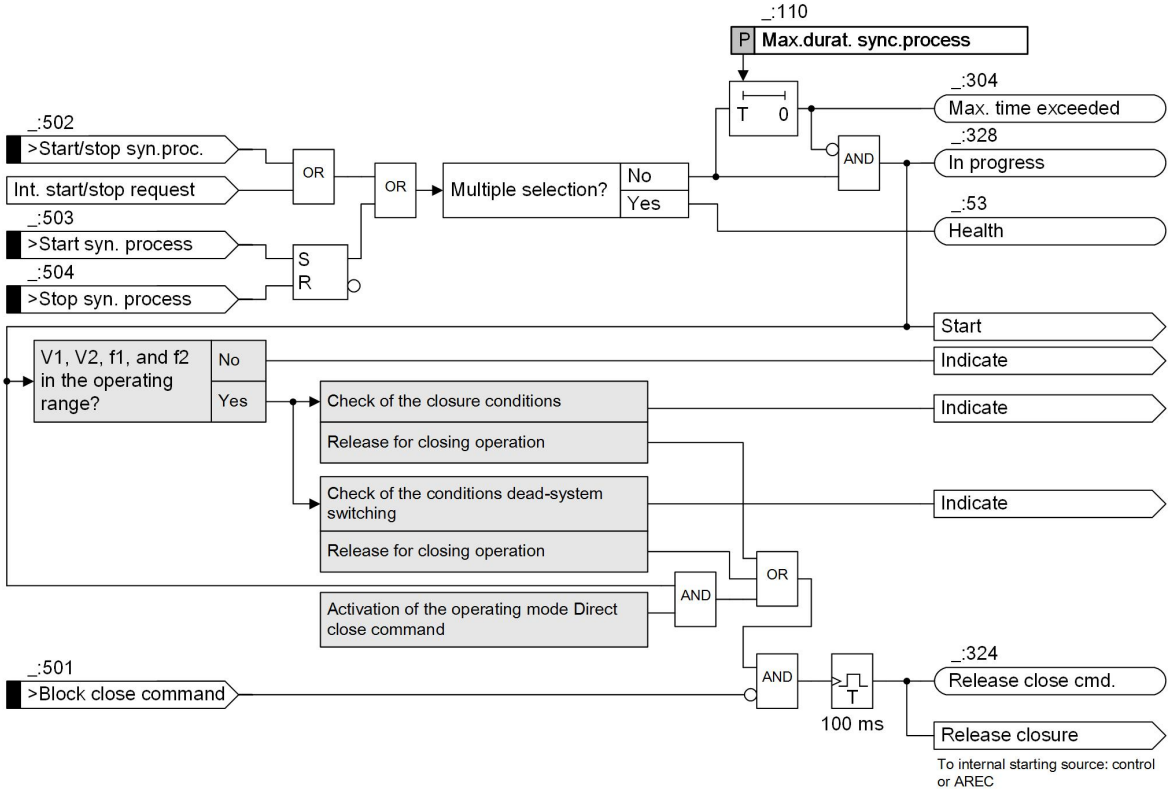
There are consistency checks that validate the connections of voltage measuring points to the function group:

- The connection type must be identical for all measuring points connected to the same interface.
- It is not permitted to route a measuring point to the function group using the option VN.
- The rated voltage (primary and secondary) must be identical for all measuring points connected to the same interface.
- If more than 1 measuring point is connected to 1 voltage interface, a function block must be expanded to enable selection of the synchronization voltage.

CFC Control

The voltages are selected by CFC logic on the basis of the measuring point IDs. If more than one measuring point is connected to interfaces V_{sync1} or V_{sync2} of the function group **Circuit breaker**, the function block **V sync select.** has to be removed from the library in the function group **Circuit breaker**. A CFC logic (see following example) has to define IDs for the *V sync1* or *V sync2* inputs of this function block in order to ensure the correct measuring point connection for the Synchrocheck function.



[scdynmsx-160212-01.tif, 1, en_US]

Figure 7-81 CFC Logic: Voltage Selection Using Measuring Point ID

If (defined by the switch or disconnector positions) no measuring point can be selected, the ID0 is used. If ID0 is selected, the indication *(_:2311:304) Blocked no V selected* is set. The synchrocheck is blocked. If you have activated the parameter **(_:5071:108) Direct close command**, unsynchronized switching is still possible.

7.5.6 Sequence of Functions

[lo_synf01_01, 6, en_US]

Figure 7-82 Sequence of Functions

Start

The synchronization stage must be started to check the closing conditions. The synchronization stage can be started device-internally by the control or externally via binary input signals (see *7.5.12 Interaction with Control and External Triggering*).

At the start, the system checks whether there is a multiple selection of the synchronization stage (see **Supervision** in *7.5.4.1 Description*). If this is the case, the process is terminated. After a successful start, the indication **`In progress`** is cleared and the supervision time for the maximum duration of the synchronization process (parameter **`Max.durat. sync.process`**) is started. The system also checks whether the voltages and frequencies are in the operating range (see *7.5.4.1 Description*). If this is not the case, the closing conditions are not checked.

Checking the Closing Conditions, Closure

After starting, the parameterized closing conditions are checked, depending on the selected operating mode (see *7.5.8.1 Description* to *7.5.11 Direct Close Command*). Every condition fulfilled is explicitly indicated here. Conditions not fulfilled are also indicated. If all conditions are fulfilled, the synchronization stage sets the indication **`All sync. conditio. OK`**. The indication is active until all conditions are fulfilled. The further behavior for issuing the release for closing depends on the type of the stage (see *7.5.7.1 Description* and *7.5.8.1 Description*). The release is signaled via the **`Release close cmd.`** indication. This indication is active for 100 ms. With an internal start, the control performs the actual closure, depending on the internal starting source.

Switching to Dead Line/Busbar

If operating modes for switching to dead parts of an electrical power system are configured, the associated conditions are also checked after the start (see *7.5.10.1 Description*). The fulfilled conditions are signaled. An

adjustable supervision time starts after the closure conditions are fulfilled (parameter **Supervision time**). If the conditions remain valid until expiry of the time, the function gives the release for closure after expiry of the time.

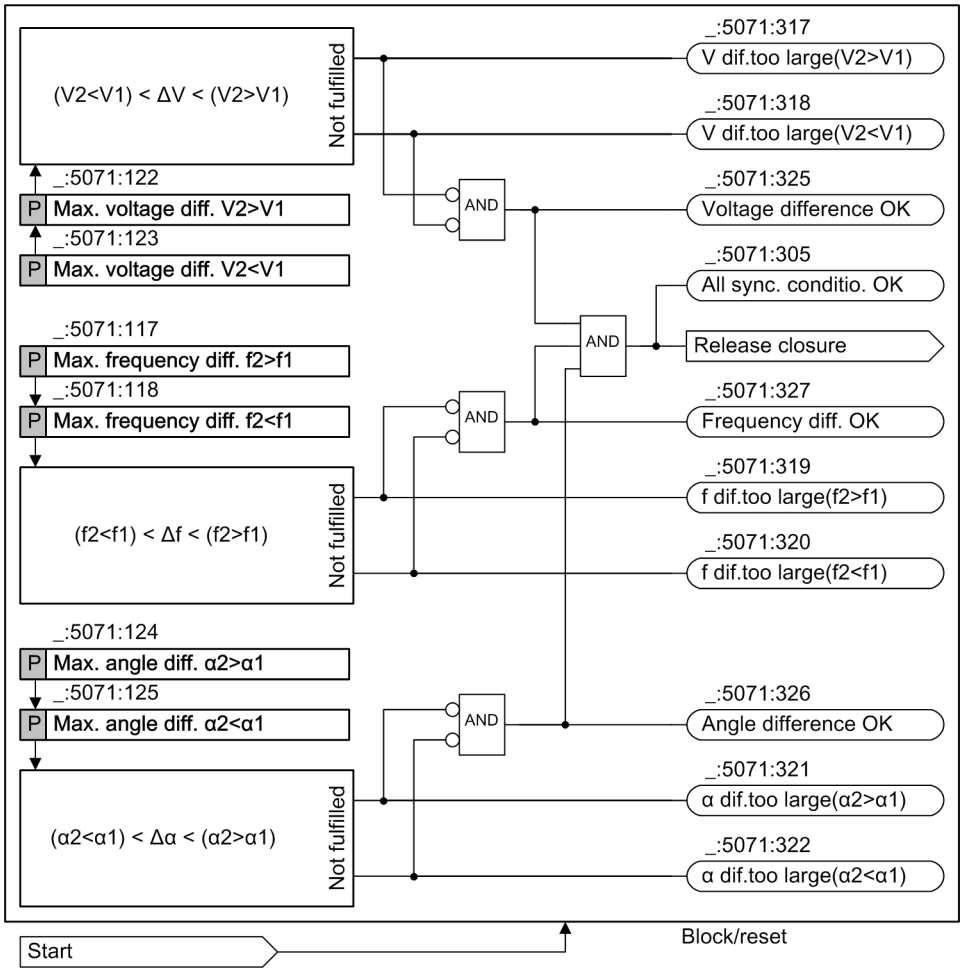
Direct Close Command

If the **Direct close command** operation is active, the function instantaneously initiates the release for closure after the successful start (see chapter *7.5.11 Direct Close Command*). A combination of direct close command with other release conditions is not advisable, as these conditions are bypassed by the direct close command.

End of the Process

If the function is started via the device-internal control, these functions also terminate the synchronization process upon closure. The process is terminated via the corresponding binary signals in case of external starting.

If the supervision time (**Max.durat. sync.process** parameter) has expired, the process is also completed and the indication **Max. time exceeded** is issued. A renewed synchronization is only possible if the stage is restarted.



Blocking Closure

You can use the input signal *>Block close command* to block the release signal for the closure (signal **Release close cmd.**) as well as the closure itself. The measurement continues to operate during the blocking. If the blocking is revoked and the release conditions are still fulfilled, the release is given for closure.

7.5.7 Stage Synchrocheck

7.5.7.1 Description

Checking Closing Conditions

[lo_synche-01, 2, en_US]

Figure 7-83 Closing Conditions for the Synchrocheck Function

With this operating mode, the values ΔV, Δf, and Δα are checked before connecting the 2 parts of the electrical power system. The indication **`All sync. conditio. OK`** signals that the setting values (conditions) have been reached and that the release for closure has been given (see **Checking the Closing Conditions, Closure** in *7.5.6 Sequence of Functions*).

Every fulfilled condition is signaled individually via the indications **`Voltage difference OK`**, **`Frequency diff. OK`**, and **`Angle difference OK`**.

If a condition is not fulfilled, detailed information on why the condition is not fulfilled is provided via indications. If the differential voltage is outside the setting limits, for example, the indication **`V dif.too large(V2<V1)`** is issued. The indication indirectly contains information that the voltage V2 has to be increased for a successful synchronization.

With the **Expanded delta-f options** stage type configured and an activated **`(_:140) Limit dfdiff/dt for sync. op`** parameter, the frequency difference rate of change is also checked. If the permissible frequency change rate (parameter **`(_:141) Max. value dfdiff/dt syn`**) is exceeded, the indication **`(_:329) dfdiff/dt too large`** is issued.

Continuous Supervision

With the parameter **Continuous supervision** selected, even if there is no start command for the signal *start*, the device can continuously monitor the voltage difference, frequency difference, and angle difference of the circuit breaker. Meanwhile, the indications *in progress*, *release close command*, and *max. duration time expired* are not issued.

If you want to release the close command, a start command for the signal *start* is necessary.

If you keep the default setting, then the stage **Synchrocheck** runs as normal.

7.5.7.2 Application and Setting Notes

Parameter: Sync. operating mode

- Default setting **Sync. operating mode** = *on*

With the parameter **Sync. operating mode**, you can switch the operating mode of the synchronization condition *on* or *off*. The operating mode is activated in the default setting.

Parameter: Maximum Differential Values of Voltage, Frequency and Angle

- Default setting **(_:5071:122) Max. voltage diff. V2>V1** = *5.0 V*
- Default setting **(_:5071:123) Max. voltage diff. V2<V1** = *5.0 V*
- Default setting **(_:5071:117) Max. frequency diff. f2>f1** = *0.10 Hz*
- Default setting **(_:5071:118) Max. frequency diff. f2<f1** = *0.10 Hz*
- Default setting **(_:5071:124) Max. angle diff. α2>α1** = *10°*
- Default setting **(_:5071:125) Max. angle diff. α2<α1** = *10°*

2 parameters are available for the differential values voltage, frequency, and angle. Unbalanced closing ranges can be set with this, if required.

The permissible differential values must ensure that no protection tripping or damage occurs in the system owing to compensation processes (circulating current) and power swings after interconnection of the parts of the power system. The settings must not be configured too closely on the other side so that necessary closures are not blocked.

Typical differential values are selected in the default setting. Depending on the system, the settings must be checked and adjusted, if necessary.

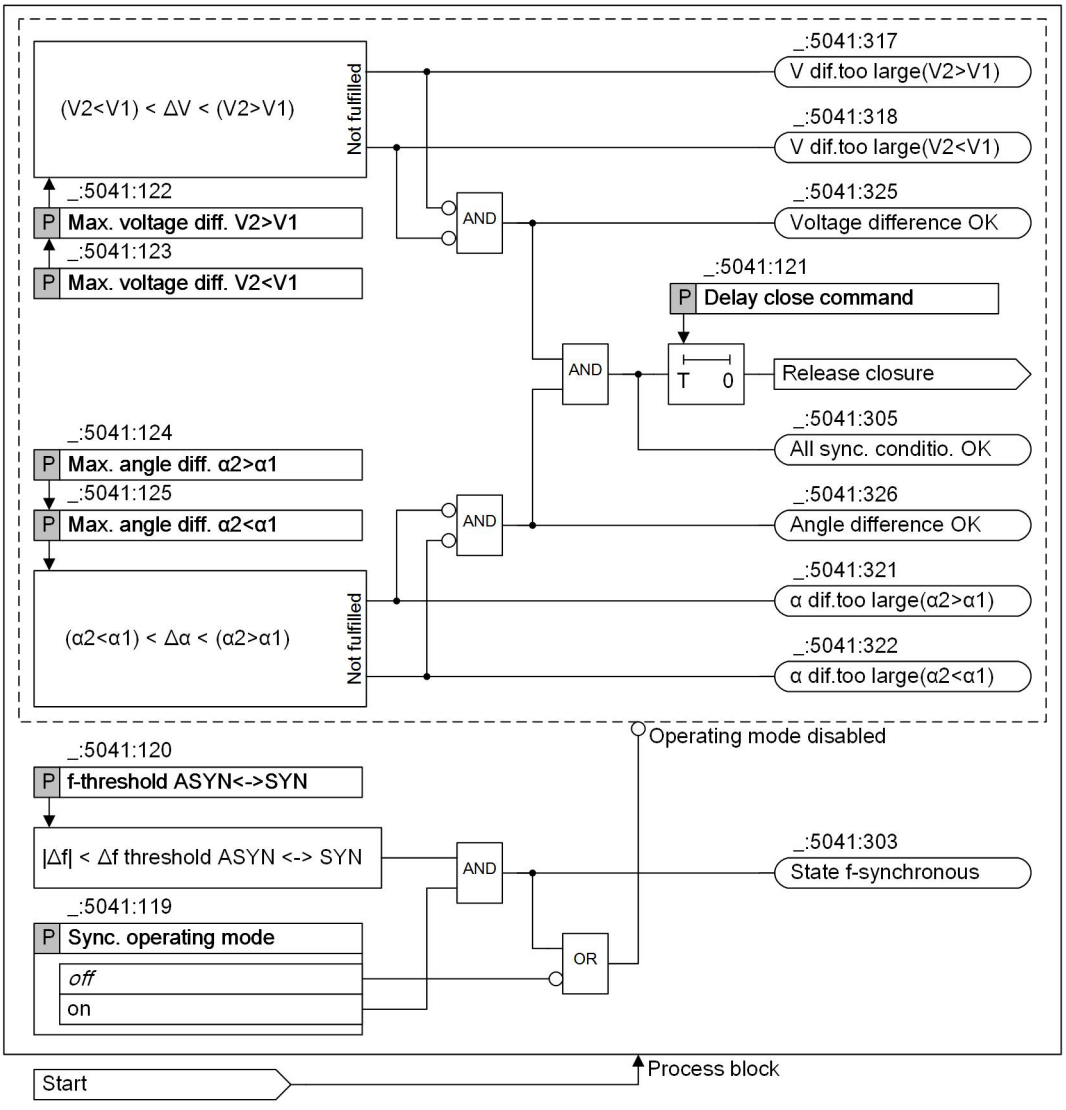
7.5.8 Stage Synchronous/Asynchronous

7.5.8.1 Description

A distinction according to synchronous and asynchronous systems can be made with this type of stage.



If galvanically coupled systems are switched in parallel, synchronous systems are present. A typical characteristic for synchronous systems is equality of frequency ($\Delta f \approx 0$). If the frequency difference falls below the setting value of the **f-threshold ASYN<->SYN** parameter, synchronous systems are to be assumed. If the frequency difference exceeds the setting value of the **f-threshold ASYN<->SYN** parameter, asynchronous systems are to be assumed. This status occurs in galvanically isolated systems, for example.

Both states have their own operating mode with its own closing conditions. Both operating modes can be switched on and off separately (parameter **Sync. operating mode** and **Async. operating mode**). The following combinations result from this:

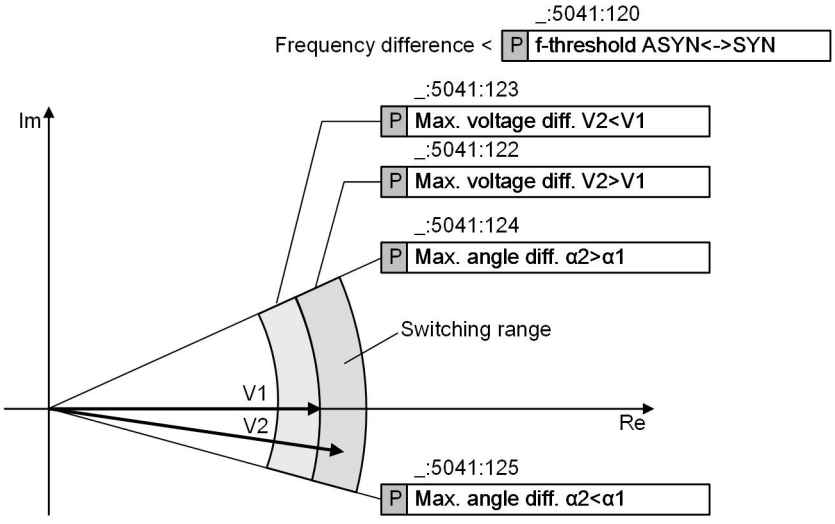
Sync. operating mode	**Async. operating mode**	Functionality
on	***on***	If the frequency difference is below the set threshold value **f-threshold ASYN<->SYN**, the operating mode synchronous is active. In other cases, the operating mode asynchronous is active.

off	***on***	Regardless of the frequency difference and the threshold value **f-threshold ASYN<->SYN**, the operating mode is exclusively active asynchronously.
on	***off***	If the frequency difference is below the set threshold value **f-threshold ASYN<->SYN**, the operating mode synchronous is active. In other cases, the stage is inactive, that is, a switching release cannot be issued.
off	***off***	Both operating modes are deactivated. No activation release can be given via these operating modes either.

Checking the Closing Conditions in Synchronous Systems

[lo_synsyn-01, 3, en_US]

Figure 7-84 Closing Conditions when Switching Synchronous Systems

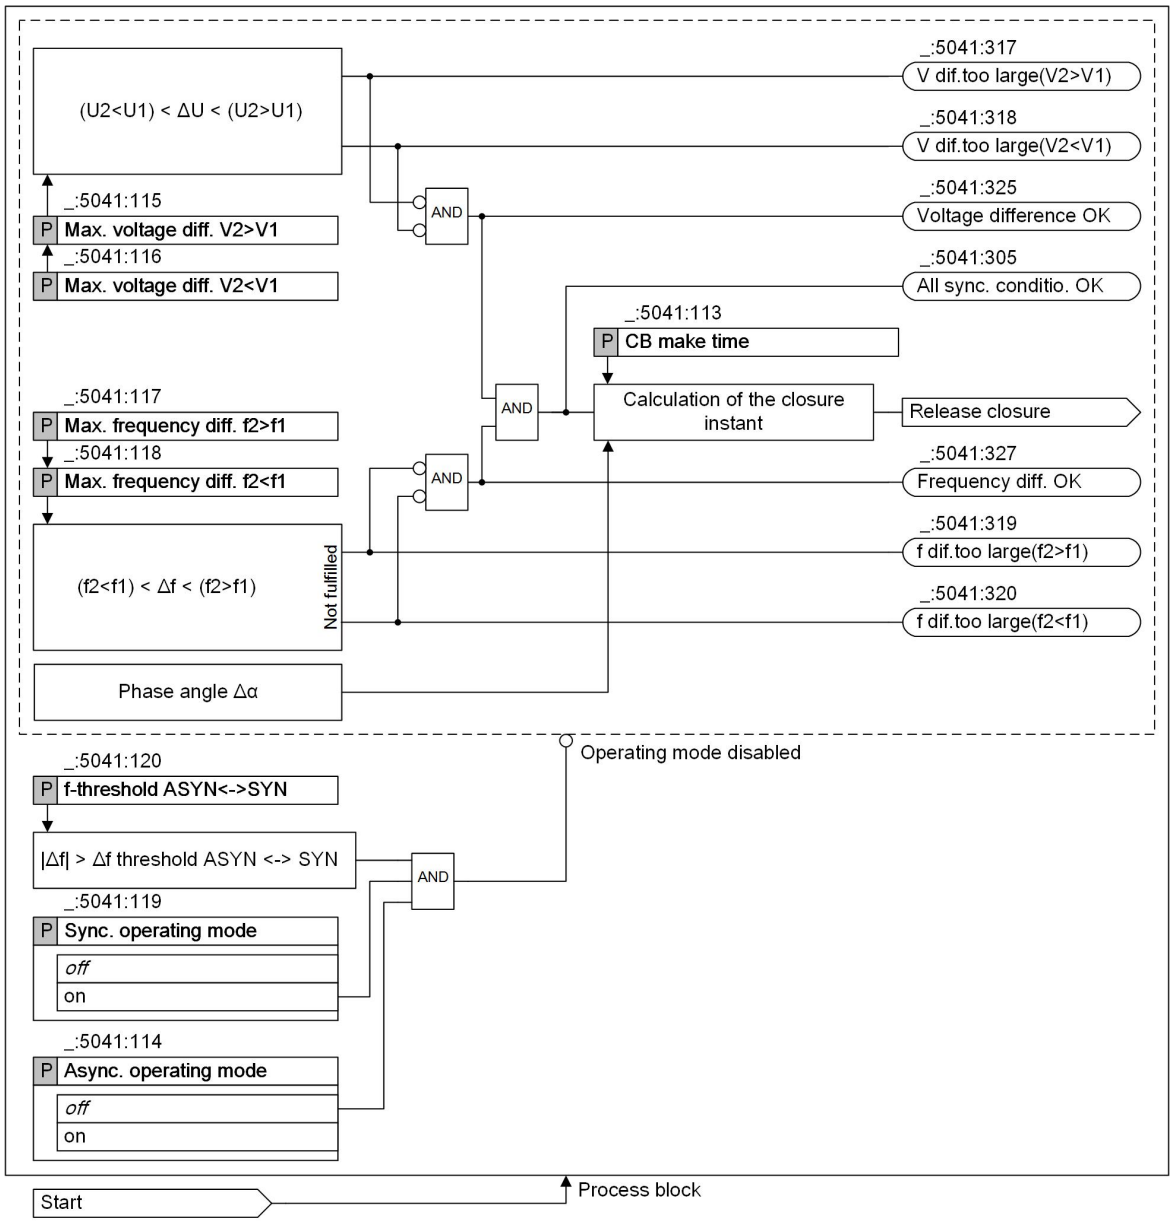


The frequency difference is very low in the synchronous systems operating mode. It is below the threshold value **f-threshold ASYN<->SYN**. The status is signaled via the **State f-synchronous** indication.

The parameters ΔV and Δα are checked for issuing an activation release (see *Figure 7-85*). The indication **All sync. conditio. OK** signals that both setting values (conditions) are reached. If the conditions remain fulfilled over the set time delay (parameter **Delay close command**), the release for closing is given (see also *7.5.7.1 Description*).

Every condition fulfilled is signaled individually via the indications **Voltage difference OK** and **Angle difference OK**.

If a condition is not fulfilled, detailed information on why the condition is not fulfilled is provided via indications. If the differential voltage is outside the setting limits, for example, the indication **V dif.too large(V2<V1)** is issued. The indication indirectly contains information that the voltage V2 has to be increased for a successful synchronization.

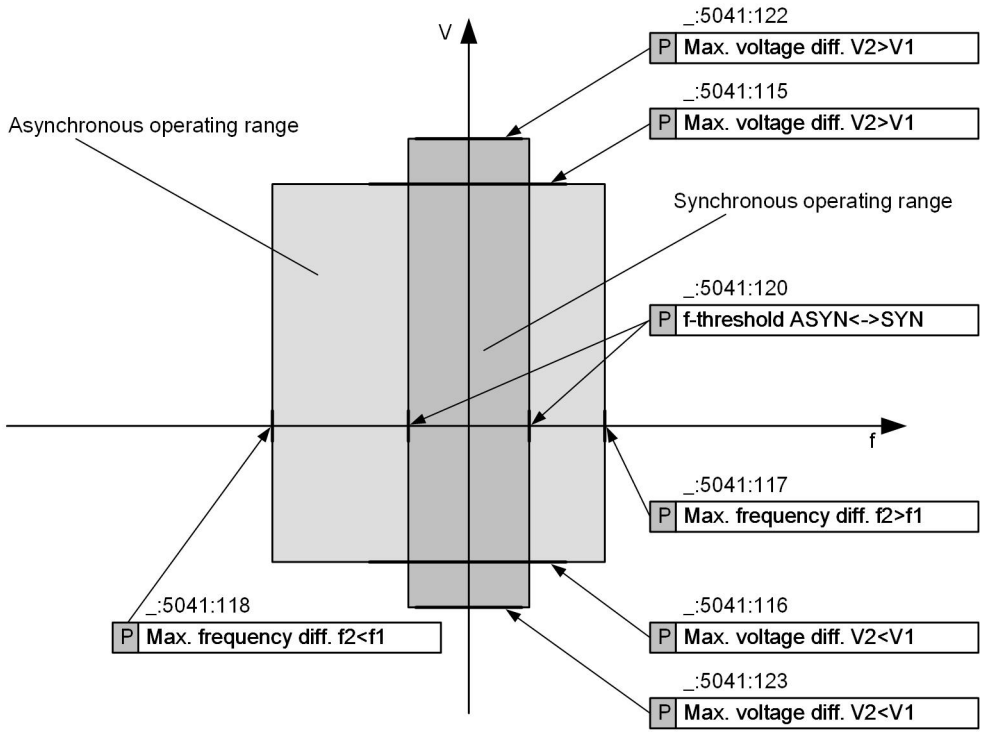


With the **Expanded delta-f options** stage type configured and an activated **(_:142) Limit dfdiff/dt for asyn. op** parameter, the frequency difference rate of change is also checked. If the permissible frequency change rate (parameter **(_:143) Max. value dfdiff/dt asyn**) is exceeded, the indication **(_:329) dfdiff/dt too large** is generated.

[lo_synzus-01, 2, en_US]

Figure 7-85 Connecting Under Synchronous System Conditions

Checking Closing Conditions in Asynchronous Systems



[lo_synasy-01, 4, en_US]

Figure 7-86 Closing Conditions when Switching Asynchronous Systems

In this operating mode, compliance with the voltage difference ΔV and frequency difference Δf conditions is checked. The function calculates the time point of the close command taking into account the angular difference Δα and the make time of the circuit breaker. This is calculated so that the voltage phasors are equal at the moment of pole contact by the circuit breaker (ΔV ≈ 0, Δα ≈ 0).

Ranges in the Voltage-Frequency Diagram (V-f Diagram)

Figure 7-87 shows the setting parameters for synchronous and asynchronous conditions in the V-f diagram. The frequency band is very narrow owing to the functional principle in the case of synchronous systems.

[lo_synarb-01, 2, en_US]

Figure 7-87 Operating Range under Synchronous and Asynchronous Conditions for Voltage (V) and Frequency (f)

Continuous Supervision

With the parameter **Continuous supervision** activated, even if there is no start command for the signal *start*, the device can continuously monitor the synchronous condition of the circuit breaker. Meanwhile, the indications *in progress*, *release close command*, and *max. duration time expired* are not issued.

If you want to release the close command, a start command for the signal *start* is necessary.

If you keep the default setting, then the stage **Synchronous/Asynchronous** runs as normal.

7.5.8.2 Application and Setting Notes

Parameter: Synchronous operating mode, Asynchronous operating mode

- Default setting **(_:5041:119) Sync. operating mode** = *on*
- Default setting **(_:5041:114) Async. operating mode**= *on*

The operating modes of the stages can be activated or deactivated via the parameters. The operating modes are deactivated in the default setting for safety reasons.

The following combination options are possible:

Sync. operating mode	Async. operating mode	Description
on	***on***	If the frequency difference is below the set threshold value **f-threshold ASYN<->SYN**, the operating mode **synchronous** is active. In other cases, the operating mode **asynchronous** is active. If you wish to interconnect galvanically isolated systems, then select this operating mode.
off	***on***	Regardless of the frequency difference and the threshold value **f-threshold ASYN<->SYN**, the **asynchronous** operating mode is exclusively active. The make time of the circuit breaker is always taken into account for determining the connecting point. Select this operating mode if you wish to activate machines, for example generators or asynchronous motors. However, if synchronous conditions with a low Δf are present, a close command is generated in this operating mode without a kick pulse.
on	***off***	Use this operating mode for galvanically connected systems. Closure is only possible with synchronous systems (with low Δf).
off	***off***	Both operating modes are deactivated. No closing release can therefore be given via this operating mode. This configuration is only advisable for special applications. Select this operating mode if you only wish to switch, for example de-energized parts of the power system.

Parameter for asynchronous operation: Max. voltage diff. of voltage and frequency

- Default setting **(_:5041:115) Max. voltage diff. V2>V1** = ***2.0 V***
- Default setting **(_:5041:116) Max. voltage diff. V2<V1** = ***2.0 V***
- Default setting **(_:5041:117) Max. frequency diff. f2>f1** = ***0.10 Hz***
- Default setting **(_:5041:118) Max. frequency diff. f2<f1** = ***0.10 Hz***

For more information, see **Parameter for synchronous operation**.

Parameter for synchronous operation: Maximum voltage diff. of voltage and angle

- Default setting **(_:5041:122) Max. voltage diff. V2>V1** = ***5.0 V***
- Default setting **(_:5041:123) Max. voltage diff. V2<V1** = ***5.0 V***
- Default setting **(_:5041:124) Max. angle diff. α2>α1** = ***10***°
- Default setting **(_:5041:125) Max. angle diff. α2<α1** = ***10***°

2 parameters are available for the differential values voltage, frequency, and angle. Unbalanced closing ranges can be set with this, if required.

The permissible differential values must ensure that no protection tripping or damage occurs in the system owing to compensation processes (circulating current) and power swings after interconnection of the parts of the power system. The settings must not be configured too closely on the other side so that necessary closures are not blocked.

Typical differential values are selected in the default setting. Depending on the system, the settings must be checked and adjusted, if necessary.

Parameter: Switchover between synchronous and asynchronous operation

- Recommended setting value **(_:5041:120) f-threshold ASYN<->SYN** = ***0.01 Hz***

This parameter is used to set the frequency difference for switching over between synchronous and asynchronous operation.

Siemens recommends using the default setting of ***0.01 Hz***.

7.5.9 Expanded Checks (df/dt and Smoothing of Oscillations)

When configuring the function block **Expanded delta-f options**, you can expand the synchronization checks to include the following aspects:

- Limitation of the frequency change rate

  With this option, you can define additional upper limits for the rate of permissible frequency difference change. The release checks for both stage types take these additional upper limits into consideration. Both activation (parameters **(_:140) Limit dfdiff/dt for sync. op** and **(_:142) Limit dfdiff/dt for asyn. op**) and the upper limits (parameters **(_:141) Max. value dfdiff/dt syn** and **(_:143) Max. value dfdiff/dt asyn**) for the frequency change rate are adjustable selectively for synchronous and asynchronous conditions. Both stage types consider the frequency change rate when issuing the release for switching and indicate when the rate is exceeded.

  If you also activate the option to compensate for low-frequency oscillations (parameter **(_:150) Suppr. frequ. oscillations**), the frequency change rate is stabilized in the presence of such oscillations. Stabilization is in effect for asynchronous as well as synchronous operating modes.

- Compensation for low-frequency oscillations

  If you activate this option (parameter **(_:150) Suppr. frequ. oscillations**), low-frequency oscillations, for example, as a consequence of power swings in the range of 0.8 Hz to 1.6 Hz, are detected and smoothed. This stabilizes the release checks in the presence of frequently changing violations of upper and lower limits for the specified frequency threshold values. The option affects the frequency check of the stage type **Synchrocheck** and the synchronous operating mode of the stage type **Synchronous/Asynchronous**. It does not affect the asynchronous operating mode.

  In the example of the following figure, the synchrocheck function would initiate energization, if the allowed frequency difference was set to 10 mHz without the parameter **Suppr. frequ. oscillations** as soon as the frequency f2 enters the 10-mHz band. If the parameter **Suppr. frequ. oscillations** is activated, energization is not initiated, since the average value of f2 is outside the band.

[dw_synfre-01, 2, en_US]

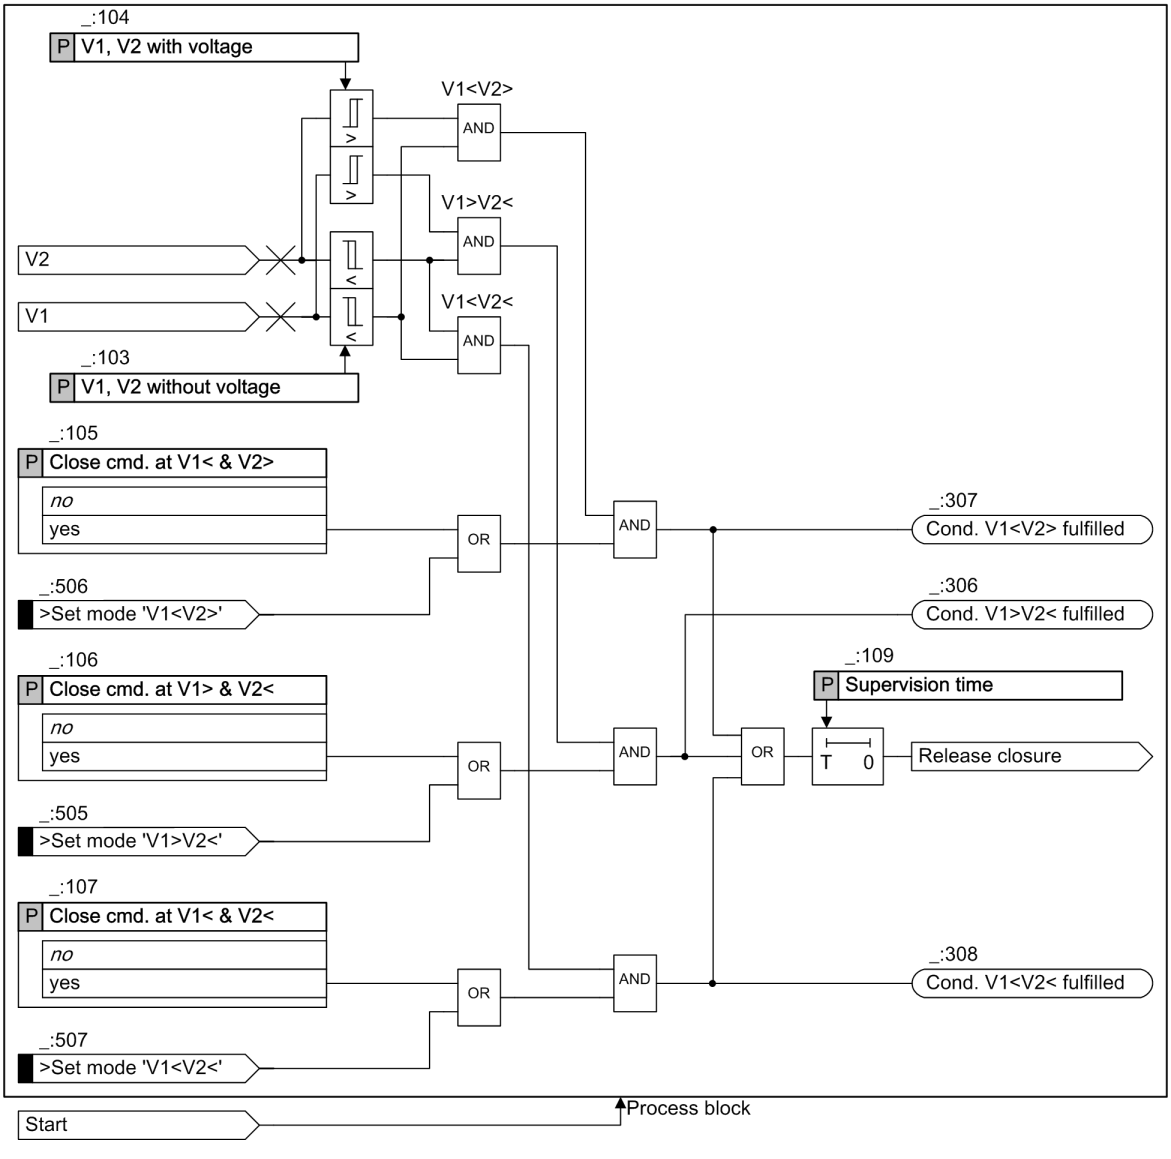
Figure 7-88 Example: Frequency Difference between the Constant Frequency f1 and the Sinusoidal Oscillating Frequency f2

With this option active, the range of function measured values is expanded by the smoothed frequency. Release of switching in synchronous networks occurs after one second at the earliest. This time is needed to smooth the frequency measured values.

The actual frequency can be larger or smaller than the smoothed value at any instant. The parameter **Max. diff. "f threshold"** makes it possible to limit the increase in instantaneous frequency value in relation to the respective frequency threshold value.

7.5.10 Closing at De-Energized Line/Busbar

7.5.10.1 Description



If at least one of 2 parts of an electrical power system is de-energized, the parts of the electrical power system can be connected together via the following operating modes.

If the measured voltage is less than the threshold **V1, V2 without voltage**, the zero potential of the part of the electrical power system is detected. In this case, all phases are compared to the parameter **V1, V2 without voltage**. The energized side must be in the defined operating range with respect to voltage and frequency (see chapter *7.5.4.1 Description*) and all phases must exceed the threshold **V1, V2 with voltage**.

The following additional closing conditions can be selected, which are then applied next to the closing conditions for the synchronism:

Settings	Description
Close cmd. at V1> & V2<	Closing release under the condition that the part V_1 of the power system is energized and the part of the electrical power system U_2 is de-energized.
Close cmd. at V1< & V2>	Closing release under the condition that the part V_1 of the power system is de-energized and the part of the electrical power system U_2 is energized.
Close cmd. at V1< & V2<	Closing release provided mains adapters V_1 and V_2 are de-energized.

Each of these conditions can be made effective individually via parameters or binary input. You can also set parameters for combinations, for example a release for closure, if **Close cmd. at V1> & V2<** or **Close cmd. at V1< & V2>** has been fulfilled.

[lo_syn003-01, 2, en_US]

Figure 7-89 Release Conditions for Switching to De-Energized Line/Busbar

The indications **Cond. V1>V2< fulfilled**, **Cond. V1<V2> fulfilled** and **Cond. V1<V2< fulfilled** indicate that the relevant conditions are fulfilled.

If the following 2 conditions are met, these indications refresh automatically:

- You set the parameter **Sync. operating mode** to ***on***.
- You select the parameter **Continuous supervision**.

You can use the **Supervision time** parameter to set a supervision time for which the closing conditions must at least be fulfilled with de-energized connection, before closing is allowed.

7.5.10.2 Application and Setting Notes

If at least one of 2 parts of an electrical power system is de-energized, the parts of the electrical power system can be connected together via the following operating modes. The above potential release conditions are independent of one another and can also be combined.

NOTE

For reasons of safety, the releases have been deactivated in the default setting and are therefore at ***no***. Even if you wish to apply one of these operating modes, Siemens recommends leaving the setting at ***no*** for reasons of safety. Set the operating mode only dynamically via the assigned binary input signal (for example **>Operating mode 'U1>U2<'**) (see also *Figure 7-89*). This prevents one of these operating modes from being incorrectly activated statically thereby resulting in an incorrect switching.

Parameter: **Close cmd. at V1< & V2>**

- Recommended setting value **(_:5071:105) Close cmd. at V1< & V2>** = ***no***

Settings	Description
no	No release for closing is possible via this operating mode.
yes	If part V1of the power system is de-energized and part V2 of the power system is energized, the release for closure is given upon starting the synchronization stage after the supervision time has passed. The setting depends on the operational requirements. Note the above information.

Parameter: **Close cmd. at V1> & V2<**

- Recommended setting value **(_:5071:106) Close cmd. at V1> & V2<** = ***no***

Settings	Description
no	No release for closing is possible via this operating mode.
yes	If part V1of the power system is energized and part V2 of the power system is de-energized, the release for closure is given upon starting the synchronization stage after the supervision time has passed. The setting depends on the operational requirements. Note the above information.

Parameter: **Close cmd. at V1< & V2<**

- Recommended setting value **(_:5071:107) Close cmd. at V1< & V2<** = ***no***

Settings	Description
no	No release for closing is possible via this operating mode.
yes	If the parts V1 and V2 of the power system are de-energized, the release for closure is given upon starting the synchronization stage after the supervision time has passed. The setting depends on the operational requirements. Note the above information.

Parameter: V1, V2 with voltage

- Recommended setting value **(_:5071:104) V1, V2 with voltage** = ***80 V***

The setting value indicates the voltage above which a part of the power system (feeder or busbar) can be regarded as activated with certainty.

You must set the value below the minimum expected operational undervoltage. Siemens therefore recommends a setting value of approx. 80 % of the rated voltage. All voltages connected according to the parameterized measuring-point connection type are subjected to the appropriate Vmin/Vmax test.

Parameter: V1, V2 without voltage

- Recommended setting value **(_:5071:103) V1, V2 without voltage** = ***5 V***

The setting value indicates the voltage below which a part of the power system (feeder or busbar) can be regarded as deactivated with certainty.

Siemens recommends a setting value of approx. 5 % of the rated voltage for this. All voltages connected according to the parameterized measuring-point connection type are subjected to the appropriate Vmin/Vmax test.

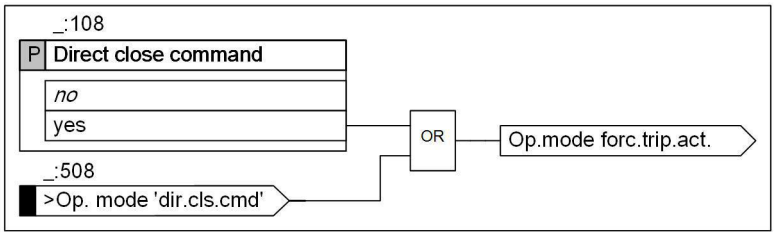
Parameter: Supervision time

- Recommended setting value **(_:5071:109) Supervision time** = ***0.1 s***

The parameter defines a supervision time for which the above additional closing conditions have to be at least fulfilled at de-energized switching, before the release for closing is given. In order to include transient phenomena, Siemens recommends a value of ***0.1 s***.

Parameter: Direct close command

- Recommended setting value **(_:5071:108) Direct close command** = ***no***



In this operating mode, the function initiates a closing release without any testing upon start of the synchronization stage. The closure occurs immediately.

NOTE

For safety reasons, Siemens recommends leaving the setting at***no***. If a direct close command is necessary, Siemens recommends only using this operating mode dynamically via the binary input signal **>Op. mode 'dir.cls.cmd'** (see *Figure 7-91*). This prevents this operating mode from being incorrectly activated statically thereby resulting in an incorrect switching.

7.5.11 Direct Close Command

You can activate the operating mode direct close command statically via the **Direct close command** parameter or dynamically with the binary input signal **>Op. mode 'dir.cls.cmd'** (see *Figure 7-90*).

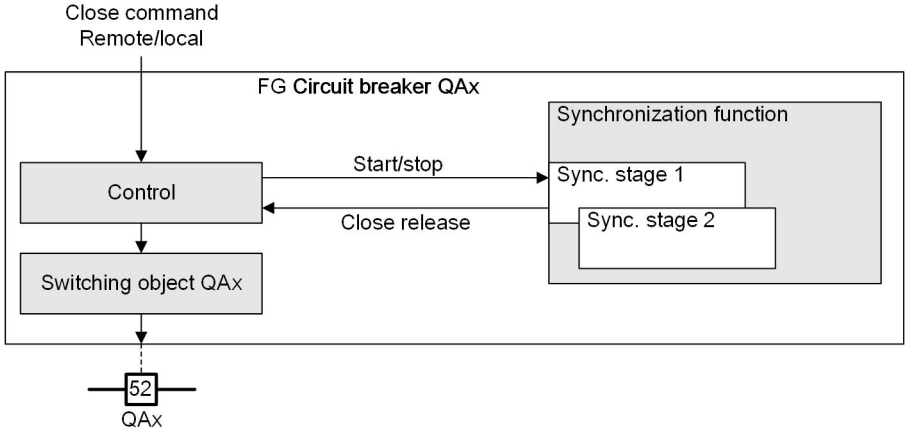
[lo_syndir_01, 2, en_US]

Figure 7-90 Activation of the Operating Mode Direct Close Command

The operating mode **Direct close command** function initiates a closure release without any testing upon start of the synchronization stage. The closure occurs immediately.

The combination **Direct close command** with other operating modes is not recommended, as the other operating mode is bypassed.

If the synchronization function is defective (standby of the sync stage = alarm or warning), a direct close command is executed or not executed, depending on the type of fault (see also supervisions in chapter *7.5.4.1 Description*).



7.5.12 Interaction with Control and External Triggering

With Control

The control and synchronization functions are always located in a **Circuit-breaker** function group. The control and also the synchronization function always operate with the circuit breaker, which is linked to the function group **Circuit breaker**.

As soon as the synchronization function is in the **Circuit-breaker** function group, the circuit breaker is subject to compulsory synchronization. If all synchronization stages are deactivated, the circuit breaker cannot be activated via the control, as no release can be generated for the closure. The circuit breaker is no longer subject to compulsory synchronization after deletion of the synchronization function. Closure without synchronization is then possible via the control.

If closure is to be synchronized via the control, the control automatically generates an internal signal which starts the synchronization function. The functional sequence is described in chapter *7.5.6 Sequence of Functions*. After fulfilling all closing conditions, the synchronization sends a release signal to the control, which closes the circuit breaker and then stops and synchronization function.

[lo_synaw1-01, 3, en_US]

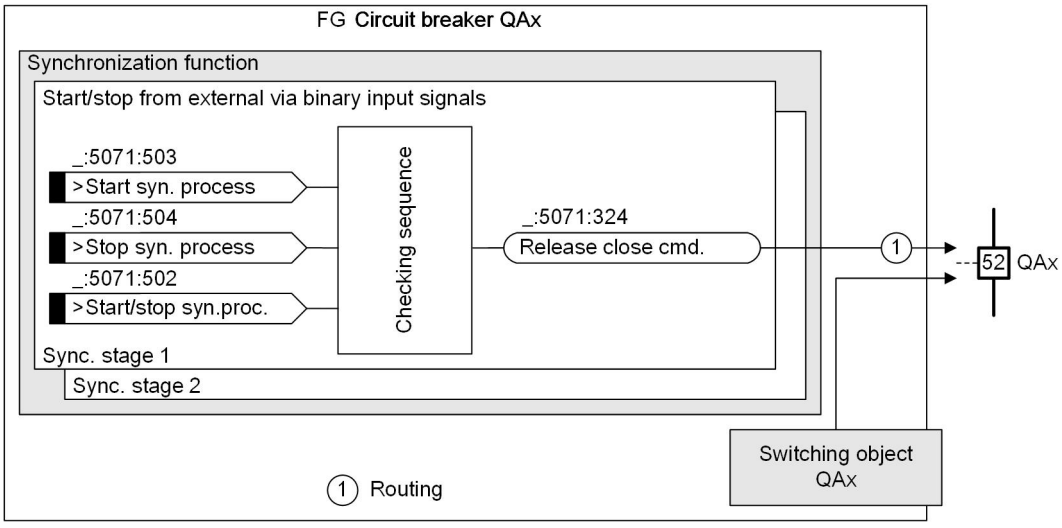


Figure 7-91 Interaction of the Control with the Synchronization Function

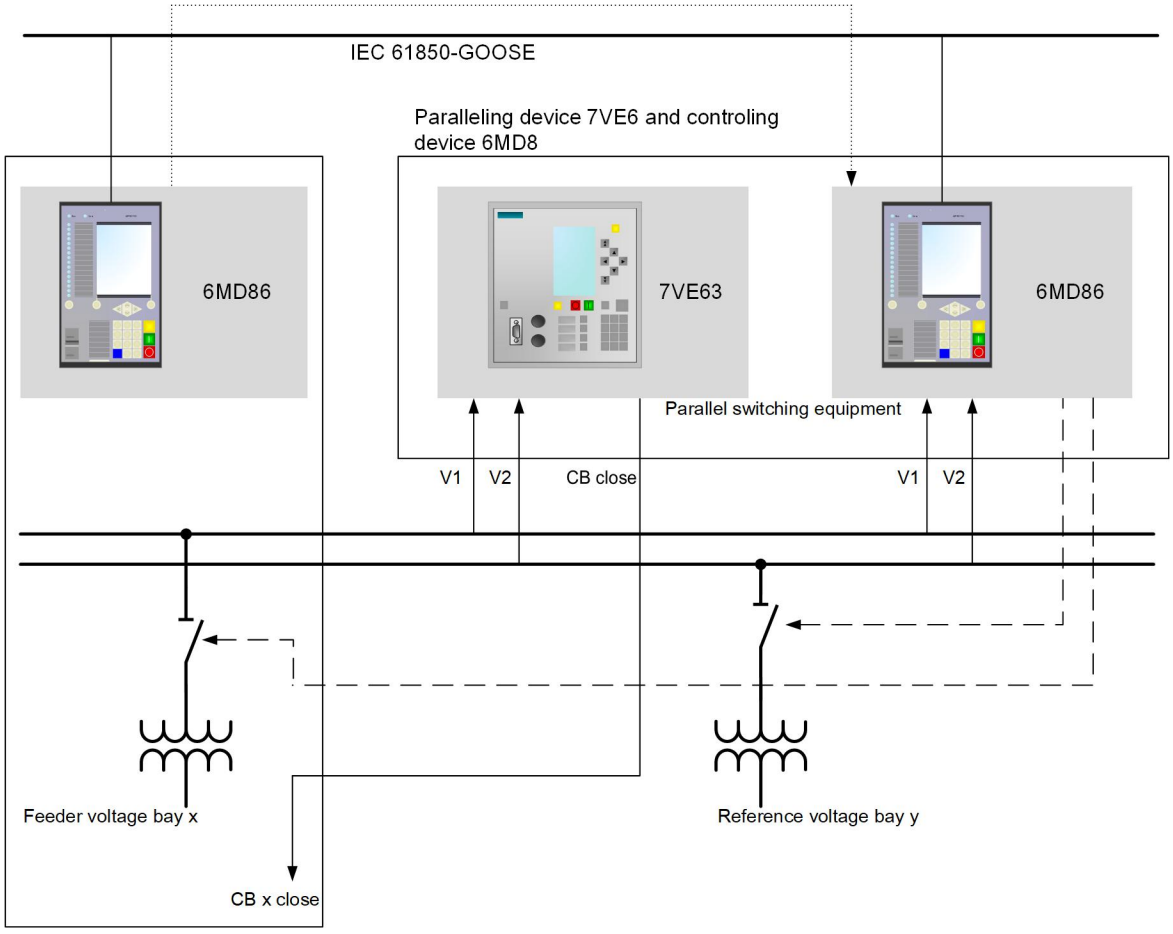
With External Control

You have the option of controlling the synchronization function externally via binary input signals. This can be done as follows:

- Edge-controlled
- Via the signals **>Start syn. process** and **>Stop syn. process**
- State-controlled via the signal **>Start/stop syn.proc.** (see also *7.5.6 Sequence of Functions*).

The start is followed by the functional sequence (see *7.5.6 Sequence of Functions*). If the conditions are fulfilled, the output signal **Release close cmd.** is output. The switched object QAx of the function group **Circuit breaker** is not closed. The output signal **Release close cmd.** must be explicitly routed to the binary output in order to close the circuit breaker.



[lo_synaw3-01, 3, en_US]

Figure 7-92 Interaction of the Synchronization Function with External Control

7.5.13 External Synchronization

7.5.13.1 Description

The purpose of the **External synchronization** function is to control an external synchronization device.

[dw_ctrl_ext_sync_device, 3, en_US]

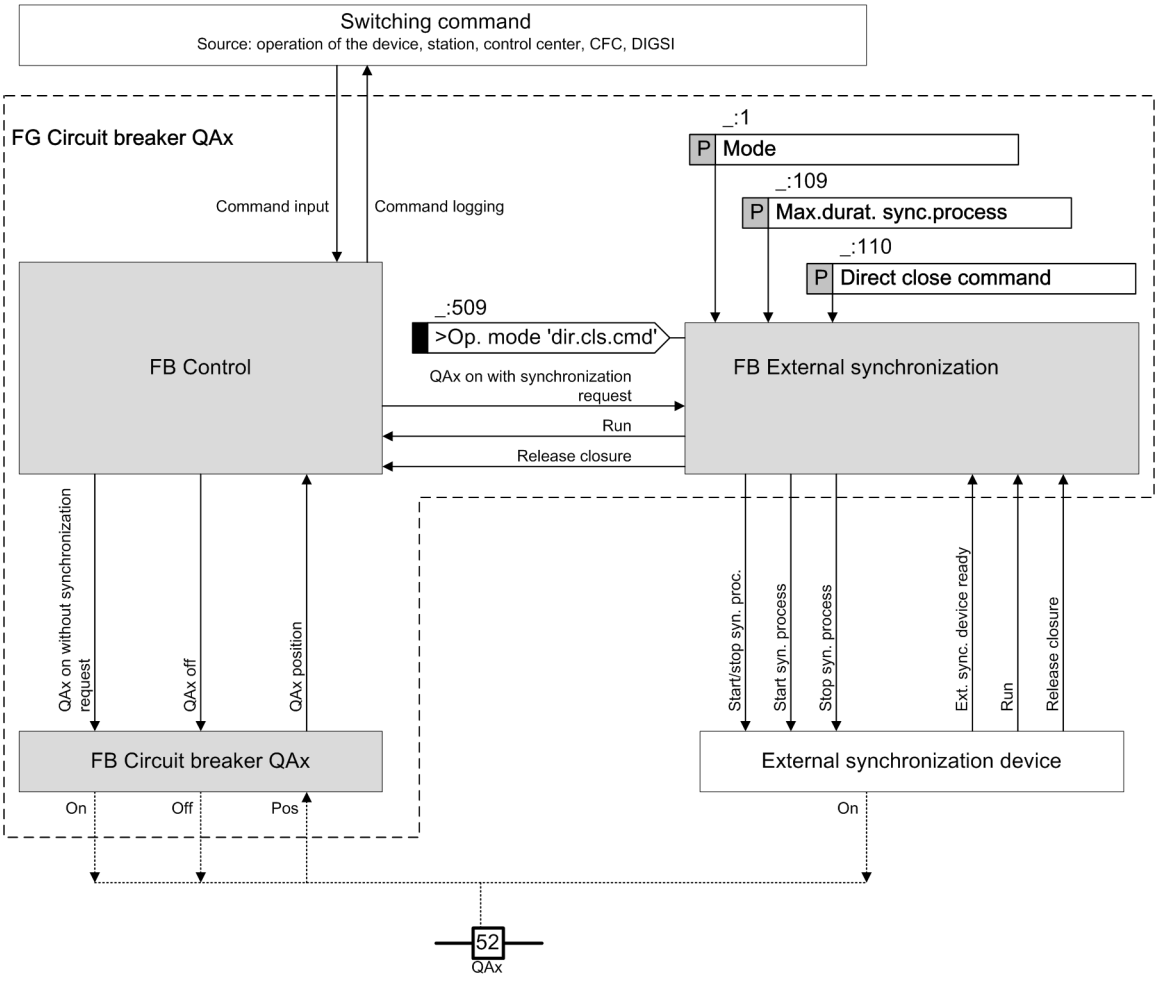


Figure 7-93 Triggering an External Synchronization Device

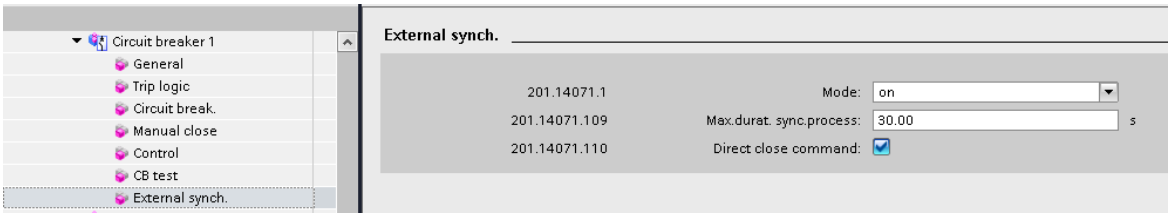
The bay controller in bay x should switch the circuit breaker in bay x in synchrony. The synchronization check is carried out in the central paralleling device 7VE6. In addition to the paralleling device, another central bay controller ensures the switching of the correct measuring voltages and the routing of the CB close command from the 7VE6 to the correct circuit breaker in bay x. The bay controller x provides the information to the central bay controller via IEC61850-GOOSE.

The **External synchronization** is designed as a function block which can be used in the Circuit-breaker function group. The additional **External synchronization** function block integrates the external synchronization into command processing, so that the corresponding feedback can be forwarded to the command source.

If a circuit-breaker close command with a synchronization requirement is present, the external synchronization device is started. After successfully checking the synchronization conditions, the close command is issued from the external synchronization device to the circuit breaker. If a circuit-breaker close command without synchronization requirement is present, the circuit-breaker close command is issued directly from the **Circuit-breaker** function group to the circuit breaker. Also, each circuit-breaker trip command is issued directly to the circuit breaker.

In case of a failure of the external synchronization device, you can also close the circuit breaker directly without considering the synchronization conditions.



[dw_extsyn-02, 1, en_US]

Figure 7-94 Interaction between Control and External Synchronization

Parameterization with DIGSI

In the DIGSI library, the function is visible inside the **Circuit-breaker** function group as the **External synchronization** function block. You can instantiate the function block in the **Circuit-breaker** function group and the **Circuit-breaker (control)** function group. You can instantiate only 1 **External synchronization** function block within these function groups at a time.

[scextsyn-041116-01, 1, en_US]

Figure 7-95 Instantiating the **External Synchronization** Function Block in the **Circuit-Breaker** Function Group

It is not possible to jointly instantiate the **External synchronization** function block with the **25 synchronization** function in the same **Circuit-breaker** function group.

Notes for Optional Input Interconnections

You have the option of connecting the input signals *>Close cmd. released* and *>In progress*. If you omit these interconnections, observe the following instructions:

Input *>Close cmd. released*:

If you do not interconnect the input signal *>Close cmd. released* the execution of a circuit-breaker close command with synchronization requirement is confirmed directly (execution successful: OPR+), as soon as the output signal *Start syn. process* is set. In this case, the **(_:109) Max.durat. sync.process** setting has no meaning. If you use a control model with feedback monitoring, consider that the feedback monitoring will start immediately when the *Start syn. process* signal is tripped. The **(_:4201:103) Feedback monitoring time** setting must therefore be set higher than the maximum synchronization time of the external synchronization device plus the circuit-breaker make time. If *>Close cmd. released* is not routed, the output *Start/stop syn. proc.* is not set.

Input*>In progress*:

The interconnection of the input signal *>In progress* is intended to check whether the synchronization device has received the *Start syn. process* signal. If you do not interconnect this input signal and the external synchronization device rejects a start command, the negative acknowledgment of the circuit-breaker close command does not occur until the maximum synchronization time (parameter **(_:109) Max.durat. sync.process**) has expired.

Input *>Op. mode 'dir.cls.cmd'*:

In case of a failure of the external synchronization device, you can also close the circuit breaker directly without considering the synchronization conditions. To do this, activate the input signal *>Op. mode 'dir.cls.cmd'* or the parameter **(_:110) Direct close command**. The close command is then issued directly by the bay controller.

7.5.13.2 Application and Setting Notes (External Synchronization)

Parameter: Mode

- Default setting **(_:1) Mode** = ***on***

With the **Mode** parameter, you switch the external synchronization function on or off. If you set the **Mode** parameter to ***off***, a circuit-breaker close command with synchronization requirement is rejected.

Parameter: Max.durat. sync.process

- Default setting **(_:109) Max.durat. sync.process** = ***30 s***

The **Max.durat. sync.process** parameter defines the maximum synchronization time. The time starts when the **External synchronization** function block sends a close command to the external synchronization device. The command must be executed within this time. If the close command is not executed within this time, the **External synchronization** function block sends a command to cancel closing to the external synchronization device.

Parameter: Direct close command

- Default setting **(_:110) Direct close command** = ***no***

In case of a failure of the external synchronization device the **Direct close command** parameter is used to close the circuit breaker directly without considering the synchronization conditions. If the parameter is activated a close command with synchronization requirement will not be transmitted to the external synchronization device, but directly carried out by the bay controller.

7.6 User-Defined Function Block [Control]

7.6.1 Overview of Functions

The **User-defined function block [control]** allows the switching-authority check of a control command, the check of whether the position has been reached, a double-activation blocking, and the definition of interlocking conditions for user-defined controllables.

7.6.2 Function Description

The **User-defined function block [control]** is located in the folder **User-defined functions** in the DIGSI 5 Library.

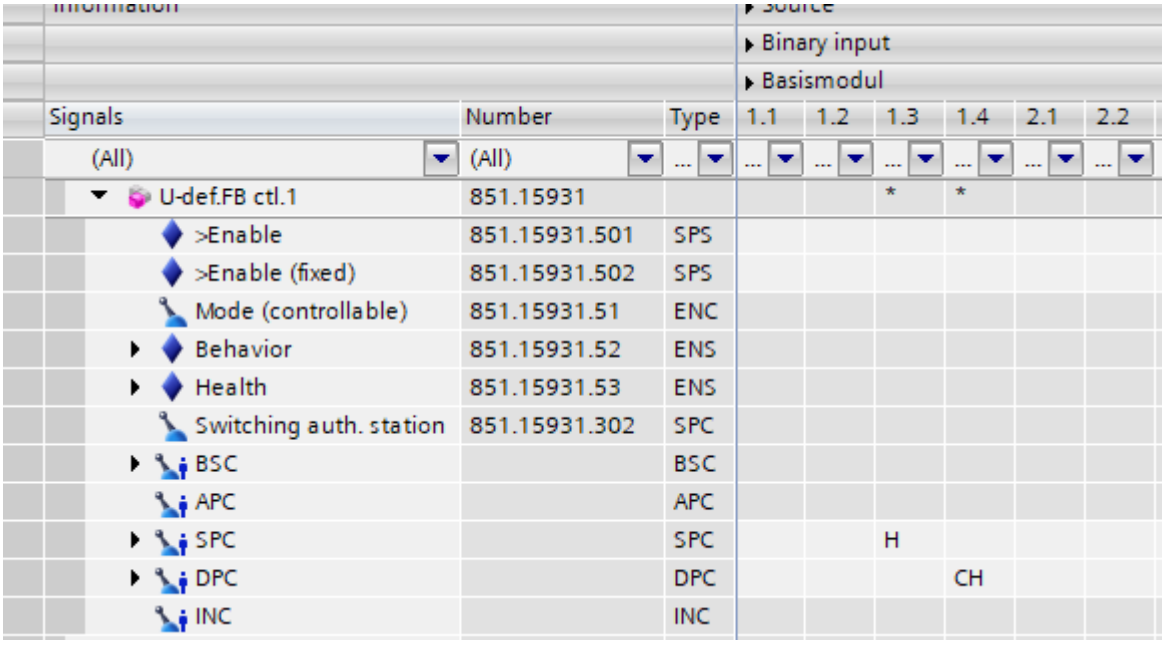
You can instantiate the user-defined function blocks on the top level (in parallel to other function groups) as well as within function groups and functions.

The task of the function block is to check the switching authority and the interlocking conditions for the user-defined control commands instantiated within it. For these control commands, the function block checks whether the required switch position is equal to the current switch position (actual/set point comparison).
If you activate the double-activation blocking, commands from switching objects and user-defined control signals will be rejected as long as a command is still being performed for one of the other switching objects for which double-activation blocking has also been set.

With the binary release signals, you can determine a switchgear interlocking protection for all the user-defined control signals instantiated in the function block. Unlike the switching devices (circuit breaker, disconnector), there is only one release input here, since there is only one switching direction for the signal types INC and APC. The signal types DPC, SPC, and BSC have 2 switching directions, but still only one release input. This release input can be operated based on the result of a logic created in the CFC, or can be directly connected to a binary input or a variable. If the input **>Enable** is activated, the switching command can be performed. If it is not activated, the switching command is rejected, with the reason *Interlocking violation*.

This applies in a similar way to the input **>Enable (fixed)**, although with this input, the interlocking cannot be revoked by key switch S1 or an *unlocked* switching authority.

The following table shows the reaction of the function to the assignment of its inputs.



Input >Enable	Input >Enable (fixed)	Effect on control command
1	0	Rejected
0	1	Successful if device mode = *unlocked* Rejected if device mode = *locked*
1	1	Successful
0	0	Rejected

NOTE

The default setting for the state of the inputs is **1**, that is, the switching commands are not locked.

You can instantiate every user-defined signal (for example, SPS, DPC, INC) in the function block and route the corresponding indications (see following figure).

Information			Source					
			Binary input					
			Basismodul					
Signals	Number	Type	1.1	1.2	1.3	1.4	2.1	2.2
(All)	(All)	...	...	...	...	...	...	...

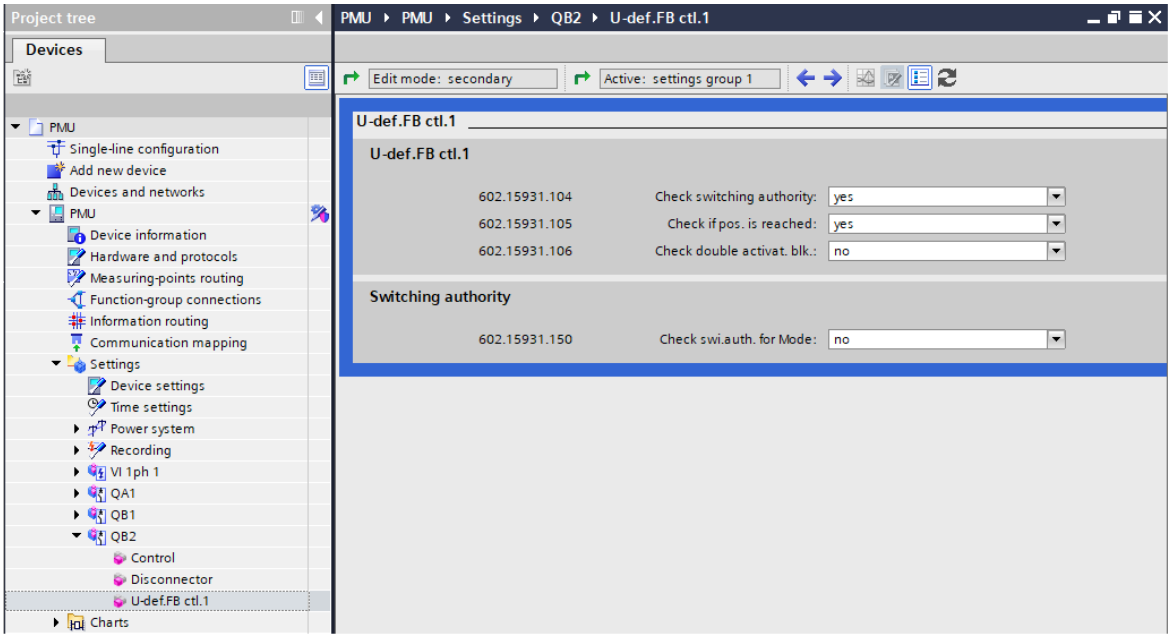
SPC		SPC			H			
DPC		DPC				CH		
INC		INC						



[sc_user_01, 1, en_US]

Figure 7-96 Information Routing with Inserted User-Defined Function Block [Control]: Process Indications and Some Single-Point Indications

7.6.3 Application and Setting Notes

The function block contains the parameters **(_:104) Check switching authority**, **(_:105) Check if pos. is reached**, **(_:106) Check double activat. blk.**, and **(_:150) Check swi.auth. for Mode**. The parameter settings **Check switching authority** and **Check if pos. is reached** affect all controllables instantiated **in the** function block. Other signal types are not affected by these parameters and objects.

On the other hand, the parameter setting **Check swi.auth. for Mode** affects the controllable **Mode (controllable)** of the function block.

[sc_user_02, 1, en_US]

Figure 7-97 Parameterization Options of the User-Defined Function Block [Control]

Parameter: **`Check switching authority`**

- Default setting **`(_:104) Check switching authority`** = ***`yes`***

With the **`Check switching authority`** parameter, you determine whether the command source of switching commands must be checked (see chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*).

Parameter: **`Check if pos. is reached`**

- Default setting **`(_:105) Check if pos. is reached`** = ***`yes`***

With the **`Check if pos. is reached`** parameter, you check at a switching command whether the switching direction equals the current position.

Parameter: **`Check double activat. blk.`**

- Default setting **`(_:106) Check double activat. blk.`** = ***`no`***

With the **`Check double activat. blk.`** parameter, you check whether commands from switching objects and user-defined control signals should be rejected, as long as a command is still being executed for one of the other objects.

Parameter: **`Check swi.auth. for Mode`**

- Default setting **`(_:150) Check swi.auth. for Mode`** = ***`no`***

With the **`Check swi.auth. for Mode`** parameter, you specify whether the switching authority for the command source must be checked when switching the controllable **`Mode (controllable)`** to the mode ***`On`***, ***`Off`***, or ***`Test`***. If you set the parameter **`Check swi.auth. for Mode`** to ***`yes`***, the switching command is only executed with the appropriate switching authority (see chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*).

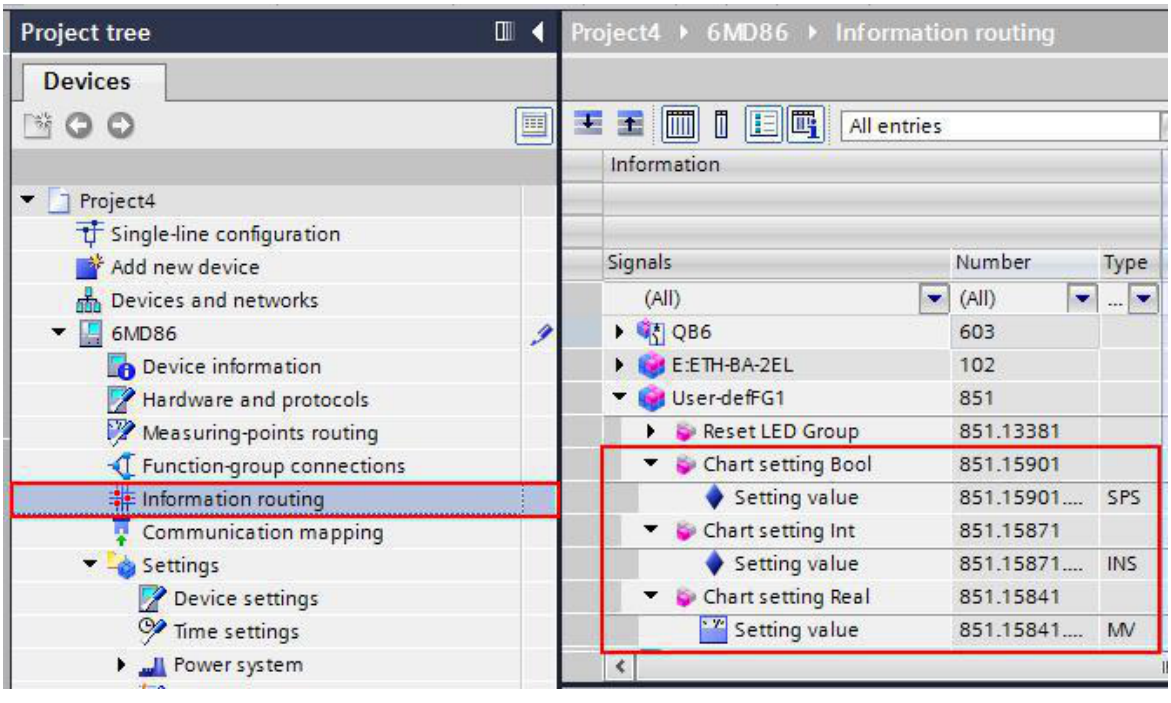
7.7 CFC-Chart Settings

7.7.1 Overview of Functions

If you want to process a parameter in a CFC chart and this parameter is to be changeable during runtime using DIGSI or HMI, you can use the function blocks **CFC chart of Boolean parameters**, the **CFC chart of integer parameters** and the **CFC chart of floating-point parameters**. Instantiate the appropriate function block depending on the parameter value needed (logical, integer, or floating point). In this way, the current value of the parameter can then be used in the CFC chart at runtime.



7.7.2 Function Description

You can find the CFC-chart parameters **`Chrt sett.Bool`**, **`Chart setting Int`**, and **`Chrt sett.real`** in the DIGSI library in the **User-defined functions** folder. Drag and drop the desired function block into a function group or a function. Set the appropriate parameter value of the function block in DIGSI using the parameter editor or via HMI under the **Settings** menu item. You can then use the parameter as an input signal in CFC charts.

With **Exp. options**, you define the range and the unit of the value. This prevents users from entering incorrect setting values.

NOTE

The user-defined function groups and the user-defined functions can be used to group the CFC-chart parameters. You can rename for the function block and change the parameter value in the DIGSI Information routing matrix to suit your specific application.

[sc_cfc_param, 1, en_US]

Figure 7-98 CFC-Chart Parameters within Information Routing

7.7.3 Application and Setting Notes

Parameter: **Chrt sett.Bool**

- Default setting **Chrt sett.Bool** = ***False***

You can use the parameter **Chrt sett.Bool** in a CFC chart as an input signal with a Boolean value. This input value can then be changed during the runtime of the CFC chart.

Parameter: **Chart setting Int**

- Default setting **Chart setting Int** = ***10***

You can use the parameter **Chart setting Int** in a CFC chart as an input signal with an integer value. This input value can then be changed during the runtime of the CFC chart.

Parameter: **Chrt sett.real**

- Default setting **Chrt sett.real** = ***100.000***

You can use the parameter **Chrt sett.real** in a CFC chart as an input signal with a floating-point number. This input value can then be changed during the runtime of the CFC chart.

7.7.4 Settings

Addr.	Parameter	C	Setting Options	Default Setting

7.8 Tap Changers

7.8.1 Function Description

With the device control function, you can change a transformer tap by moving it higher or lower and monitor the proper execution of the adjusting commands.

The function has built-in comprehensive options for measuring the tap changer position as well as supervision and monitoring functions. The supervision and monitoring functions are used to check the voltage and supply information about the tap position for adaptive matching of the transformer differential protection

The following options are provided for control:

- Direct user commands via the device keypad or routed binary inputs
- User-defined conditions via the CFC

If the tap changer reaches the end positions, the control function issues the *(_:301) End higher pos.reached* or *(_:302) End lower pos.reached* indication.

The transformer tap controller is controlled by the function group **Tap changer**, which you can select from the DIGSI library (group **Switching devices**).

[sc_tssdig, 1, en_US]

Figure 7-99 Tap Changer Functionality in the DIGSI Information Matrix

The central element is the Controllable **Position** of type BSC (Binary Controlled Step Position Information, based on IEC 61850). You connect this Controllable in the matrix to the desired number of binary inputs that indicate the current tap position.

For more information, refer to*7.8.2 Application and Setting Notes*.

The **Position** Controllable also contains parameters. If you wish to change the settings, you must select the Controllable in the DIGSI information matrix and change the settings by way of the Properties dialog. The taps are controlled via the commands **Higher command** and **Lower command**, each of which must be connected to one binary output.

Example

The following 2 figures show a CFC chart as an example for transformer tap control with the routing of the function keys for stepping up or stepping down.

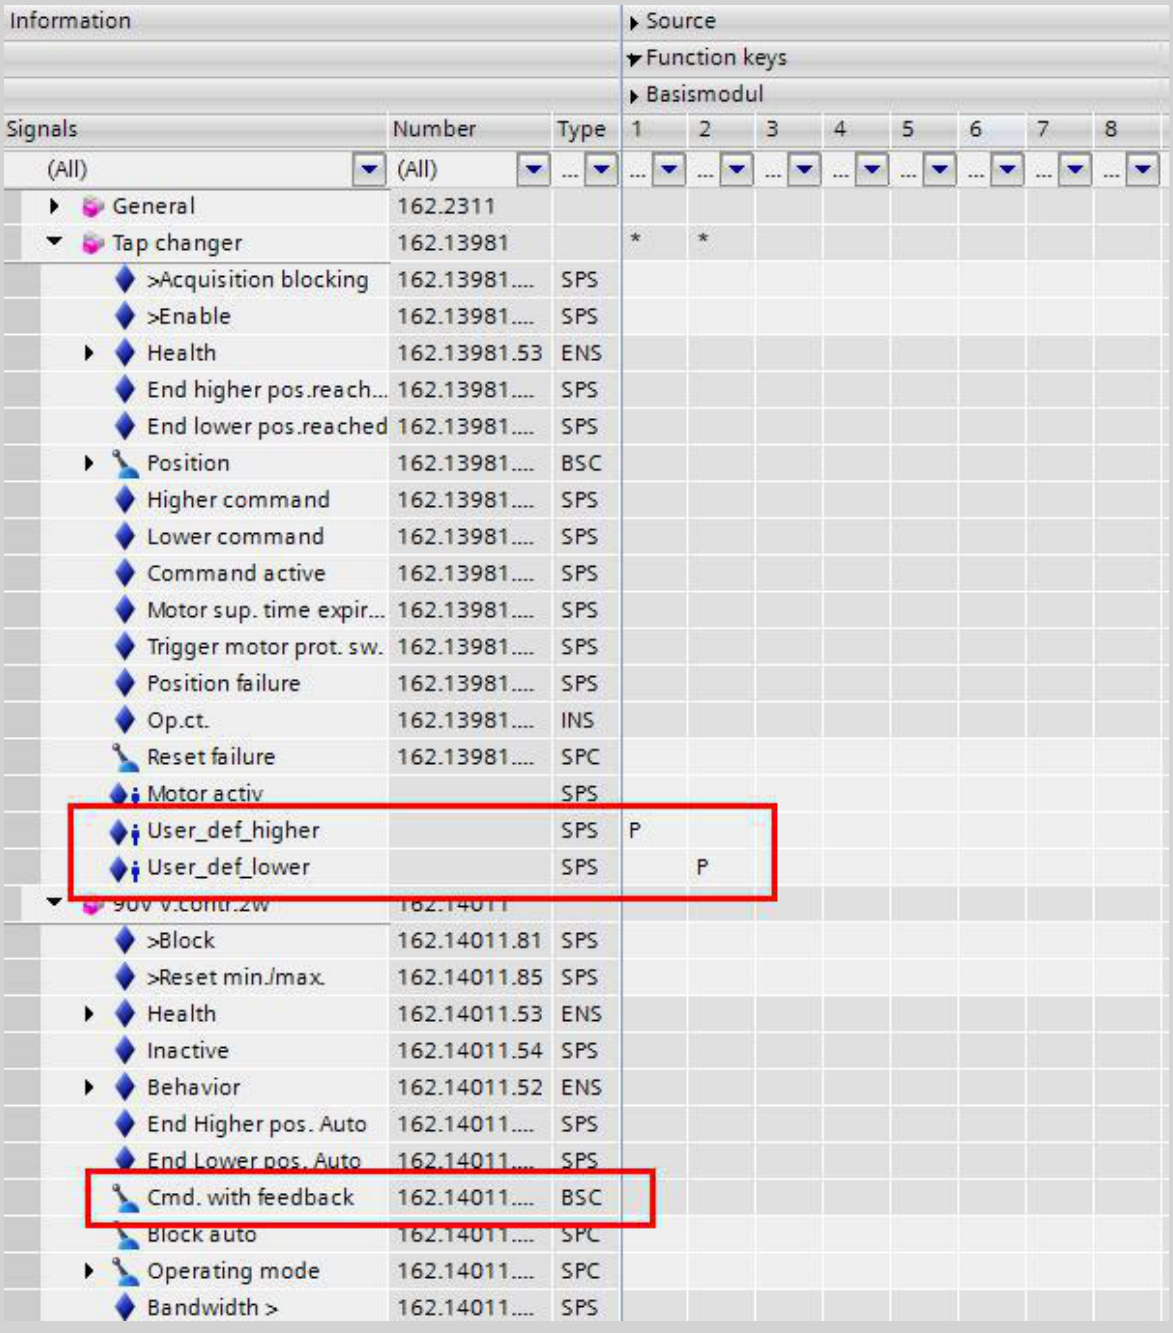

Figure 7-100 Routing of the Function Keys and CFC Signals

To use the function keys, you create 2 user-defined single-point indications (SPS). These are used for the function keys (for example, <F1>, Higher function key and <F2>, Lower function key) and as the input signals for the appropriate CFC blocks. In addition, you must use the controllable **`Cmd. with feedback`** for the CFC chart and set the control model to ***`direct w. enh. security`***.

You can select the control direction using the following values at the **Val** input of the **BSC_DEF** building block:

- 1 means **step up**
- 0 means **step down**

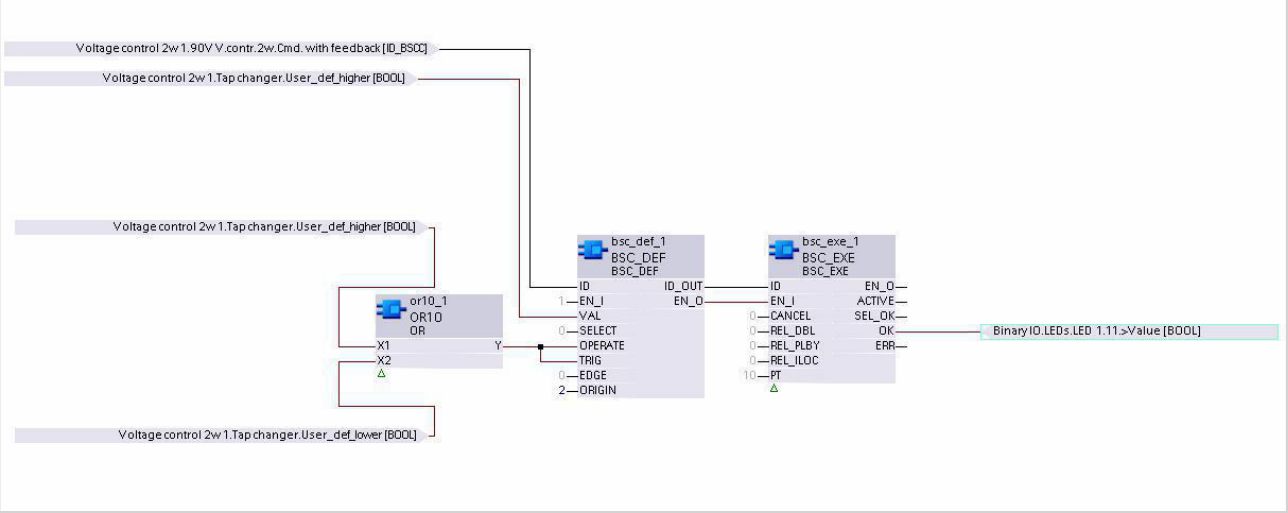

Figure 7-101 CFC Chart

Pressing the function keys to step up or down incrementally can be displayed using this simple CFC chart.

Motor Supervision Time

The runtime of the motor-drive mechanism can be monitored from the device. This function is used to identify failures of the motor-drive mechanism during the switching procedure and to trip actions if necessary. To use the **`Motor supervision time`**, you must route the motor sliding contact (most significant binary input) and set the proper motor runtime.

The motor sliding contact is active until the tap changer has reached the new position. This time is compared to the **`Motor supervision time`**. If the new tap position is not reached within the motor runtime, the *`Motor sup. time expired`* indication is set. The *`Trigger motor prot. sw.`* indication with which the motor can be switched off is output for a duration of 1.5 s.

Adjusting-Command Supervision

Adjusting-command supervision is used for checking the proper operation of the tap-changer mechanism. The **Tap changer** function calculates the next logical tap position as a result of the higher/lower tap command. The time of position detection is determined as a function of the availability of the motor sliding contact. After resetting the active motor sliding contact, the **Tap changer** function reads the new tap position value. If the value for the calculated tap position could not be received within the parameterized time **`Motor supervision time`**, the error message *`Position failure`* is output.

The following position errors of the tap changer are taken into consideration during this:

- Invalid tap position: The tap position is outside the predefined range of **`minimum value`** and **`maximum value`**
- Adjusting command in the wrong direction (for example, if a higher tap was commanded and the tap changer responds with a lower position and vice versa)
- No operation of the tap changer (for example, if the tap-changer motor is defective or the position indication is not functioning)
- Illogical tap-change operation (for example, if no logical tap position following the previous position is indicated)

The value of 0 during an unexpected interruption of the auxiliary voltage represents a special case. An invalid tap-changer position without a corresponding adjusting command is signaled in the **Position** controllable only as an invalid tap position.

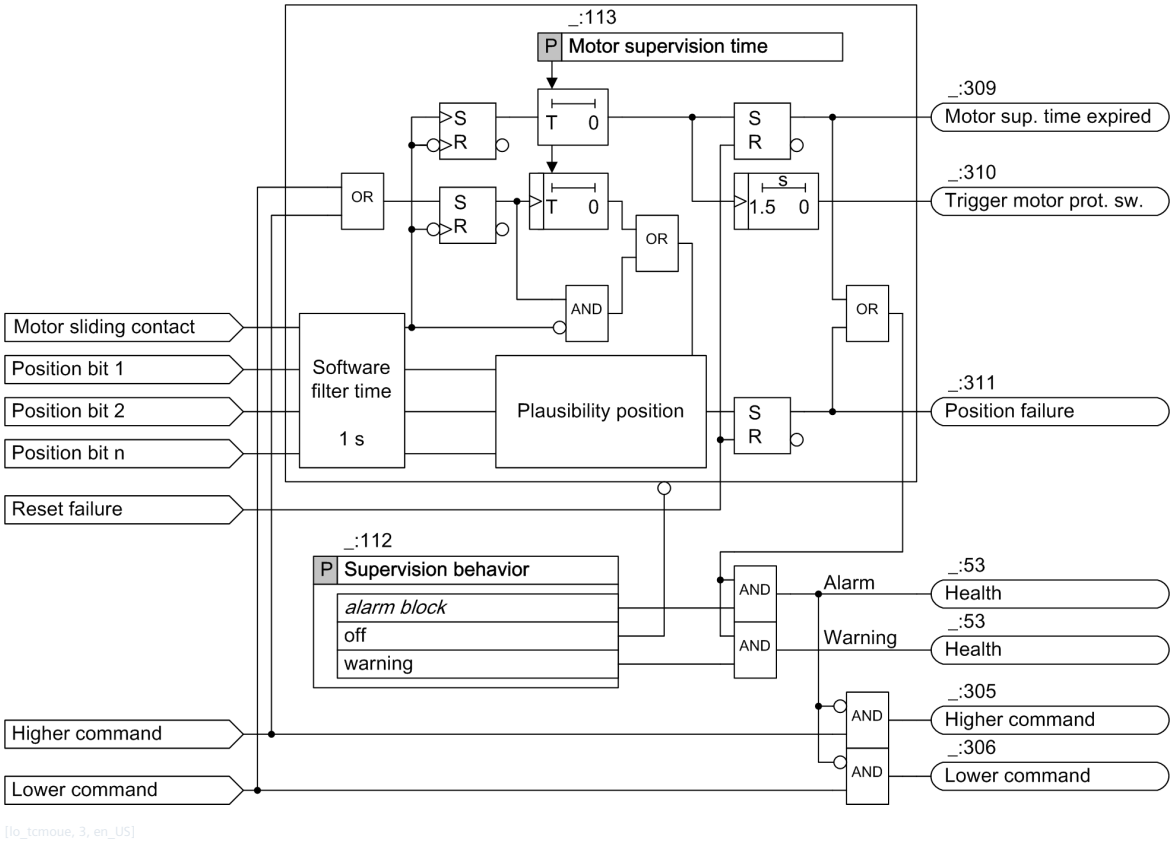

Figure 7-102 Position and Motor Supervision Logic

The user-defined signals **Higher command** and **Lower command** are provided via a CFC chart (refer to *7.8.1 Function Description*).

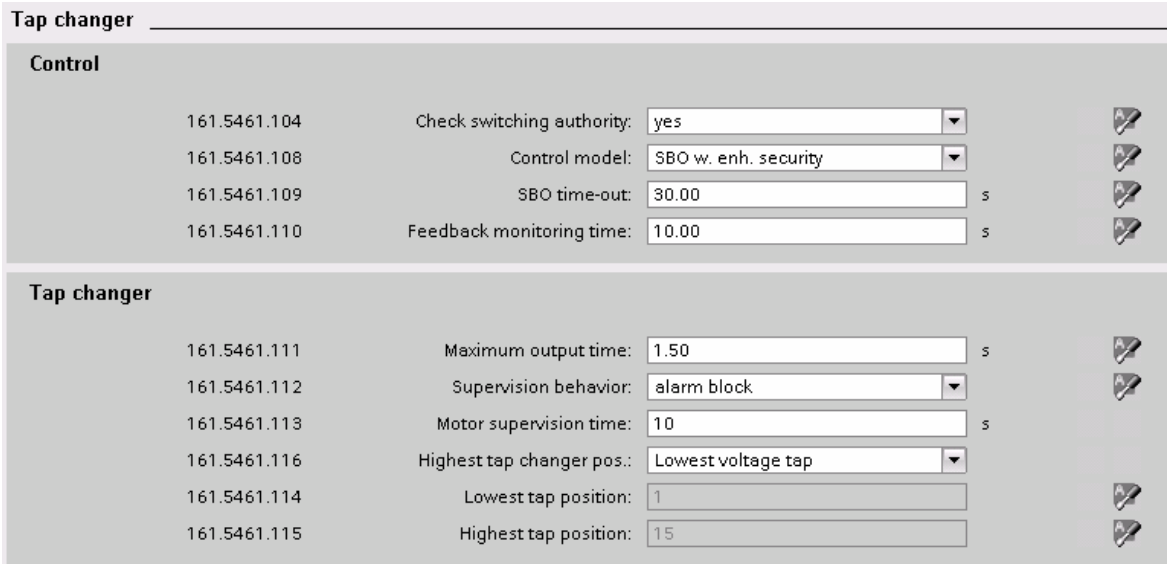
Supervision Behavior

Depending on the setting of the **Supervision behavior** parameter, the function reaches a health state of **Alarm** or **Warning**. You can set the parameter **Supervision behavior** to ***off***, ***alarm block*** or ***warning***.

In the ***alarm block*** mode, the function is set to the health state **Alarm**. All tap-changer commands are blocked.

In the ***warning*** mode, the function is set to the health state **Warning**. Executing tap-changer commands is still possible.

You can manually reset the health state of ***alarm block*** or ***warning*** using the controllable **Reset errors** (Main menu → Device functions → Reset functions → Tap changer). As an alternative to this, you can also switch off the supervision function and then switch it on again.



Operating Counter

The device counts the number of successfully completed adjusting commands with the *Op.Ct.* switching cycle counting value. The counting and memory levels are protected against an auxiliary-voltage failure. The switching cycle counting value can be set to 0 or to any other starting value.

You can access the statistical values via the operation panel on the device (measured values/statistics), via DIGSI, or using various communication protocols.

7.8.2 Application and Setting Notes

Parameters of the Tap Changer Function Group

[scstuslt-100713-01.tif, 2, en_US]

Figure 7-103 Parameters of the Tap Changer

NOTE

If run positions, this means internal tap changer positions without voltage changes, are available, the following must be observed:

If these tap changer positions contain a suffix a and c or + and -, and additional switching pulses are not required, adjust the parameter for the feedback and motor supervision time to the actual motor runtime when passing through a run position. Siemens recommends parameterization with capturing of the motor sliding contact.

Parameter: `Check switching authority`

- Default setting **`(_:104) Check switching authority`** = ***`yes`***

With the **`Check switching authority`** parameter, you specify whether the switching authority (on site, remote) is checked in the case of an adjusting command (see also chapter *7.4.1 Command Checks and Switchgear Interlocking Protection*).

Parameter: `Control model`

- Default setting **`(_:108) Control model`** = ***`SBO w. enh. security`***

Use the **`Control model`** parameter to specify the control model according to IEC 61850-7-2. The following selection options are available:

- ***`direct w. normal secur.`***
- ***`SBO w. normal secur.`***
- ***`direct w. enh. security`***
- ***`SBO w. enh. security`***
- ***`status only`***

Parameter: SBO time-out

- Default setting **(_:109) SBO time-out** = ***30 s***

With this setting, you specify the time for detecting the time-out of the SBO command. The range of values extends from 0.01 s to 1800.00 s. This is the time that can elapse between command acceptance and command execution (command model as per IEC 61850-7-2).

Parameter: Feedback monitoring time

- Default setting **(_:110) Feedback monitoring time** = ***10 s***

Reaching a new tap position after the switching command is monitored. If a new tap position is not reached, you specify with this setting the time when the command is canceled. The range of values extends from 0.01 s to 1800.00 s.

Parameter: Maximum output time

- Default setting **(_:111) Maximum output time** = ***1.50 s***

This parameter specifies the maximum output time. The range of values extends from 0.01 s to 1800.00 s. For activating motors to change the tap position, a time of 1.50 s is practical.

Parameter: Supervision behavior

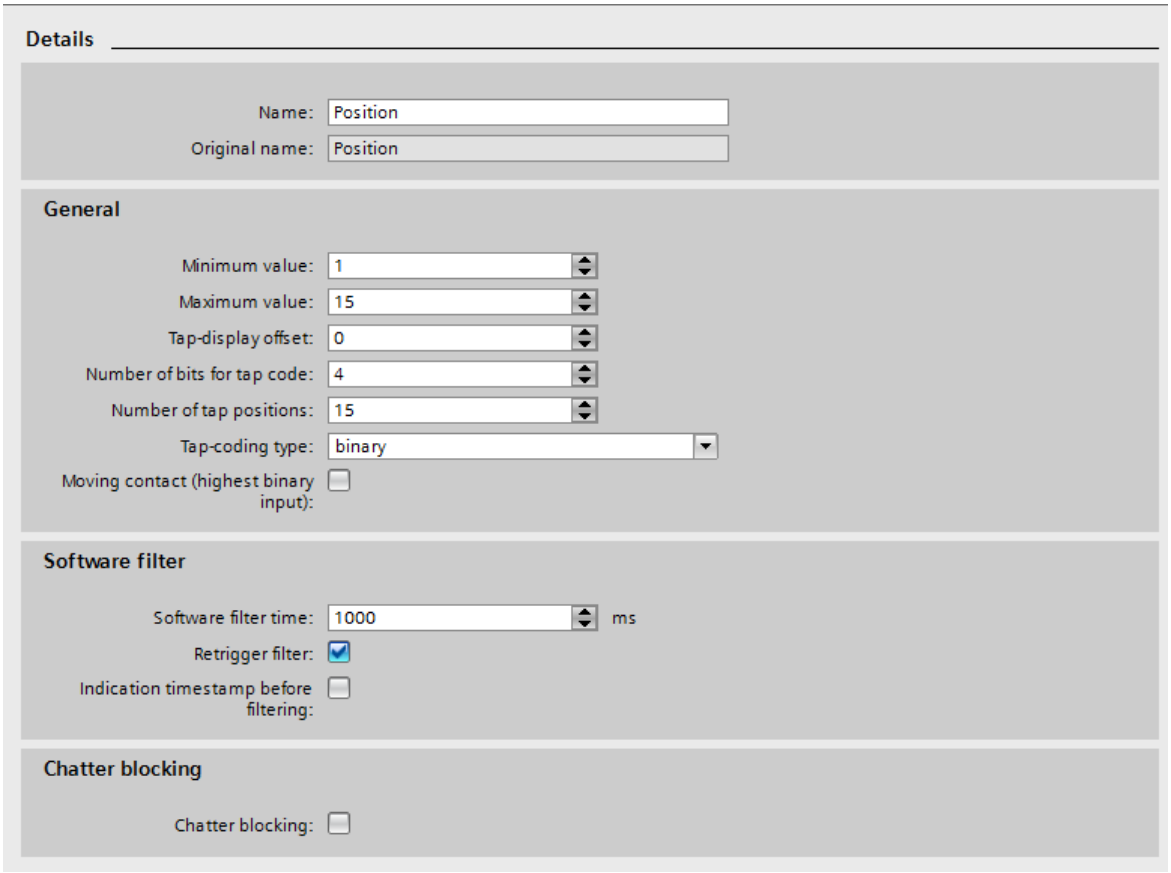
- Default setting **(_:112) Supervision behavior** = ***alarm block***

You can select whether the supervision is switched off (***off***) or if only a warning is indicated (***warning***). With the ***alarm block*** setting, an alarm indication is generated and the function is blocked.

Parameter: Motor supervision time

- Default setting **(_:113) Motor supervision time** = ***10 s***

After the motor supervision time has elapsed, the indication *Motor sup. time expired* is displayed. You can find additional information in *7.8.1 Function Description*. The range of values extends from 5 s to 100 s.



Parameter: Highest tap changer pos.

- Default setting **(_:116) Highest tap changer pos.** = ***Lowest voltage tap***

With the **Highest tap changer pos.** parameter, you specify whether the lowest or highest voltage is present at the highest tap changer position.

Additional Settings (Properties Dialog Position)

Additional settings are assigned to the controllable *Position*. To display and adjust the settings, select *Position* in the DIGSI information matrix and select the Properties dialog. To do this, click the **Properties** tab.

[sc_deegts, 1, en_US]

Figure 7-104 Properties Dialog

Parameter: `Minimum value`

- Default setting **`Minimum value`** = ***1***

Parameter: `Maximum value`

- Default setting **`Maximum value`** = ***15***

The parameters **`Minimum value`** and **`Maximum value`** are initially calculated by DIGSI 5 on the basis of the tap coding, the **`Number of tap positions`** and the **`Tap-display offset`**. They represent the allowed control area of the position value. Positions outside this area are defined as invalid. This control area can be further restricted within the initially set physical range (see **`Number of tap positions`** and **`Tap-display offset`**).

Parameter: `Tap-display offset`

- Default setting **`Tap-display offset`** = ***0***

If you want to move the height of the displayed value in a positive or the negative direction with respect to the height of the actual value, enter the value for this in the **`Tap-display offset`** field.

Parameter: `Number of bits f. tap code`

- Default setting **`Number of bits f. tap code`** = ***4***

With the **`Number of bits f. tap code`** parameter, you set the number of bits you need for encoding the transformer taps. The number is dependent on the selected **Encoding** and on the **Moving contact**. For example, you need 3 bits for 7 binary-encoded transformer taps. The range of values extends from 2 to 32.

Parameter: `Number of tap positions`

- Default setting **`Number of tap positions`** = ***`15`***

With the **`Number of tap positions`** parameter, you set the number of transformer taps. The range of values extends from 2 to 127. The output of the tap position is limited from -63 to +63. If the number of taps is > 63, set the **`Tap-display offset`** parameter so that the output of the tap position is within the range of -63 to +63.

Parameter: `Tap-coding type`

- Default setting **`Tap-coding type`** = ***`binary`***

In the **`Tap-coding type`** list box, select the interpretation type of the indication pending at the binary input.
You can select from the following options:

- ***`binary`***
- ***`1-of-n`***
- ***`BCD`***
- ***`table`***
- ***`BCD signed`***
- ***`gray`***

The tap changer position can also be routed via a GOOSE signal (BSC) or a 20-mA measuring transducer input.
You can find more information on this in the document **Measuring the transformer tap changer using an analog measuring transducer input in SIPROTEC 5** in the Download area under *`SIPROTEC 5 and DIGSI 5 downloads`* → *`SIPROTEC 5 General`* → *`Application Notes`* → *`Control`*.
A selection of tap-coding types is described in greater detail using examples in the following text.

Routing of the Binary Inputs (Tap-Coding Type binary)

The following table shows the routing of 3 binary inputs (BI 1 to BI 3) with 4 transformer tap positions designated 3 to 6. BI4 is the moving contact. The encoding is in ***`binary`***.

Table 7-27 Routing of the Binary Inputs (Tap-Coding Type binary)

	Example					
	BI1	BI2	BI3	BI4	BI5	BI6
Tap changer	X	X	X	X	–	–
Meaning	Bit 1	Bit 2	Bit 3	Moving contact	–	–
Tap = 1	1	0	0		–	–

With 3 binary inputs, a maximum of 2^3 -1 = 7 tap positions can be mapped in binary code. If all routed binary inputs indicate 0, this is interpreted as a connection error and is reported by Position **---** or **-64** with quality **invalid**. The representation of transformer taps should start with the metered value 3. You must configure the information properties as follows for the example:

Tap-coding type:	binary
Number of tap positions:	7
Number of bits f. tap code:	4
Tap-display offset:	2
Moving contact (highest binary input):	Yes

The 3 binary inputs must be numbered sequentially, for example, BI 1, BI 2, BI 3, and BI 4 for the moving contact.

Routing of the Binary Inputs (Tap-Coding Type BCD)

The following table shows the routing of 6 binary inputs (BI 1 to BI 6) with 39 transformer tap positions designated 1 to 39. The encoding is in ***BCD***. BI 7 is the moving contact.

Table 7-28 Routing of the Binary Inputs (Tap-Coding Type BCD)

	Example						
	BI1	BI2	BI3	BI4	BI5	BI6	BI7
Tap changer	X	X	X	X	X	X	X
Meaning	BCD 1	BCD 2	BCD 4	BCD 8	BCD 10	BCD 20	Moving contact
Tap = 21	1	0	0	0	0	1	–

With 6 binary inputs, a maximum of 39 tap positions can be mapped with the tap-coding type of BCD. This yields the number of tap positions from 1 to 39. If all routed binary inputs indicate 0, this is detected as tap 0. The 7 binary inputs must be numbered sequentially, for example, BI 1, BI 2, BI 3, BI 4, BI 5, BI 6, and BI 7 for the moving contact.

Tap-coding type:	BCD
Number of tap positions:	39
Number of bits f. tap code:	7
Tap-display offset:	0
Moving contact (highest binary input):	Yes

Individual Tap-Coding Type (table)

With the ***table*** parameter setting, you can specify an individual **Tap-coding type**.

In the **Representation of encoding** section, select the number system in which your code table entries will take place, alternatively:

- ***Binary (2 characters)***
- ***Octal (8 characters)***
- ***Decimal (10 characters)***
- ***Hexadecimal (16 characters)***

The selected option is valid for all inputs in the **Encoding** column.

If you change the number system and there are already entries in this column, these will be converted to the new number system. The selection area becomes visible as soon as you have selected the setting ***table*** in the **Tap-coding type** list box.

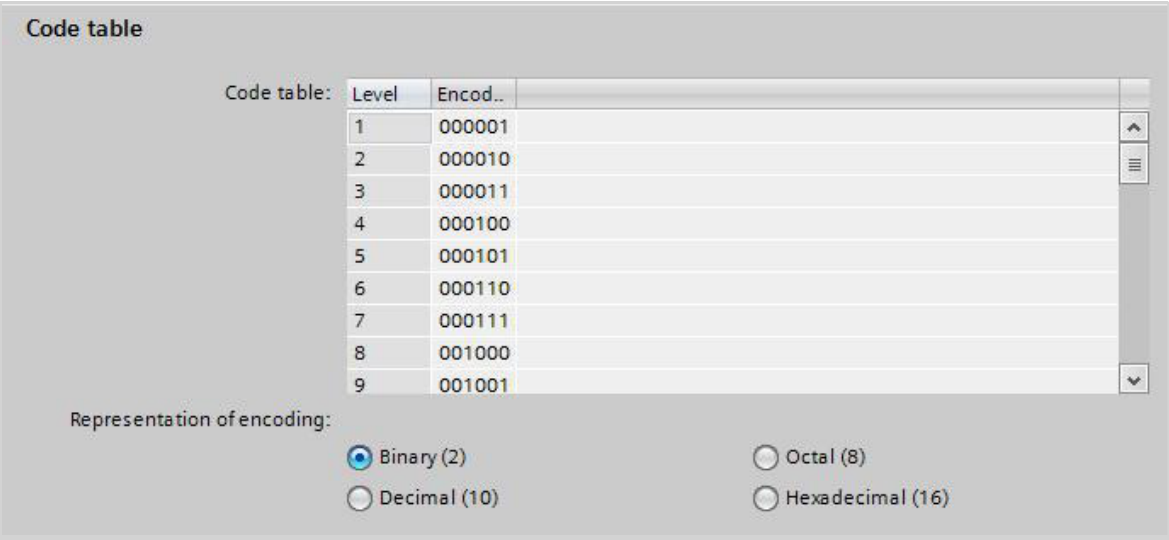


Figure 7-105 Code Table for the Tap-Coding Type table

NOTE

If the binary inputs used for encoding are all inactive, this indicates an invalid tap position (regardless of the display offset). For an invalid tap position, the display shows the position **---** or **-64** with quality **invalid**, exception BCD signed, see *Routing of the Binary Inputs (Tap-Coding Type BCD signed), Page 1954*.

Enter the encoding for the tap in the **Encoding** column in the **Code table**. Enter the value according to the number system previously selected. Select the desired number of taps and number of bits for tap coding. Taps with the same encoding and taps with 0 coding are not permitted.

Routing of the Binary Inputs (Tap-Coding Type BCD signed)

The following table shows the routing of 3 binary inputs (BI 1 to BI -3) with 7 transformer tap positions designated 3 to 3. The encoding uses ***BCD signed***.

Table 7-29 Routing of the Binary Inputs (Tap-Coding Type BCD signed)

	Example					
	BI1	BI2	BI3	BI4	BI5	BI6
Tap changer	X	X	X	–	–	–
Meaning	BCD 1	BCD 2	Sign	–	–	–
Tap = 1	1	0	1	–	–	–

Using 3 binary inputs, a maximum of 7 tap positions can be mapped with the tap coding type of BCD signed. This yields the number of tap positions from -3 to 3. If all routed binary inputs indicate 0, this is recognized as tap 0. The 3 binary inputs must be numbered sequentially.

Tap-coding type:	BCD signed
Number of tap positions:	7
Number of bits f. tap code:	3
Tap-display offset:	0
Moving contact (highest binary input):	No

Routing the Tap Position to Binary Outputs

For the output of the adjusting commands, route the information **step up** and **step down** on one relay each, see following figure.

Information			Source														Destination		
			Binary input											Function keys	CFC		Binary output		
			Base module											Base module			Base module		
Signals	Number	Type	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8	2.1	2.2	2.3				1.1	1.2	1.3

[sc_trass7, 1, en_US]

Figure 7-106 Routing the Tap Setting Commands

Parameter: `Moving contact (highest binary input)`

- Default setting **`Moving contact (highest binary input)`** = ***no***

If the tap position is only to be recognized as valid and implemented when the motor sliding contact signals that it has reached the taps, then activate the **`Moving contact (highest binary input)`** option. If this parameter is set, the new position is only labeled with an ***** when the moving contact drops out.

Parameter: `Software filter time`

- Default setting **`Software filter time`** = ***1000 ms***

With this parameter, you set the **`Software filter time`** for capturing the tap position. The range of values extends from 0 ms to 100 000 ms. Within this time, brief changes on the binary inputs are suppressed.

Parameter: `Retrigger filter`

- Default setting **`Retrigger filter`** = ***Yes***

With this parameter, you switch retriggering of the filtering time by a position change on or off.

Parameter: `Indication timestamp before filtering`

- Default setting **`Indication timestamp before filtering`** = ***no***

With this parameter, you specify whether the hardware filtering time is accounted for in the time stamp of position capture.

Parameter: `Chatter blocking`

- Default setting **`Chatter blocking`** = ***no***

With this parameter, you switch **`Chatter blocking`** on or off.

7.8.3 Settings (Properties Dialog)

The settings listed here can only be reached and changed by way of the **Properties** dialog of the **Position** Controllable.

Addr.	Parameter	C	Range of Values	Default Setting
General Information				
-	Minimum value		Calculated	-
-	Maximum value		Calculated	-
-	Tap-display offset		–63 to +63	0
-	Number of bits f. tap code		2 to 32	4
-	Number of tap positions		2 to 63	15
-	Tap-coding type		• binary • 1-of-n • BCD • table • BCD signed • gray	binary
Software filter				
-	Software filter time		0 ms to 100 000 ms	1000 ms

NOTE

7.9 Voltage Controller

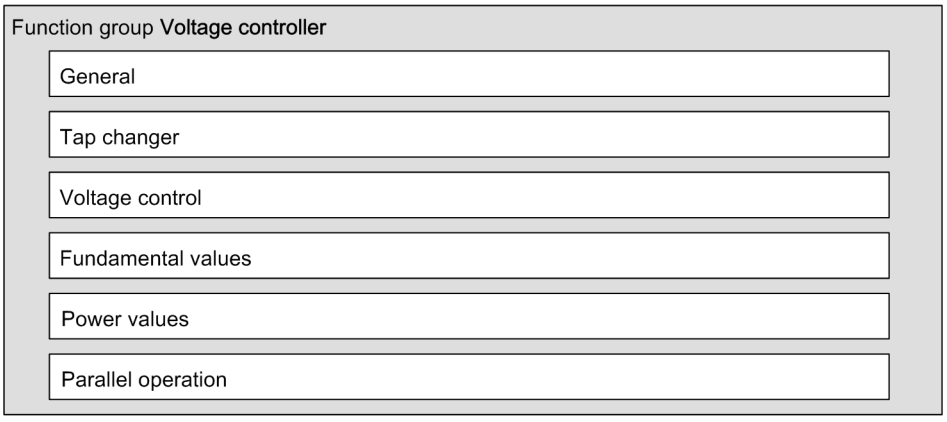
7.9.1 Overview of Functions

The transformer voltage controller functionality (ANSI 90V) is used to control power transformers (two-winding transformers, three-winding transformers, grid coupling transformers) and auto transformers using a motor-operated tap changer. In addition, the voltage control can be used for two-winding transformers connected in parallel.

The function provides automatic voltage control within a specified voltage range on the secondary side of the transformers or, as an alternative, at a remote load point (Z compensation or R/X compensation) in the network. In order to compensate for the voltage variations in the meshed system, use the ***LDC-Z*** procedure (Z compensation). For voltage drops on the line, use the ***LDC-XandR*** procedure (R/X compensation).

The control principle is based on the fact that a higher or lower adjusting command to the tap changer, as a function of the voltage change (ΔV) per tap, causes a voltage increase or decrease.

The voltage control operates on a tap-for-tap basis and compares the measured actual voltage (Vact) with the specified target voltage (Vtarget). If the voltage difference is greater than the set bandwidth (B), a higher or lower adjusting command is sent to the tap changer once the set time delay (T1) has elapsed. Specifying the time delay (T1) depends on the set controller response (inverse or linear), so as to avoid unnecessary adjusting commands during brief voltage deviations from the target value and for coordination with other automatic voltage controllers in the system.



The voltage controller function also monitors the currents on the upper-voltage side and the low-voltage side of the transformer to block the voltage controller during impermissible operating states (overcurrent/under-current/undervoltage). The voltage controller function also has limiting values that, in special operating cases, suppress higher adjusting commands in the case of overvoltage and lower adjusting commands in the case of undervoltage.

You can also use the voltage controller function for parallel control of up to 8 two-winding transformers in different groups. You can carry out parallel control based on the Master-Follower method or using circulating reactive current minimization method. You can find more detailed information about parallel control in *7.9.3.9 Parallel Operation*.

7.9.2 Structure of the Function

The **Two-winding transformer voltage controller**, **Three-winding transformer voltage controller**, and **Grid coupling transformer voltage controller** function groups consist of 5 function blocks. Depending on the application, the function groups are preconfigured in the relevant application template by the manufacturer or can be copied into the corresponding device project during engineering.

The following figure shows, for example, the functional scope of the **Two-winding transformer voltage controller** function group.

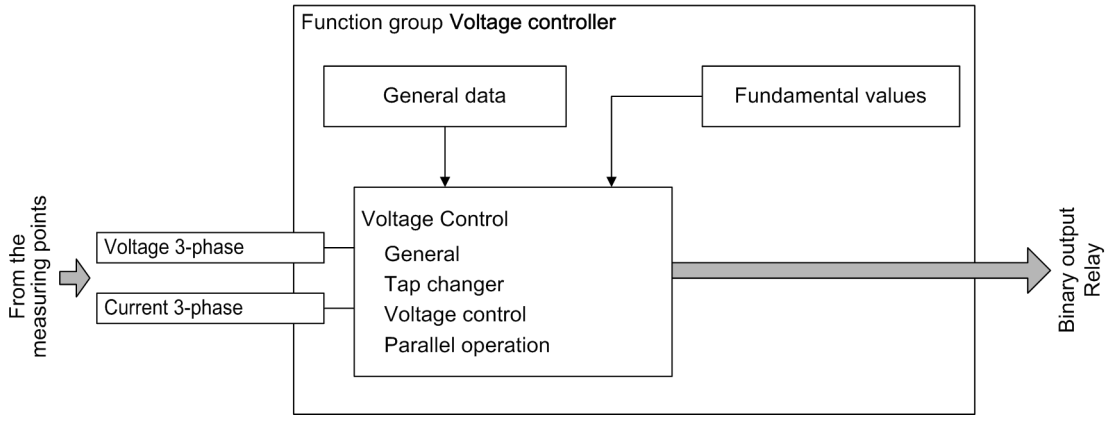
[dwvolctl-060913-01.vsd, 3, en_US]

Figure 7-107 Structure/Embedding of the Function Group

The functions **General** (GAPC), **Tap changer** (YLTC), and **Voltage controller** (ATCC) are logical node points in IEC 61850-8-1.

The tap changer (YLTC) is the interface between the voltage controller (ATCC) and the motor-operated tap changer of the transformer (OLTC). This means that the voltage controller (ATCC) sends higher and lower adjusting commands to the tap changer. This tap changer issues command pulses to the motor-operated tap changer of the transformer (OLTC). The tap changer (YLTC) measures the tap positions and monitors the action of the motor-operated tap changer (OLTC).

The **Parallel control** function is needed for the parallel operation of 2 to 8 transformers. The **Parallel control** function can only be instantiated in the **Voltage controller** function group.



The function group has interfaces to the following measuring points:

- **Two-winding transformer**:
  - Voltage, 3-phase
  - Current, 3-phase (optional)
- **Three-winding transformer**:
  - 2 x voltage, 3-phase
  - 2 x current, 3-phase (optional)
- **Grid coupling transformer**:
  - 2 x voltage, 3-phase
  - 2 x current, 3-phase

Optionally, you can assign the tap changer to a **Transformer side** function group. In this way, the current of the upper-voltage side is also monitored and the differential protection pickup blocks the voltage controller automatically.

The **Voltage controller (ATCC)** function group operates only with a 3-phase voltage connection and uses the positive-sequence voltage as control variable. Due to power-system unbalances, the positive-sequence voltage provides a more stable value. For version 8.01 and higher, you can select the control variable, depending on the connection type, via a selection parameter in the **Voltage controller** function group.

Figure 7-108 shows these interfaces as a block structure.

[dwvocnti-060913-01.vsd, 3, en_US]

Figure 7-108 Structure of the Voltage Control Function Group

You can find the information and functional measured values of the voltage controller in the DIGSI routing matrix.

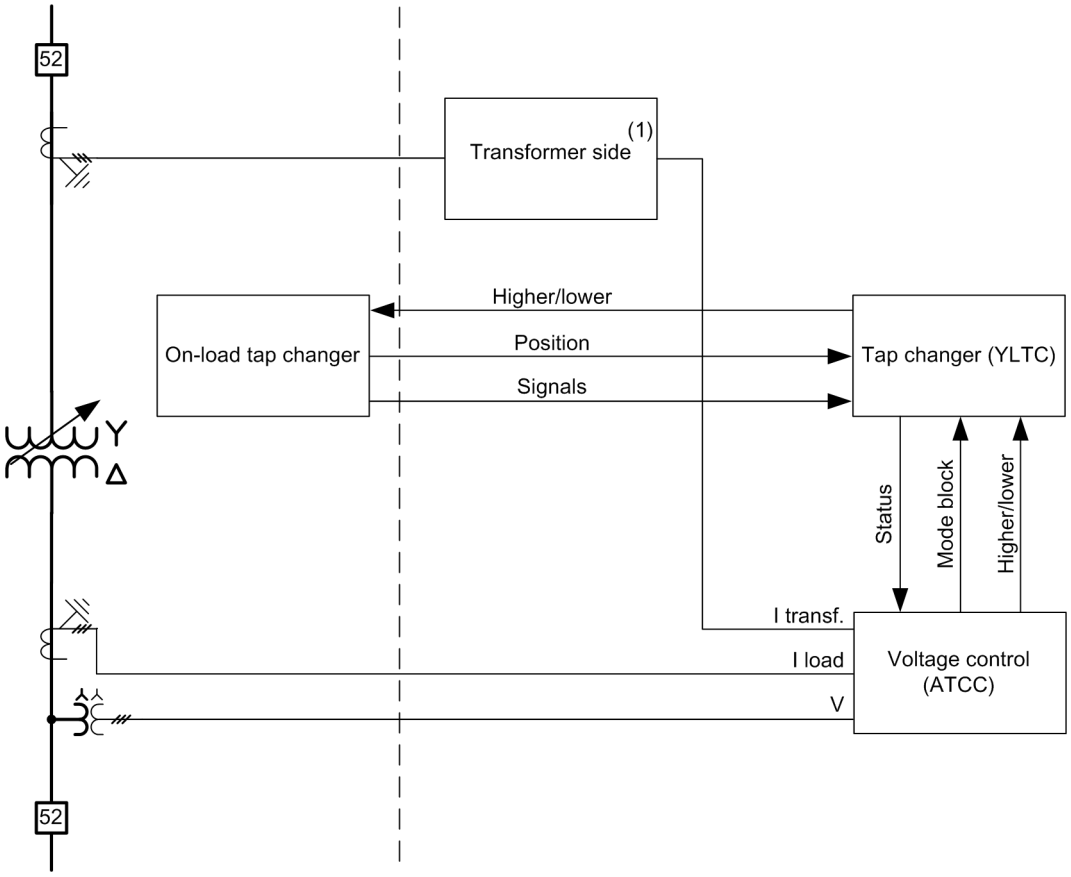
7.9.3 Function Description

7.9.3.1 General

If the load is increased in an electricity-supply system, the voltage is reduced and vice versa. The power transformers are usually equipped with transformer tap changers (OLTC) so as to keep the power-system voltage at a constant level.

As a result, the transformer ratio is changed in predefined steps. Changes to the transformer taps cause the voltage to change.

The Voltage control function is intended to control transformers with motor-operated transformer tap changers.

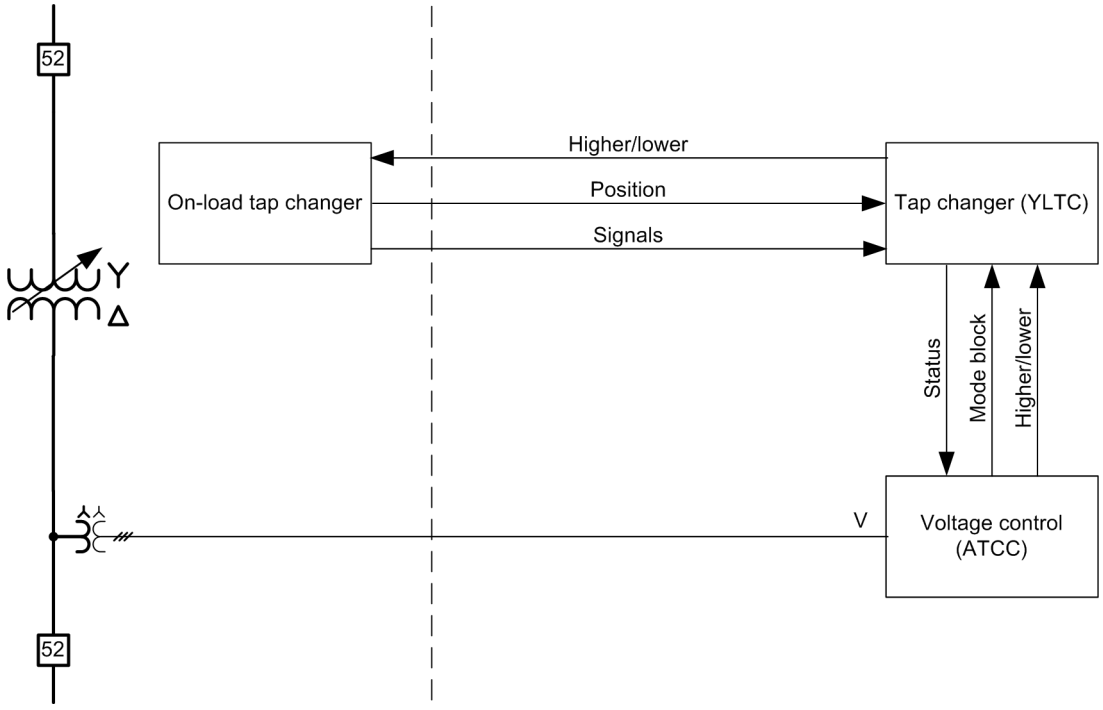


This function is designed to control the following:

- For two-winding transformers (2W): the voltage on the secondary circuit of the power transformer and parallel control of several transformers feeding the same busbar or a nodal point of a system
- For three-winding transformers (3W): the voltage of the secondary winding 1 or winding 2
- For grid coupling transformers (GC): voltage of winding 1 or winding 2, selectively depending on the power direction

Control operation is based on a step-by-step principle. To move the tap changer one position higher or lower, a single control pulse is issued to the motor-drive mechanism of the tap changer. The length of the control pulse can be set over a large range so as to handle the different types of tap-changer drives. The control pulse is issued if the measured voltage deviates from the set reference value by more than the preset voltage range for more than a given time period.

The voltage can be controlled at the voltage measuring point or at the load point in the electrical power system. In this case, the load-point voltage is calculated on the basis of the measured load current and the known impedance between the voltage measuring point and the load point.



The following figures show possible configurations of the voltage controller for two-winding transformers with and without current measurement.

[dwkonlst-060913.vsd, 1, en_US]

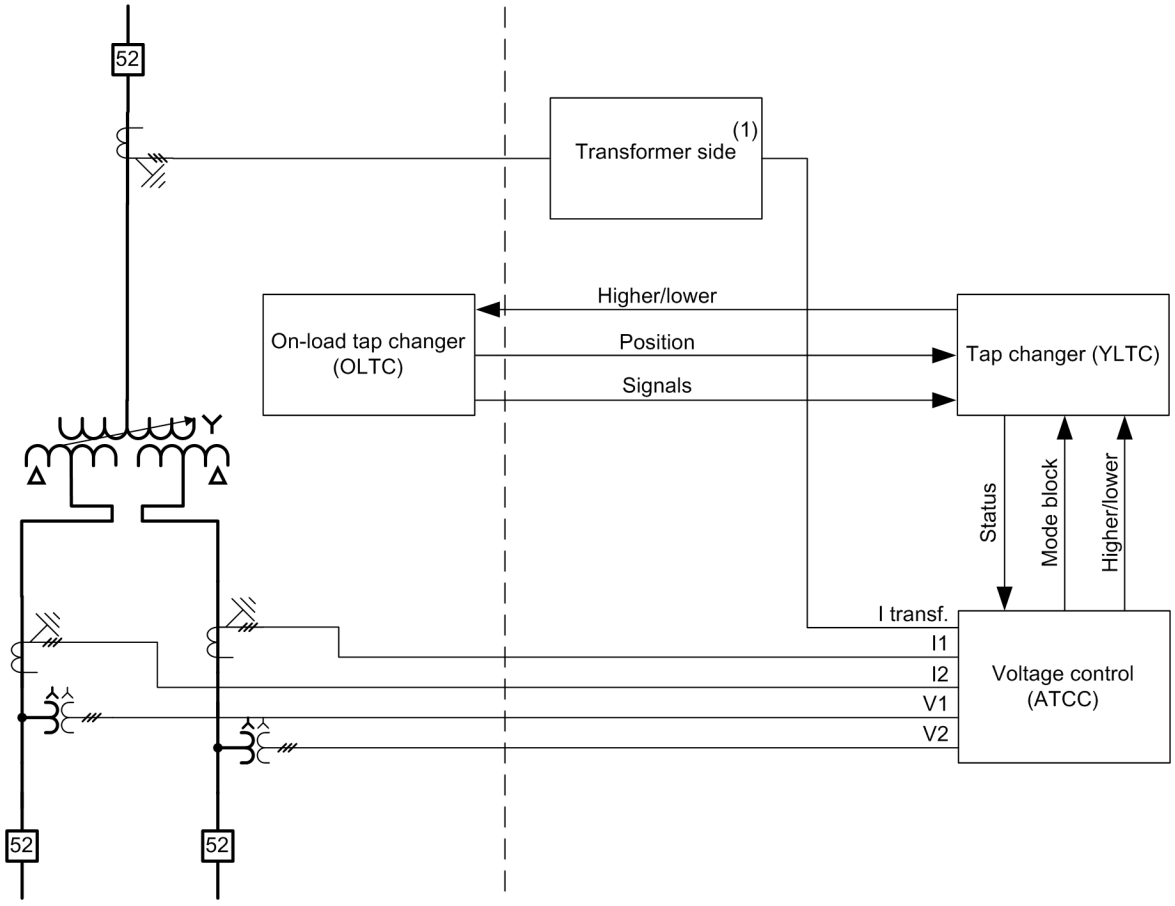
Figure 7-109 Voltage-Controller Constellation for Two-Winding Transformers with Current Measurement for Load Compensation at the End of the Line

(1) Only if a transformer side is present

[dwkonlsK-060913.vsd, 1, en_US]

Figure 7-110 Voltage-Controller Constellation for Two-Winding Transformers without Current Measurement

Three-Winding Transformers



Three-winding transformers are special power transformers that have 2 separate windings on the secondary circuit and typically supply 2 different busbars. The voltage levels on the secondary circuit of the power transformers can either be the same or different. In addition to designs with 2 tap changers on the secondary circuits, in most cases, three-winding transformers are equipped with only one tap changer or on-load tap changer on the primary side. It is therefore necessary to feed both voltages of the secondary windings to the voltage measuring inputs (V1, V2) and to specify one of them, depending on the busbar situation, to the voltage controller as the control variable.

The voltages of side 1 and 2 of the three-winding transformer are simultaneously monitored. In the process, the voltage to be controlled can be automatically selected via the load current of both sides or by using one parameter. This parameter is the settings group switching via binary input, protocol, or function keys. The uncontrolled voltage can be monitored in parallel to ensure that it remains within the defined voltage limits.

If a current measuring point is assigned to a function group, the voltage to be controlled can be automatically selected dependent on the load.

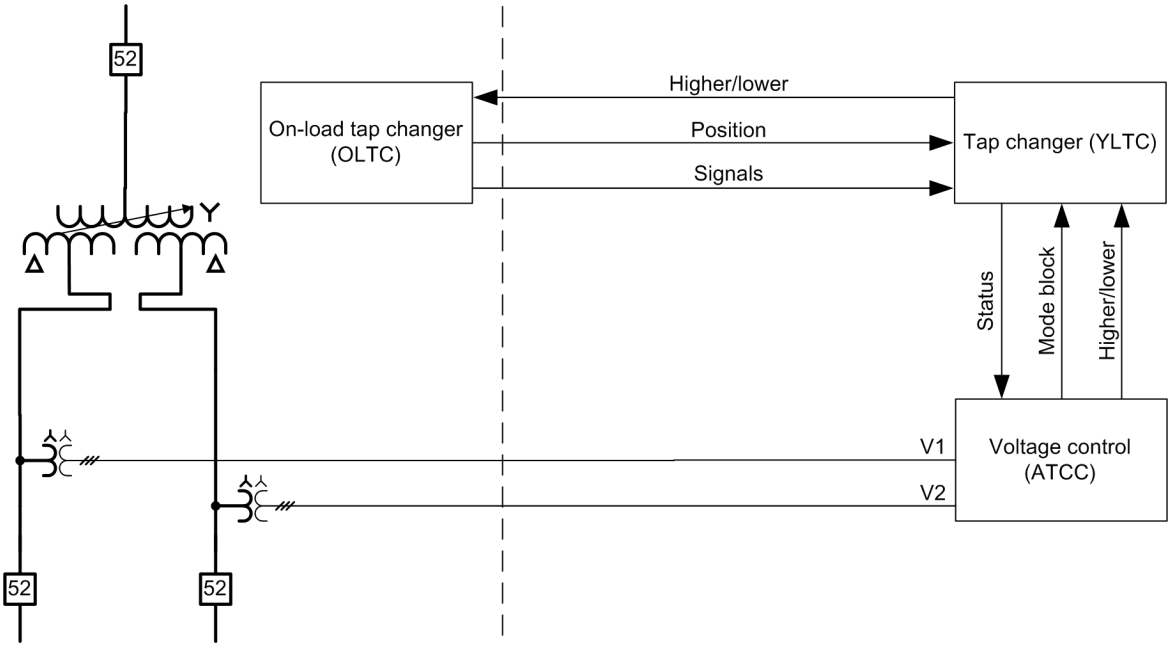
For automatic on-load tap changing, the voltage of the transformer side into which the larger load current flows is controlled. The respective uncontrolled voltage is monitored for undervoltage and overvoltage.

In contrast to overvoltage on the controlled side, for overvoltage on the uncontrolled side, the higher adjusting command is blocked and no fast step down to a lower tap occurs. In case of undervoltage on the uncontrolled side, the lower adjusting commands are blocked if this behavior is activated for undervoltage supervision.

[dw_V-constell-3wind-with-imeas.vsd, 2, en_US]

Figure 7-111 Voltage-Controller Constellation for Three-Winding Transformers with Current Measurement for Load Compensation at the End of the Line

(1) Only if a transformer side is available



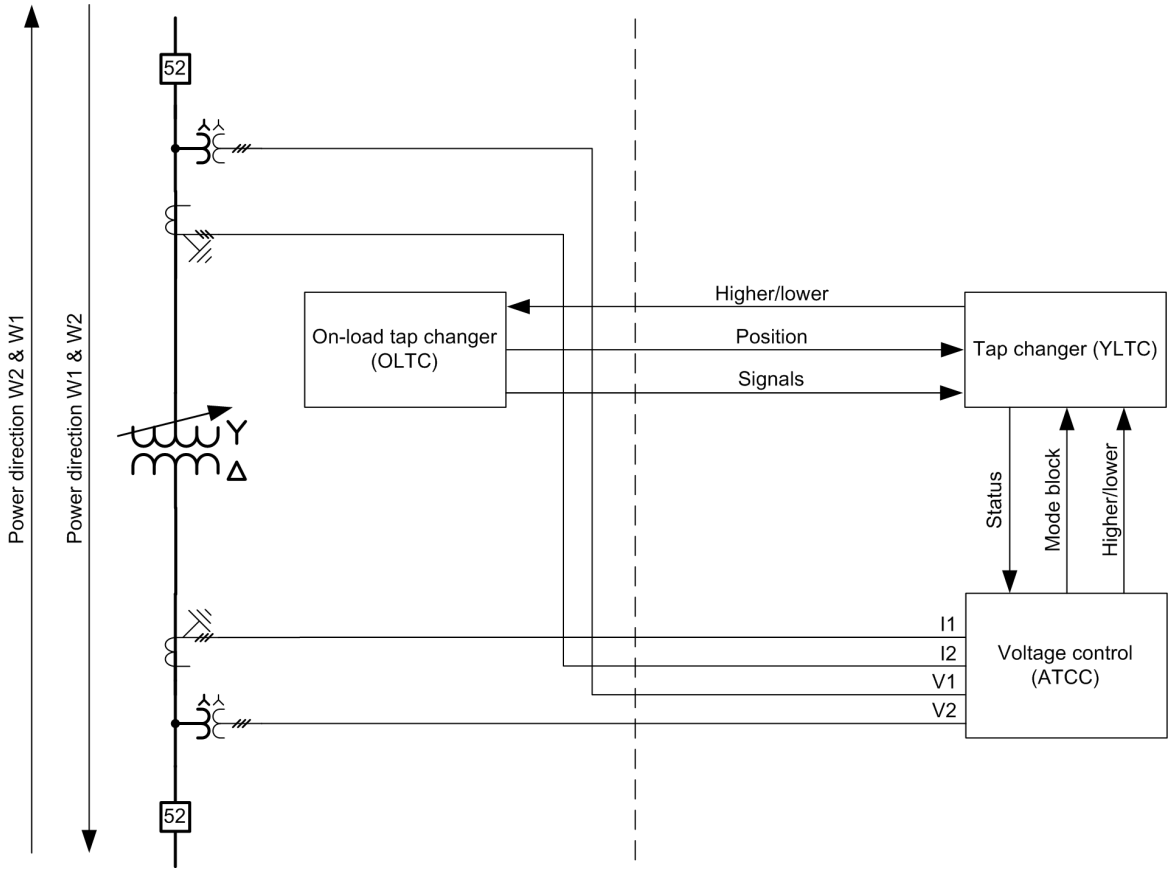


Figure 7-112 Voltage-Controller Constellation for Three-Winding Transformers without Current Measurement

Grid Coupling Transformers

Grid coupling transformers are special power transformers that connect 2 electrical power systems to one another. The load-side voltage is controlled. The power flow can change during operation. That is why both voltages and currents, winding 1 and winding 2, voltage measuring inputs (V1, V2) and current measuring inputs (I1 and I2) must be fed. A voltage must be specified as a function of the load situation to the voltage controller as the control variable.

The voltages of the windings 1 and 2 of the grid coupling transformers are simultaneously monitored. In the process, you can select the voltage to be controlled using one parameter. This parameter can be changed using the settings group switching via the binary input, protocol, or function keys.

[dw_V-constell-2wind-coupl-transf.vsd, 1, en_US]

Figure 7-113 Voltage-Controller Constellation for Grid Coupling Transformers

On-Load Tap Changer

On-load tap changers are used to set the desired tap of a stepped winding of the transformer while under load. During switchover, the desired tap of the stepped winding is first selected by means of the tap selector. Next, the on-load tap changer switches over from the current-carrying tap to the selected tap. During this switchover, one tap of the stepped winding is briefly bridged by an ohmic resistor so that the load switchover takes place without current interruption. Physically, the tap changer is installed in the transformer tank or in a separate tank.

Tap Changer

The **Tap changer** function issues the adjusting commands to the on-load tap changer and receives the corresponding feedback. The function of the tap changer inside the voltage controller corresponds to that of the separate tap changer. The higher and lower adjusting commands are generated by the voltage controller. The **`Check switching authority`**, **`Control model`**, **`SBO time-out`**, and **`Feedback monitoring time`** parameters are set only in the voltage controller.

You can find more information in chapter *7.9.4.1 General*.

Voltage Controller

The Voltage controller function controls the voltage within the bandwidth and within the set voltage limits. Using the **`Mode`** parameter, you can turn the voltage controller on or off or set it for test mode.

With the **`Number of target voltage`** parameter, you can specify up to 4 target voltages. You can only activate one of these target voltages at a time using function key, communication, or a binary input. Use the **`Set point mode active`** parameter to specify a valid target voltage via a communication network.

If the voltage controller is switched off, adjusting commands cannot be given to the tap changer in automatic operation or in manual operation. The set on-site or remote switching authority is independent of this.

You can set the voltage controller operating mode using the **Operating mode** parameter or the **Operating mode** command to automatic operation or manual operation. In automatic operation, the voltage is controlled automatically in accordance with the set parameters.

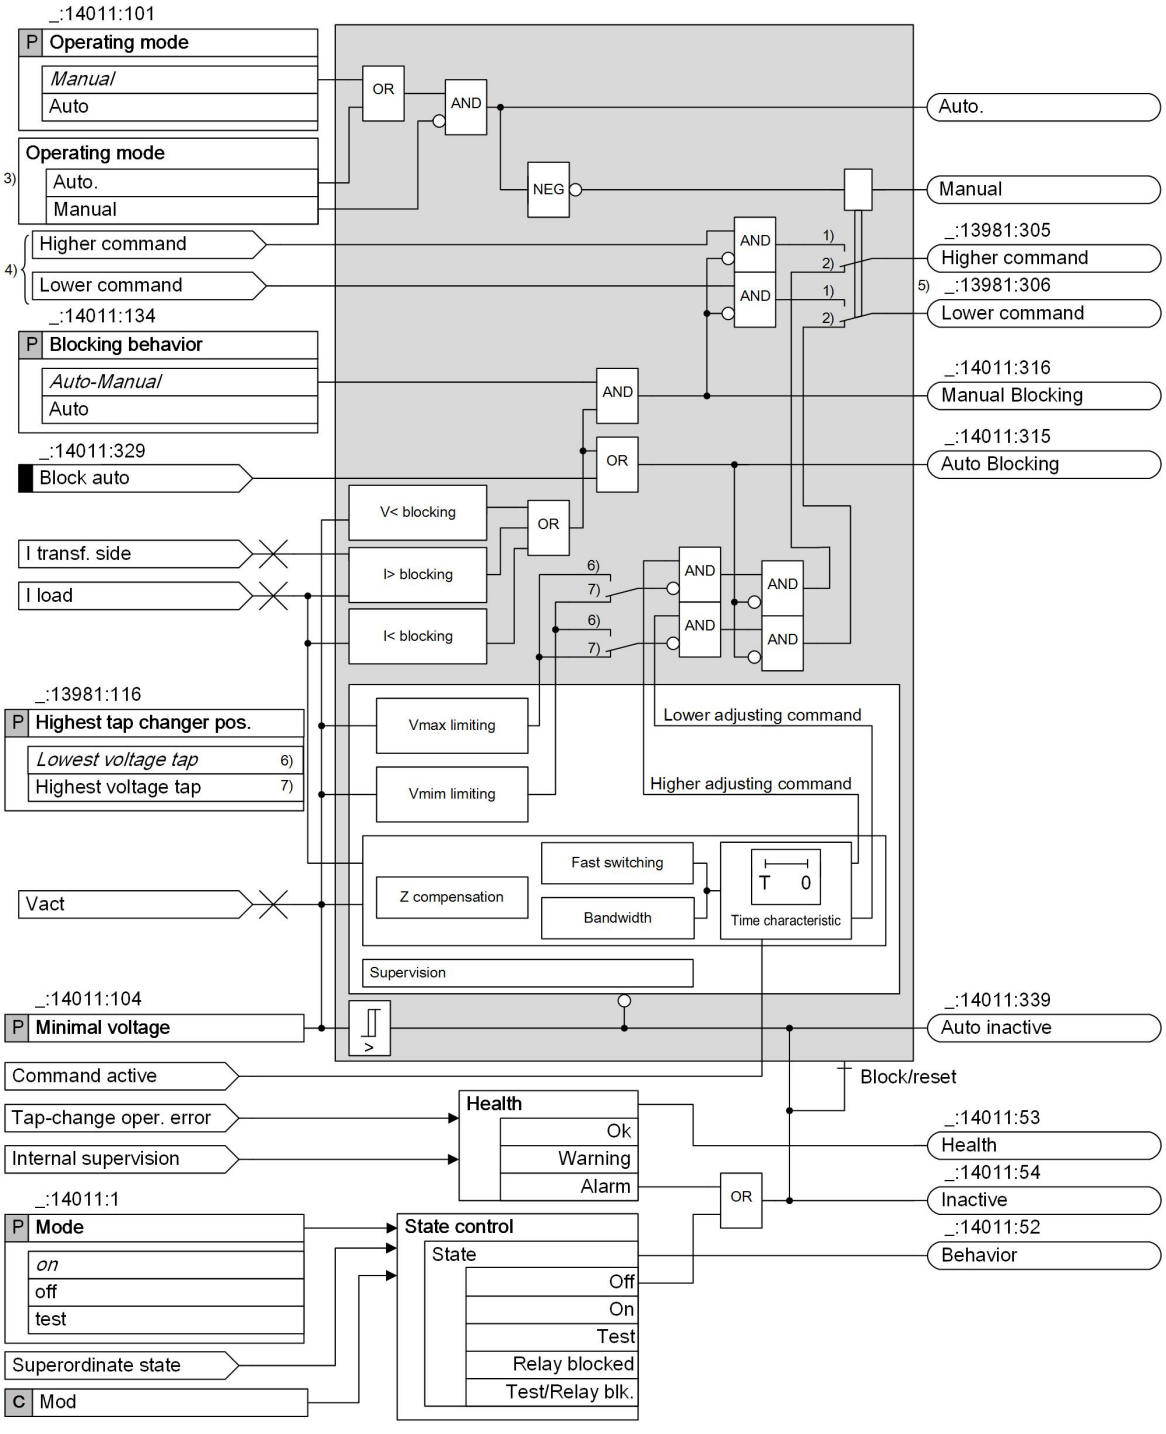
Three-Winding Transformer Voltage Controller

For the two-winding transformer voltage controller, the measurands that are used to manage the feedback control are permanently defined.

With the voltage controller for the three-winding transformer, these measurands can be specified using one parameter (parameter **Winding selection** = ***Winding 1*** or ***Winding 2***) or they can be automatically selected (**Winding selection** = ***WithMaxLoad***).

The winding is automatically selected by evaluating the load current in the windings. If the load current in one of the two windings is greater than the load current in the other winding by 5 % of the rated current for 10 s, then the winding voltage is controlled using the larger load current.

Grid Coupling Transformer Voltage Controller



For the two-winding transformer voltage controller, the measurands that are used to manage the feedback control are permanently defined.

With the grid coupling transformer voltage controller, these measurands can be selected using a parameter (parameter **Winding selection** = ***Winding 1*** or ***Winding 2***).

You can change the winding selection during operation using the settings group switching.

You can monitor the power-flow direction. If the difference in the power of ***Winding 1*** and ***Winding 2*** is greater than 10 % of the rated power on the control side, the indication *Power-flow superv.* appears and the function switches to alarm status.

7.9.3.2 Logic of the Function

[lo_volt-control, 7, en_US]

Figure 7-114 Superordinate Logic of the Voltage Controller

1) Manual operation
2) Automatic operation
3) Controllable
4) Command
5) Position and motor supervision (*7.8.1 Function Description*)

In accordance with the IEC 61850 standard, DOI LTCBlk (**Block automatic operation** command), automatic control can be blocked with a command.

The voltage controller measures the actual voltage (Vact) and compares it to the target voltage (Vtarget). If the difference between the measured voltage (control deviation D) is greater than the set bandwidth (B), a higher or lower adjusting command is sent to the tap changer once the set time delay (T1) has elapsed.

You can change the settings for control during operation with the settings group switching.

You can switchover the settings groups via the following alternatives:

- Via the on-site operation panel directly on the device
- Via an online DIGSI connection to the device
- Via binary inputs
- Via a communication connection to substation automation technology (IEC 60870-5-103, IEC 61850)

You can find more information on this in chapter *3.11.1 Settings-Group Switching*.

Measuring-Voltage Selection

The control measurand can be selected, depending on the connection type, via a selection parameter in the **Voltage controller** function group. The associated current is automatically selected for the set voltage type.

The load voltage calculated for the line compensation is likewise influenced by selection with the **`Measured value`** parameter. The load current (I_{load}) and the voltage to be controlled at the transformer are replaced according to the following table:

$$V_{load}\,[\%] = \sqrt{\left[V_{Bus}\,[\%] - \frac{\sqrt{3}\cdot I_{load}\cdot(R\cos\varphi + X\sin\varphi)}{V_{rated,obj.}}\cdot 100\,\%\right]^2 + \left[\frac{\sqrt{3}\cdot I_{load}\cdot(X\cos\varphi - R\sin\varphi)}{V_{rated,obj.}}\cdot 100\,\%\right]^2}$$

[fo_vload_in_percent, 1, en_US]

	Measured value	Load current	Control voltage	Angle
Connection type	V_1	I_1	$\sqrt{3}\cdot V_1$	$\varphi = \varphi_{V1} - \varphi_{I1}$
Phase-to-ground V_A, V_B, V_C	V_A	I_A	$\sqrt{3}\cdot V_A$	$\varphi = \varphi_{VA} - \varphi_{IA}$
	V_B	I_B	$\sqrt{3}\cdot V_B$	$\varphi = \varphi_{VB} - \varphi_{IB}$
	V_C	I_C	$\sqrt{3}\cdot V_C$	$\varphi = \varphi_{VC} - \varphi_{IC}$
Phase-to-ground V_A, V_B, V_C	$V_{A\text{-}B\ calc}$	I_A	Calculated $V_{A\text{-}B}$	$\varphi = \varphi_{VA} - \varphi_{IA}$
	$V_{B\text{-}C\ calc}$	I_B	Calculated $V_{B\text{-}C}$	$\varphi = \varphi_{VB} - \varphi_{IB}$
	$V_{C\text{-}A\ calc}$	I_C	Calculated $V_{C\text{-}A}$	$\varphi = \varphi_{VC} - \varphi_{IC}$
Phase-to-phase $V_{A\text{-}B}$, $V_{B\text{-}C}$, $V_{C\text{-}A}$	$V_{A\text{-}B\ meas}$	I_A	Measured $V_{A\text{-}B}$	$\varphi = \varphi_{VA\text{-}VB} - \varphi_{xA} - \varphi_{IA}$
	$V_{B\text{-}C\ meas}$	I_B	Measured $V_{B\text{-}C}$	$\varphi = \varphi_{VB\text{-}VC} - \varphi_{xB} - \varphi_{IB}$
	$V_{C\text{-}A\ meas}$	I_C	Measured $V_{C\text{-}A}$	$\varphi = \varphi_{VC\text{-}VA} - \varphi_{xC} - \varphi_{IC}$

The angle φ_x is between the angles of the phase-to-phase voltage $\varphi_{VA\text{-}VB}$ and the phase-to-ground voltage φ_{VA}. If the 3-phase voltage is symmetric, then the angle $\varphi_x = 30°$. If the measured voltage is not symmetric, then you can use the following formula for calculating the angle φ_x:

$$\varphi_{xa} = \arccos\left[\frac{3V_{ab}^2 - V_{bc}^2 + V_{ca}^2}{2\cdot V_{ab}\sqrt{2(V_{ab}^2 + V_{ca}^2) - V_{bc}^2}}\right]$$

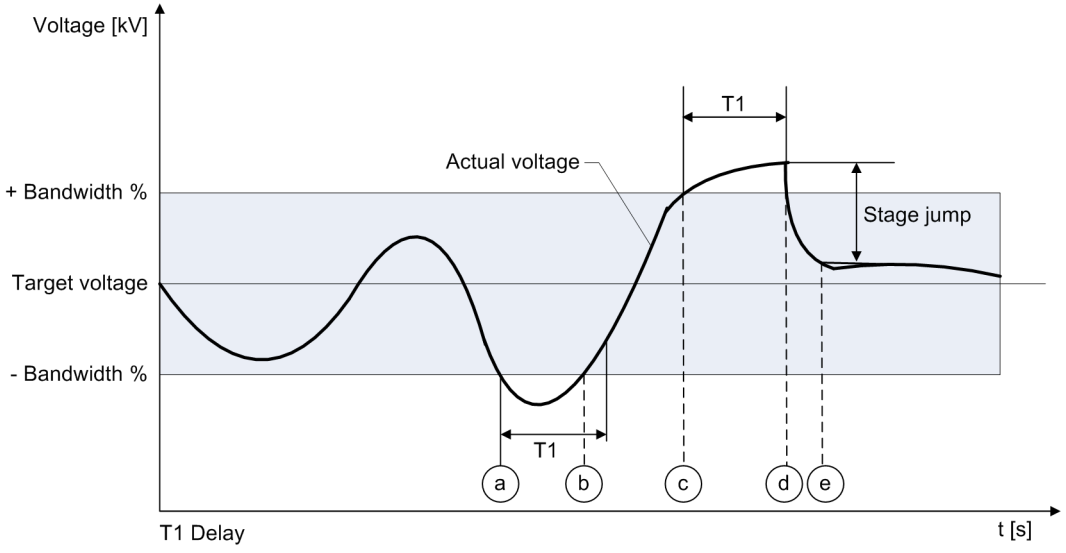
[fo_angle_bet_phases, 1, en_US]

7.9.3.3 Control Response

Control Deviation

The control deviation is calculated from the present actual voltage and the target voltage in relation to the rated voltage.

$$D = \frac{V_{act} - V_{target}}{V_{rated}} 100\ \%$$



[fokonisk-211013, 2, en_US]

D = Control deviation

Bandwidth

To minimize the number of switching operations by the tap changer, a permitted bandwidth is defined. If the actual voltage is within the bandwidth, no adjusting control commands are issued to the tap changer. If the actual voltage exceeds the defined bandwidth, an adjusting command is issued after the set time delay **`T1 delay`**. If the actual voltage returns to the voltage range of the bandwidth before **`T1 delay`** elapses, no adjusting control command is issued.

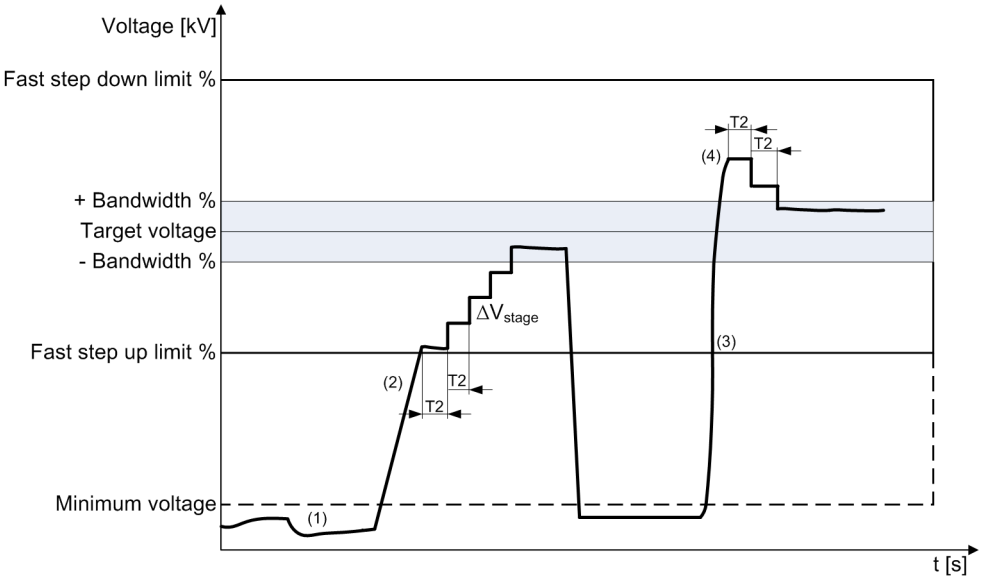
If the actual voltage returns to the voltage range of the bandwidth within the time delay T1, the running time delay T1 continues to count down, starting at the already elapsed time. If the actual voltage returns again to the set bandwidth while the time is counting down, the time delay T1 is started at the remaining time. In this way, the time delay is reduced in the event of frequent violations of the lower limit of the bandwidth. With the **`Set point mode active`** parameter, you can specify a valid bandwidth via a communication network.

[dwistspn-060913-01.vsd, 1, en_US]

Figure 7-115 Actual-Voltage Curve during Control Deviation

(a) Actual voltage outside the bandwidth
(b) Actual voltage before T1 elapses within the bandwidth - no switching
(c) Actual voltage outside the bandwidth, T1 begins to elapse
(d) Actual voltage outside the bandwidth after T1, switching procedure initiated
(e) Switching procedure concluded, actual voltage within the bandwidth

Linear, Inverse



With **linear** control response, the voltage controller reacts independently of the control deviation after the set time **`T1 delay`**. If more than one tap-position change is required to bring the actual voltage back within the bandwidth, the set time **`T2 delay`** takes effect.

With **inverse** control response, the time **T1 delay** depends on the magnitude of the control deviation. Small deviations are tolerated for longer than larger ones. If the time delay is very small in accordance with the set characteristic curve, the time **T1 Inverse Min** takes effect.

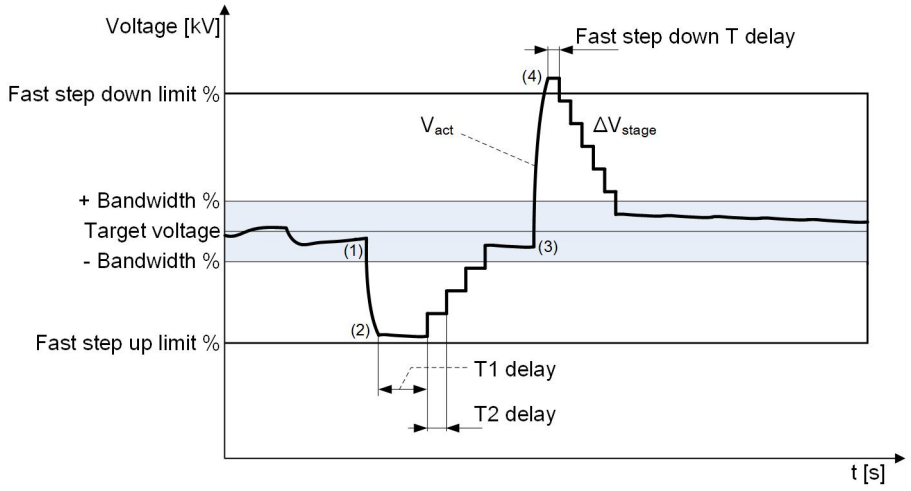
The set **inverse** characteristic curve is a function of the parameter **T1 delay**. The characteristic curves arising for different settings of the time **T1 delay** are shown in chapter *7.9.4.1 General*, margin title Parameter: **T1 characteristic**.

Zero Potential or Voltage Recovery

If the actual voltage is not within the defined bandwidth after a voltage recovery, it can be necessary for the voltage controller to send the 1st adjusting command with the T2 time. For this purpose, the parameter **Regulate with T2 at start** must be activated.

[dw_istgro-130215, 1, en_US]

Figure 7-116 Actual-Voltage Curve during Control with T2



(1) Actual voltage below the minimum voltage

(2) After switching on, the change to a higher tap occurs with time T2

(3) After the voltage recovery, the actual voltage is above the bandwidth

(4) Actual voltage outside the bandwidth. A fast step down mode is carried out with the time T2 until the bandwidth is reached.

Larger Voltage Deviations

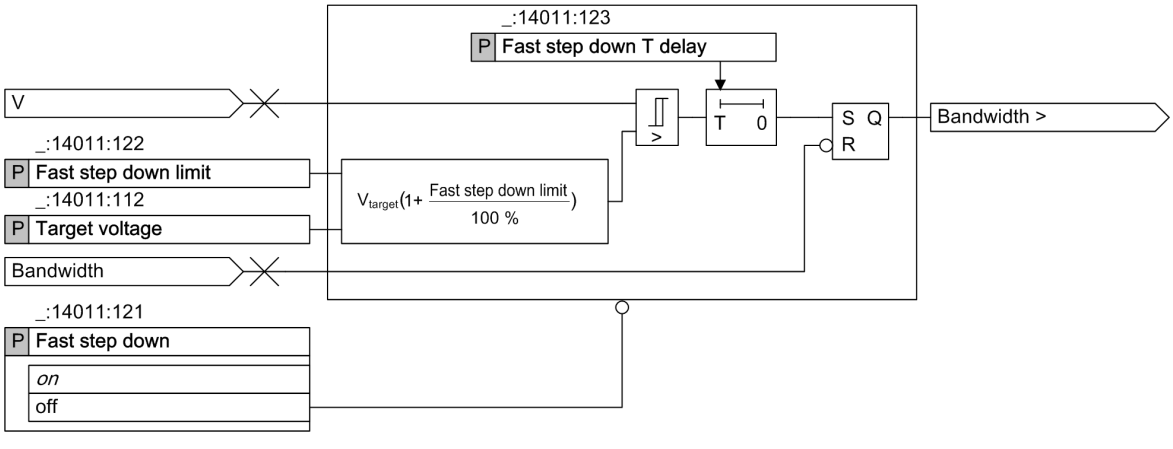
[dwistgro-060913-01.vsd, 3, en_US]

Figure 7-117 Actual-Voltage Curve During Larger Control Deviations

(1) Actual voltage outside the bandwidth

(2) The change to a higher tap occurs after T1 and then T2

(3) Actual voltage inside the bandwidth



(4) Actual voltage outside the limit for a fast step down. A fast step down mode is carried out until the bandwidth is reached.

Fast Step Up Mode and Fast Step Down Mode

The fast step down mode and the fast step up mode allow a quick reaction to abnormal voltage situations. *Figure 7-117* shows such a situation at point (4). A fast step down mode occurs until the bandwidth has been reached. The tap-position time between 2 consecutive lower adjusting commands results from the following 2 conditions:

- The completion of a tap change command after the new valid position was detected
- The measurement time for capturing the new actual voltage

The activity of the fast step down mode and the fast step up mode is displayed with the indications *(_:14011:308) Fast Step Down active* and *(_:14011:307) Fast Step Up active*.

[losnlruk-090913-01.vsd, 2, en_US]

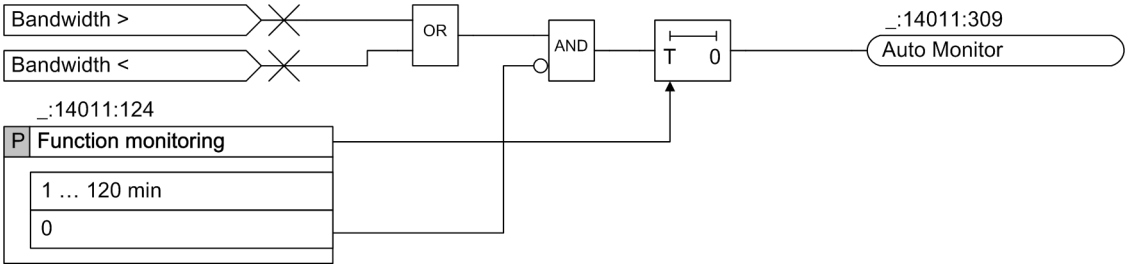


Figure 7-118 Logic of the Fast Step Down Mode

The fast step up mode works in a similar fashion.

7.9.3.4 Function Supervision

Automatic Operation

If the actual voltage exceeds or falls below the set bandwidth for longer than the set time delay, this situation is shown by the indication *(_:14011:309) Auto Monitor*. If the actual voltage returns to the voltage range, the indication is reset. You can switch off the function monitor with a time delay = 0 min.

[lofktueb-090913-01.vsd, 1, en_US]

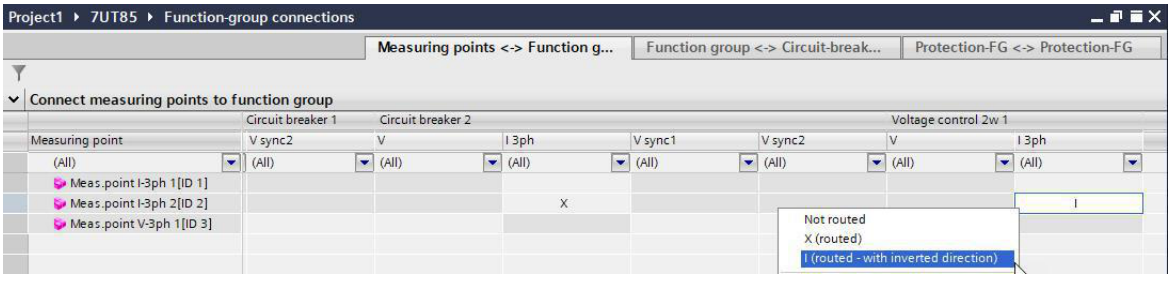

Figure 7-119 Logic of the Function Supervision for Automatic Operation

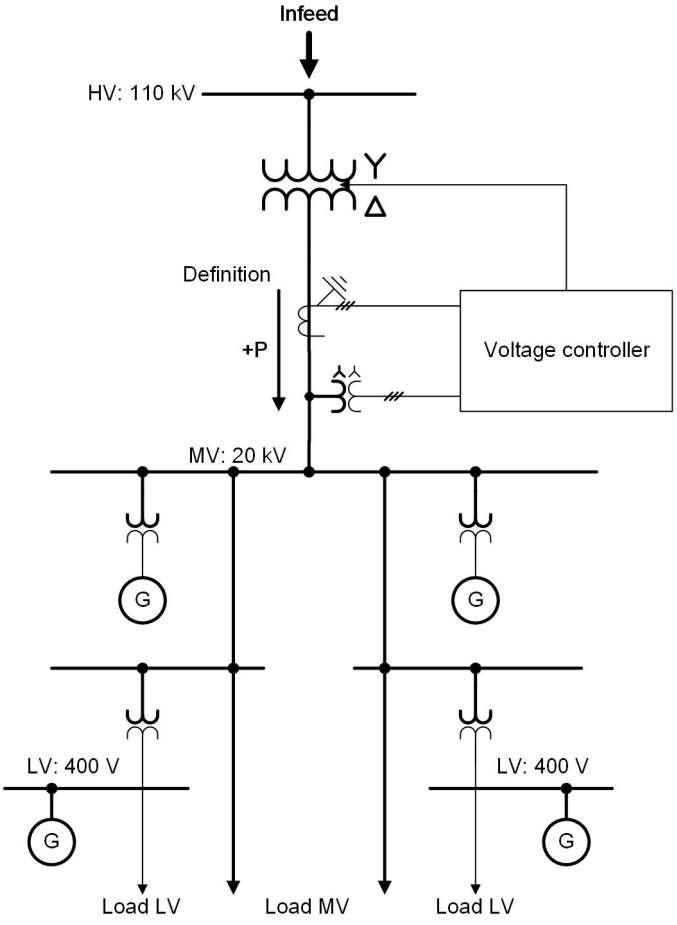
7.9.3.5 Dynamic Voltage Control (DVC)

The increasing use of renewable energy sources is a new challenge for the energy distribution system. The decentralized energy infeeds can lead to a change in the direction of the power flow, especially in medium-voltage systems. Thus, a strong infeed can lead to overvoltages in the individual nodal points and the limits according to the power-quality standard DIN EN 50160 can be reached. A dynamic procedure can be used to adapt the voltage target value. Thus, a voltage dip in case of higher load or a voltage increase due to decentralized infeed can be compensated.

*Figure 7-120*shows an example of an application. The decentralized generating units are in the medium-voltage and the low-voltage network. The active power is defined as positive (+P) in the direction of the medium-voltage busbar.



The direction of the current (neutral point of the transformer) is defined in the direction of the protected object transformer. If you use, for example, the LDC or the DVC method in the voltage controller, you must take into account the direction of the current for correct functioning.

[scfuncgrpconn-260221, 1, en_US]

Figure 7-120 Setting the Direction of the Current in the Function-Group Connections

To fit the definition of the power direction, in this case, the current measuring point must be inverted in the **Measuring-points routing** of DIGSI 5.

[dw_dsg-controller, 1, en_US]

Figure 7-121 Infeed Application Example

HS: High voltage
MS: Medium voltage
NS: Low voltage

If the transformer feeds into the medium-voltage system (+P), the voltage drops on the busbar depending on the load. According to the characteristic curve in *Figure 7-120*, the voltage controller ($V_{target\ comp} > V_{target}$ (with P = 0)) increases the voltage.

If the decentralized generating units have a high infeed, this can lead to a power reversal. The medium-voltage system now feeds into the high-voltage system. The high infeed increases the voltage on the medium-voltage busbar. In this scenario, the measured active power is negative (-P). According to the characteristic curve in *Figure 7-120*, the voltage controller ($V_{target\ comp} > V_{target}$ (with P = 0)) decreases the voltage.

With the dynamic voltage control (DVC), the voltage target value of the voltage controller is adapted via a characteristic curve depending on the power direction. Depending on the measured positive or negative active power, the calculation of the dynamic voltage target value $V_{target\ comp}$ is based on one of the 2 linear equations (see *Figure 7-120*).

NOTE

As a prerequisite for the dynamic voltage control (DVC), the voltage and current must be measured by the device. The dynamic voltage control cannot be activated in parallel to the LDC function or the paralleling function.

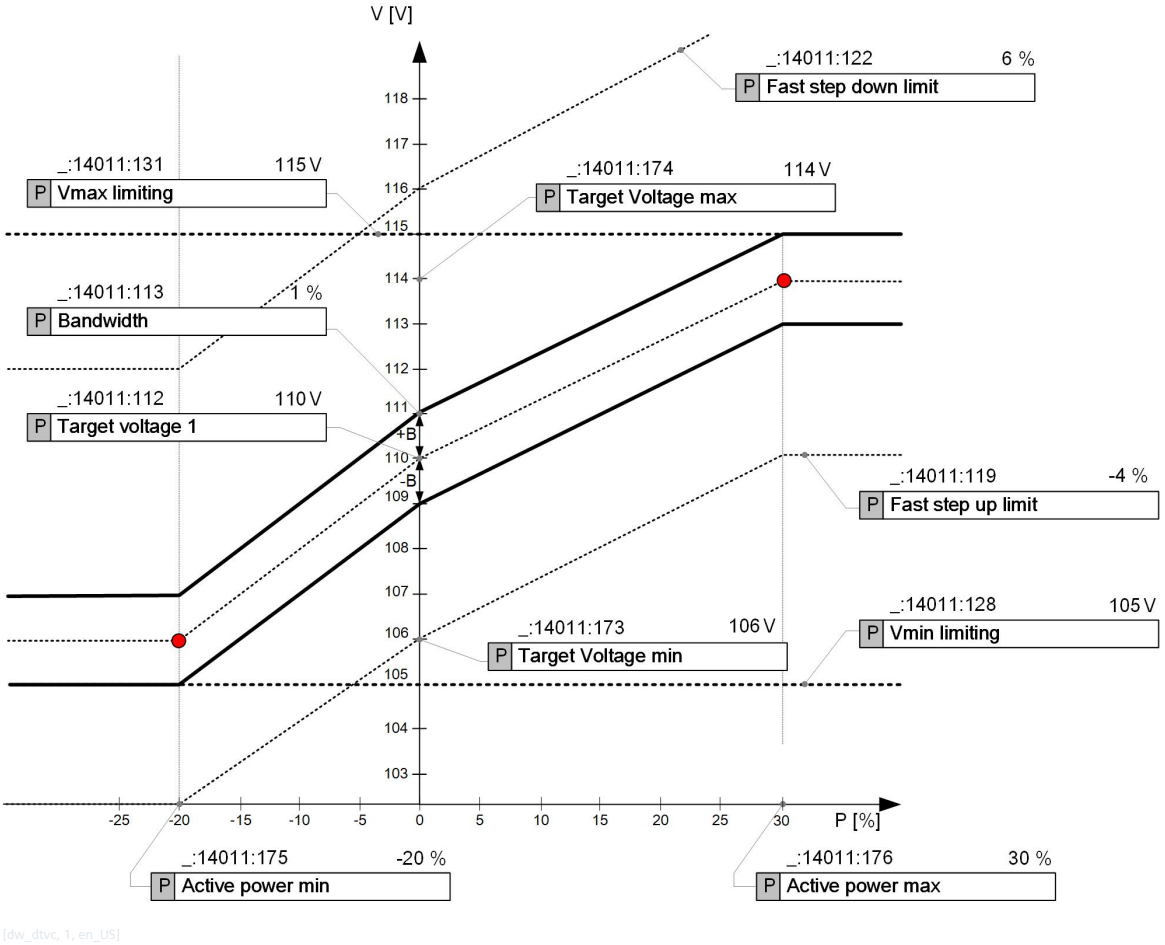


Figure 7-122 Characteristic Curve of the Dynamic Voltage Control

Behavior when Falling below Active power min (P_{min})

If the measured active power P_{meas} falls below the set value for P_{min}, the voltage value at P_{min} is taken as the current voltage target value:

$P_{meas} \leq P_{min} \Rightarrow V_{target\ min}$ is $V_{target\ comp}$

Behavior when Exceeding Active power max (P_{max})

If the measured active power P_{meas} exceeds the set value for P_{max}, the voltage value at P_{max} is taken as the current voltage target value:

$P_{meas} \geq P_{max} \Rightarrow V_{target\ max}$ is $V_{target\ comp}$

Behavior for a Measured Active Power P_{meas} = 0 MW

If the measured active power P_{meas} = 0 MW, the function takes the voltage target value V_{target} set in the voltage controller.

Linear Behavior of the Voltage Controller in Case of Negative Active Power

If the measured active power P_{meas} is in the range $P_{min} \leq P_{meas} \leq 0$, the value for the voltage target value is calculated as follows:

$$V_{target\ comp} = \left(\frac{V_{target} - V_{target\ min}}{0 - P_{min}}\right) \cdot P_{meas} + V_{target}$$

[fo_Vtargetcomp_Pmin, 2, en_US]

Linear Behavior of the Voltage Controller in Case of Positive Active Power

If the measured active power P_{meas} is in the range $0 \leq P_{meas} \leq P_{max}$, the value for the voltage target value is calculated as follows:

$$V_{target\ comp} = \left(\frac{V_{target\ max} - V_{target}}{P_{max} - 0}\right) \cdot P_{meas} + V_{target}$$

[fo_Vtargetcomp_Pmax, 1, en_US]

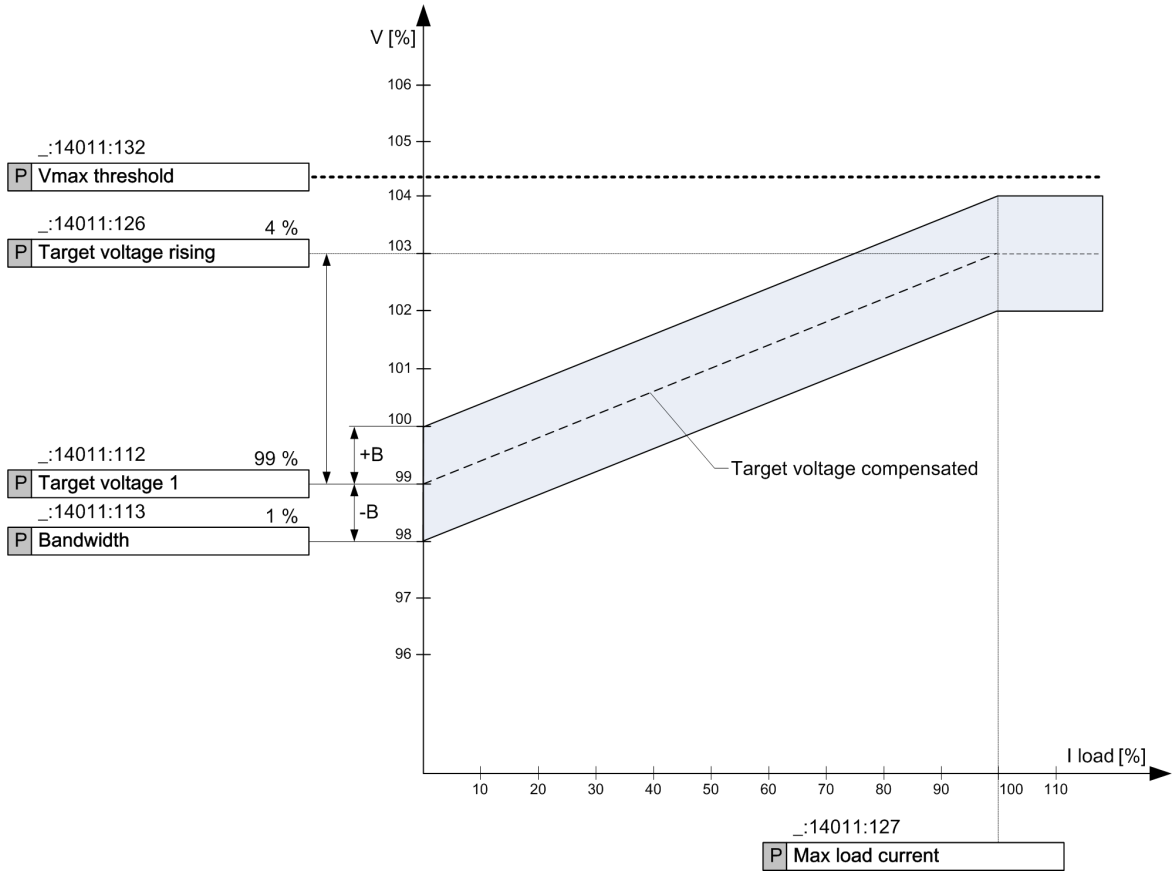
7.9.3.6 Line Compensation

When using line compensation, the voltage drop of a phase that is connected to a transformer can be included. In this case, 2 processes are available:

- Z compensation (LDC-Z)
- X and R compensation (LDC-XandR)

NOTE

Line compensation is only active if power is flowing in the direction of the line.



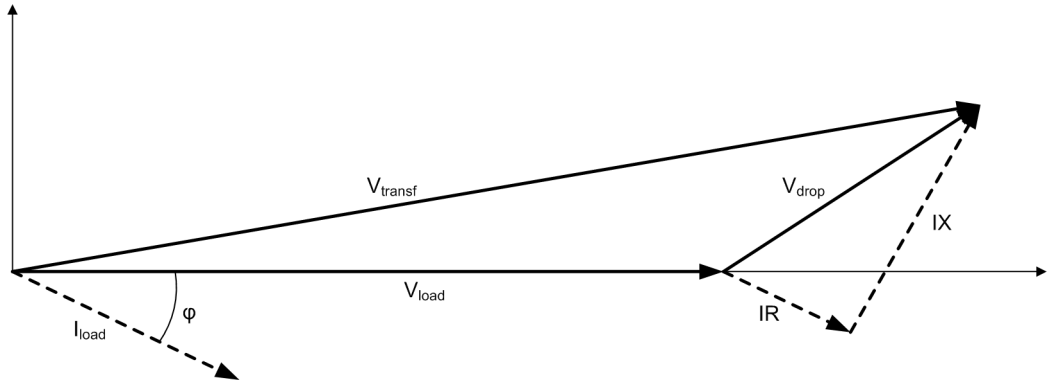
Z Compensation (LDC-Z)

Z compensation allows you to include the voltage drop of a line connected to the transformer. You can switch the **Z compensation** on or off. If cos φ is roughly constant, you can use the **Z compensation**. Setting the parameters requires the calculation of the voltage increase (**`Target voltage rising`**) taking into consideration the load current (**`Max load current`**).

The parameter **`Target voltage rising`** represents the voltage drop across the line as a % under rated load.

You can find more information and the calculation in chapter *7.9.4.1 General*.

In case of active **Z compensation**, you must limit the maximum permitted voltage increase in relation to the target voltage to avoid too high voltage at the transformer. To do this, set the parameter **`Max load current`**. In addition, the parameter **`Vmax threshold`** is active. If the actual voltage exceeds this threshold value, no more higher adjusting commands are issued.



[dwregchr-090913-01.vsd, 3, en_US]

Figure 7-123 Control Characteristic with Z Compensation

X and R Compensation (LDC-XandR)

During the application of the **X and R compensation**, you need the phase data. With this data, it is possible to precisely compensate the voltage drop of the transmission lines. This method of line compensation also operates with negative active-power values. The following figure shows the effect of this compensation type.

[dw-line-drop-kompensation-250214-01.vsd, 2, en_US]

Figure 7-124 Phasor Diagram of the X and R Compensation

V_{transf}	Voltage on the transformer, voltage to be controlled
V_{load}	Voltage of load point (target voltage, $V_{load} = V_{transf} - V_{drop}$)
V_{drop}	Voltage drop of the phase
IR, IX	Voltage drop due to R and X of the line

I_{load}	Load current
φ	Rotor angle

You can also use **X and R compensation** for parallel control of transformers. If the X value is positive, the voltage losses of the phase are compensated. If you are implementing parallel control with **X and R compensation**, then the X value is negative and considers the voltage increase from the busbar to the transformer.

If the **X and R compensation** you must limit the maximum permitted voltage increase in relation to the target voltage in order to avoid a voltage at the transformer that is too high. To do this, set the parameter **`Vmax threshold`**. If the actual voltage exceeds this threshold value, no more higher adjusting commands are issued.

7.9.3.7 Limiting Values

The limiting values cause no higher or lower adjusting commands to be given to the tap changer in the event of an upper limit violation (**`Vmax threshold`**) or lower limit violation (**`Vmin threshold`**). In this way, changing taps under abnormal voltage conditions and changing taps in the incorrect direction (for example, in the event of wiring errors) is prevented.

The lower and upper tap changer limits are included in the limiting values. The parameters **`Lower tap-position limit`** and **`Higher tap-position limit`** cause an additional restriction of the control range.

7.9.3.8 Blockings

The blockings prevent tap positions under abnormal network conditions. The following blocking functions are available:

- Undervoltage
- Overcurrent, load current
- Overcurrent on one transformer side
- Undercurrent
- External blocking (binary input)
- Blocking command LTCBlock IEC 61850
- Blocking in the event of pickup of the transformer differential protection

Using the parameter **`Blocking behavior`**, you specify whether the blockings are to take effect only in automatic operation (***`Auto`***) or in both automatic and manual operation (***`Auto-Manual`***).

Overcurrent blocking prevents tap-change operations in the event of an overload. For the current blockings, the positive-sequence system of the load current and of the current on the upper-voltage side of transformers is calculated.

By assigning the tap changer to the transformer side, you also arrange the current of the upper-voltage side. Perform this assignment in the appropriate **Transformer side** function group (see *5.1.3 Function-Group Type Transformer Side*). Here, you must use the tap changer of the voltage controller.

Undervoltage blocking prevents tap-change operations in the event of a network collapse. The output signals of the voltage controller are blocked and, depending on the operating mode, the indication *`Auto Blocking`* and/or *`Manual Blocking`* is issued.

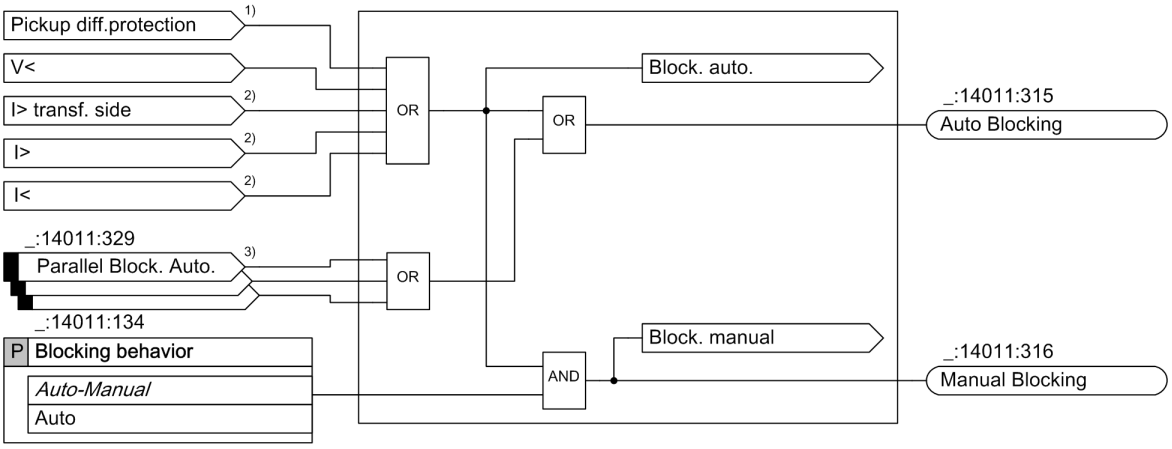


Figure 7-125 Logic Blockings

1) If transformer differential protection is available
2) If a current measurement is available
3) If parallel proxys are available (max. 7)

If assignment of the tap changer for the transformer side is available, the current of the upper-voltage side is also monitored and the differential-protection pickup automatically blocks the voltage controller.

Additional Blockings for the Three-Winding Transformer Voltage Controller

The blockings described in the above sections also apply to the controlled winding of the three-winding transformer. In addition, the blockings for undervoltage, minimum voltage, and overcurrent are used for the measurands of the uncontrolled side.

Additional Blockings for the Grid Coupling Transformer Voltage Controller

For voltage control in grid coupling transformers, the voltages and currents of both windings are always used for the blockings.

7.9.3.9 Parallel Operation

General

The parallel operation of 2 or more power transformers is intended to increase the electrical throughput or short-circuit power at a power-system node. An additional reason for the parallel operation of transformers is a reserve in the event of a failure of a transformer.

If power peaks are to be expected in the power system, multiple transformers can be connected in parallel on different busbars. This allows several feeders to be supplied simultaneously. You can control up to 8 transformers in parallel in one group. The evaluation of the measured and status values takes place via the IEC 61850 GOOSE communication.

If for the transformers used the tap positions differ, therefore creating a different transformation ratio, the no-load voltages on the low-voltage side will be different. A circulating reactive current flows via the transformers. Since the transformer impedance consists mainly of leakage inductance, the current is inductive. These currents can result in the overloading of the transformer.

The parallel operation is intended for two-winding transformers. For this application, additionally instantiate the function **Parallel operation**. For each of the transformers connected in parallel you need an additional function block **`ParallelProxy`**. The 1st **`ParallelProxy`** is preinstantiated. For a configuration with 8 transformers working in parallel, you can instantiate a maximum of 7 **`ParallelProxy`**. The exchange of the necessary information takes place via this proxy. 8 transformers can be configured to a maximum of 4 groups.

For the **Parallel operation** the following 2 methods are available:

- **Master-follower method**
- **Method of minimizing the circulating reactive current**

Table 7-30 Conditions for the Use of Both Methods

Requirements for the Transformers			Requirement for the Voltage Controller		Method
Voltage change per tap	Rated power	Short-circuit voltage deviation	Current measurement	Tap position	
Same	Same or different	<10 %	Optional	Necessary	Master/Follower
Different	Same or different	Different	Necessary	Recommended	Minimizing circulating reactive current

As the preceding table shows, before selecting the method, you must check whether the corresponding requirements are met. If you place transformers in parallel, whose short-circuit voltages differ by more than 10 % from each other, then Siemens recommends the **Method of minimizing circulating reactive current**.

Control of the Function

You can control the **Parallel operation** function using setting values or commands.

	Parameters	Values
With setting values	Parallel mode	Master, No mode, Follower, Circulat. react current
	Parallel mode changeable	by setting, controllable
	Force master changeable	by setting, controllable
With command	Parallel operation (ParOp)	independent, parallel
	Set master (ForceMast)	off, on
	Parallel groups (ParGrp)	1 to 4

The state of the control is reported as:

- No mode
- Independent
- Master
- Follower
- Circulating reactive current

If the **Parallel operation** is connected via the communication to further transformers, the state is checked for correctness. If this is not the case, an inconsistency indication is output. The communication to the transformers of a group is also monitored. If a fault is present, this is reported.

Figure 7-128 Properties Tab of the Parallel Group

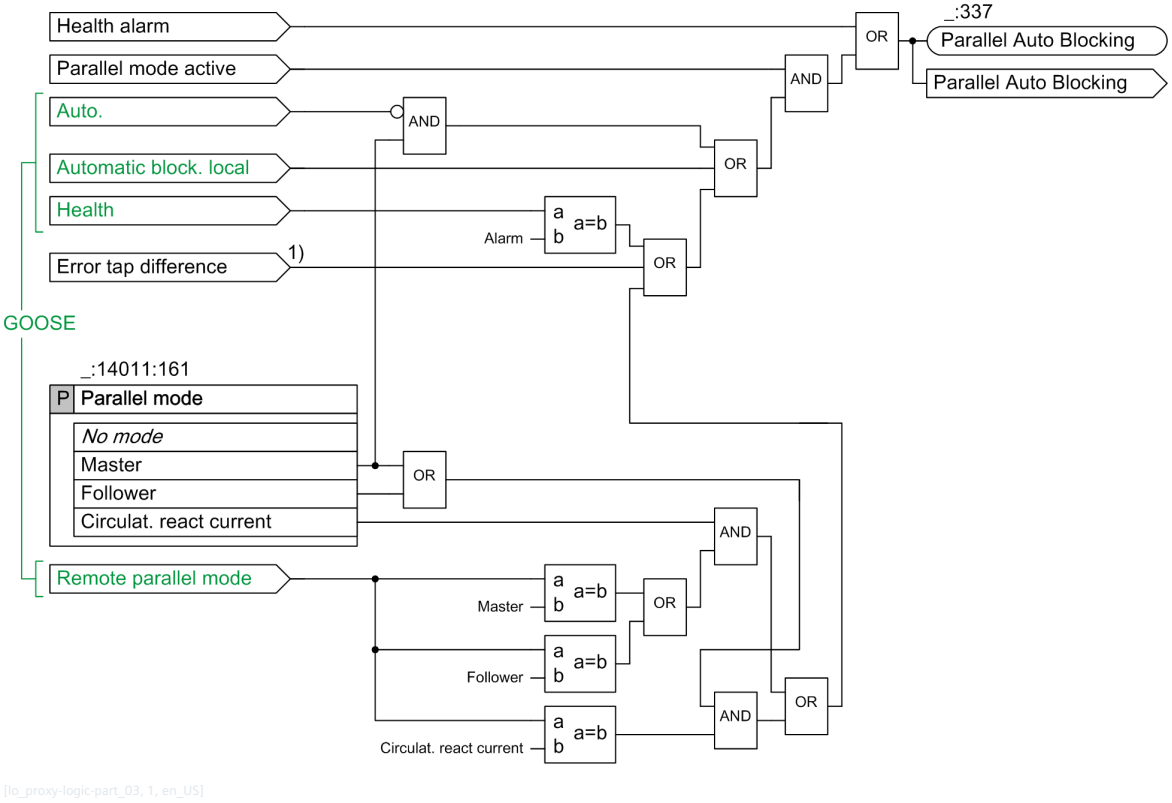
During operation you can change this assignment by command, depending on the switching state of the transformers.

Logic of the Function

[lo_proxy-logic-part_01, 1, en_US]

Figure 7-129 Grouping Logic

Parallel-Operation Detection via Group Inputs



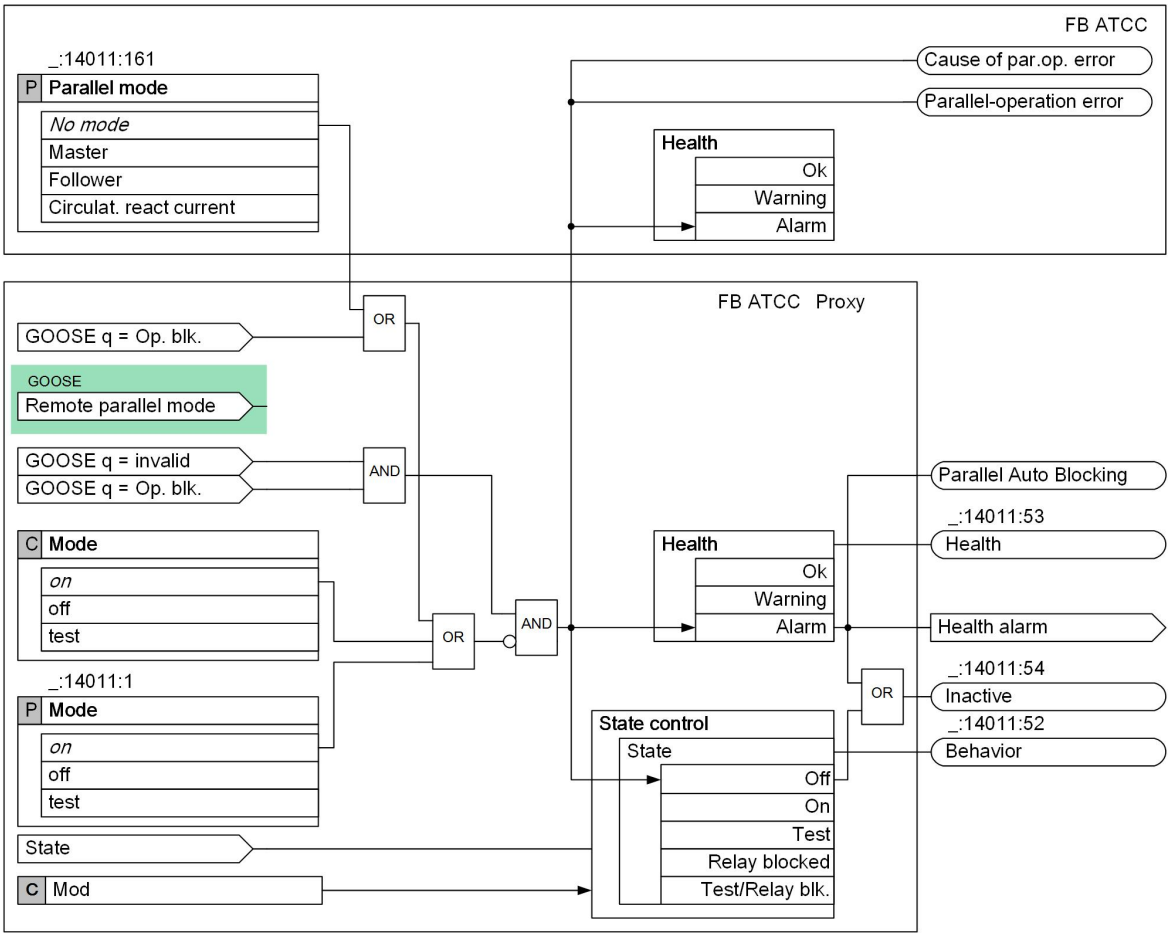
You can control up to 8 transformers in parallel in one group or in 4 groups without detecting the system topology. The devices in parallel operation use exclusively the information transmitted from devices of the

same parallel-operation group via GOOSE. The groups of the transformers to be controlled in parallel are set and changed using the control **Parallel group**, where you assign the device to a parallel-operation group. This can be done *remotely* or *locally* on the device. If ***No mode*** is set for the parallel operation, no group assignment takes place.

Parallel-Operation Detection via Topology

In addition, you have the option to detect the group assignment in parallel operation based on the position of the disconnectors and circuit breakers. To report its status, every disconnector and circuit breaker is equipped with a circuit-breaker auxiliary contact. These binary signals can be processed in a CFC chart and dynamically adapted to the switching state of the system.

The signals *Parallel group*, *Remote parallel mode* and *Parallel mode active* are transmitted via the GOOSE communication between the other transformers in the group.



[lo_proxy-logic-part_03, 1, en_US]

Figure 7-130 Logic of the Blocking of Automatic Operation in the ParallelProxy

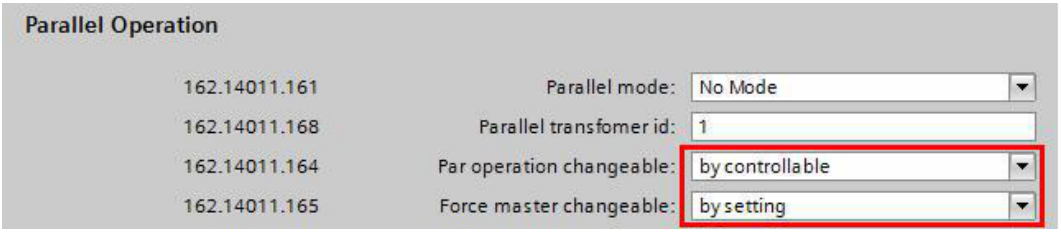
1) Only applies to the **Master-follower method**

The signals *automatic operation*, *automatic-block. local*, *Health* and *Remote parallel mode* are transmitted via the GOOSE communication between the other transformers in the group.

If the other voltage controllers in the group are set to the mode ***No mode*** or the communication is disturbed, the automatic operation is blocked. The blocking is reported. If a fault in the tap position is detected via the difference in the tap positions of the transformers, the indication *Error tap difference* is issued.

[lo_proxy-logic-part_02, 2, en_US]

Figure 7-131 Logic of the Parallel-Operation State Detection



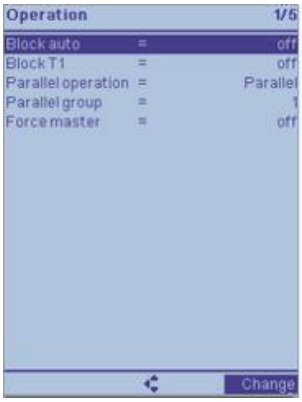
Controlling Locally/Remote

The parallel operation can be done with a parameter or via the control. With the parameter setting ***controllable***, you can also use a binary input and the status signal of a circuit breaker with a CFC block (*Figure 7-134*).

First, for the control of the **Parallel operation**, set the parameters **`Parallel mode changeable`** and **`Force master changeable`**.

You can select one of the 2 options:

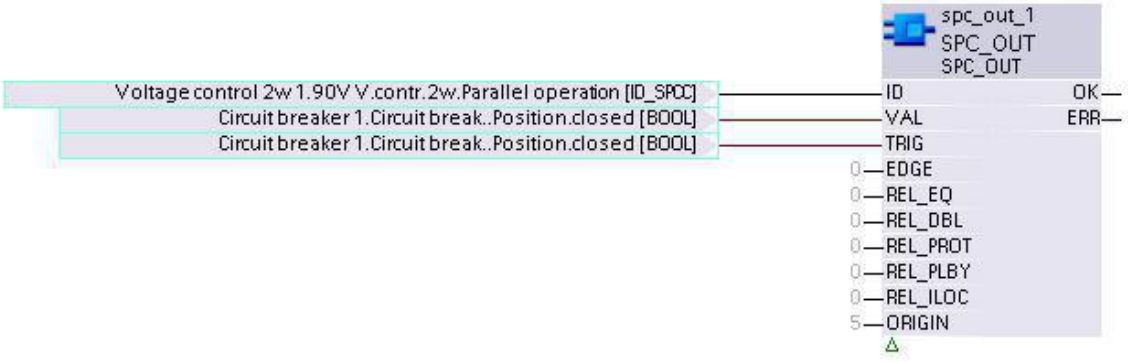
- ***by setting***
- ***controllable***



[sc_para_oper_change, 1, en_US]

Figure 7-132 Selection for Parallel Operation

If you set **`Parallel mode changeable`** to ***`controllable`***, you can read and change the settings for the parallel operation on the device under the following path:



- Main menu → Commands → Functionality → Voltage cont. 2w1 → Operation

[sc_para_hmi_oper, 1, en_US]

Figure 7-133 Menu Item for Parallel Operation on the Device Display

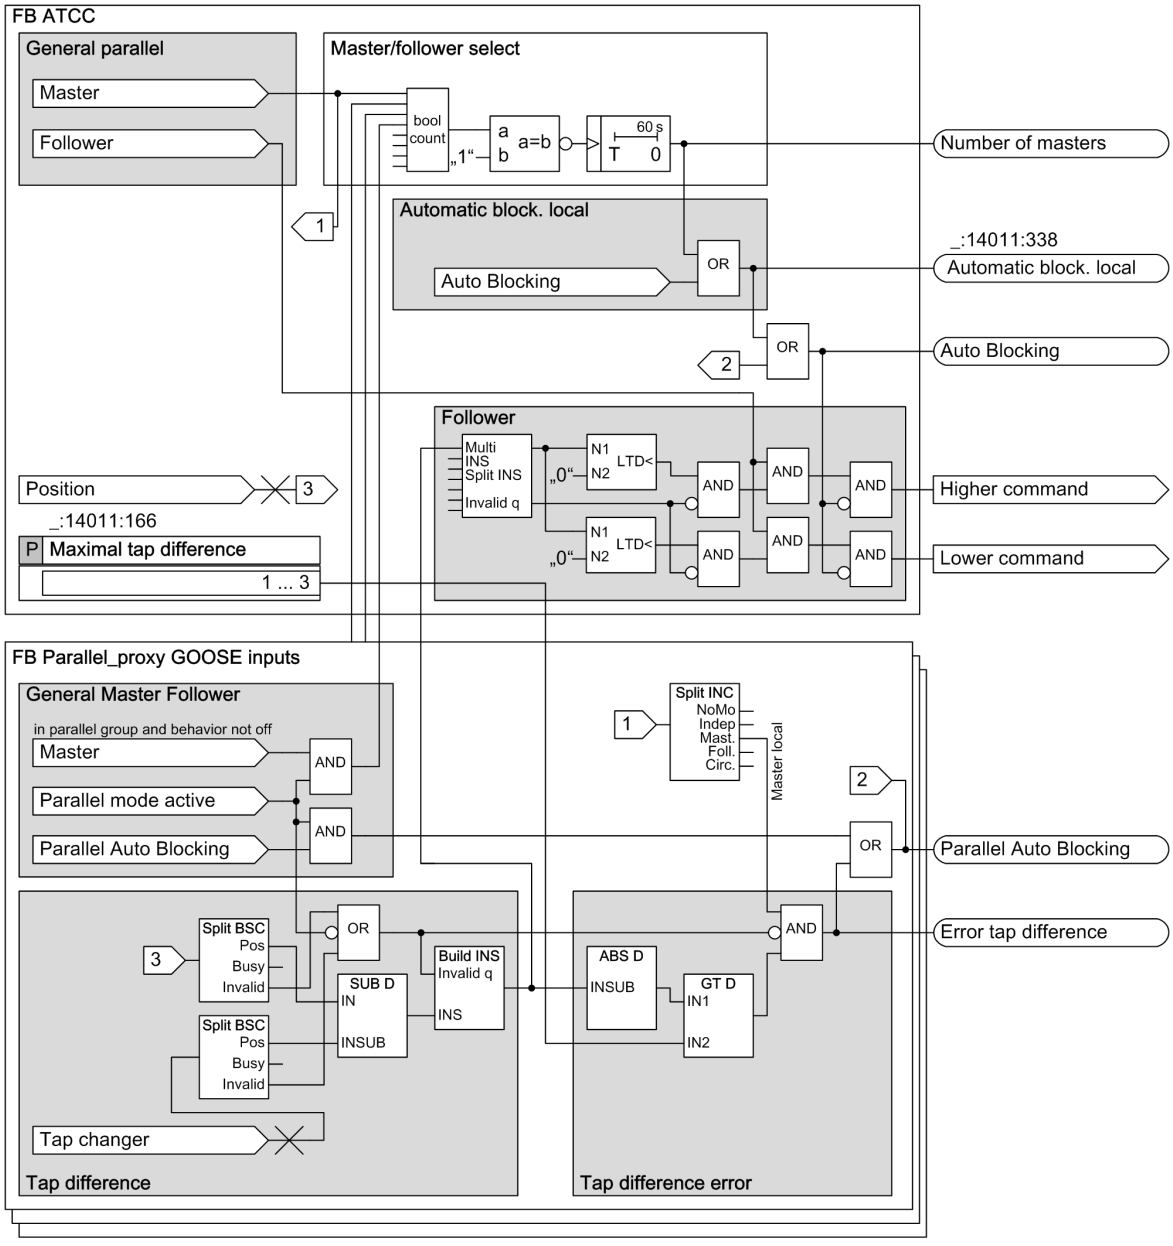
Figure 7-134 shows an example of a CFC chart for switching to parallel mode via the binary input of the circuit breaker.

[sc_switchparop_cfc, 1, en_US]

Figure 7-134 CFC Chart

Master-Follower Method

As a prerequisite for the application of this method, the following values must be almost equal:



- Transformation ratios of the transformers used
- Number of the taps
- Voltage differential between the taps

The **Master-Follower method** regulates the Follower devices to the same tap position as the Master transformer. One voltage controller takes the lead (Master device), whilst the other voltage controllers (Follower devices) follow its tap position (Master-Follower method). The Master device controls the busbar voltage automatically according to the same principles of the available voltage-controller functionality for a two-winding transformer. Compared with the Master-Slave method, this method has the advantage that losing a higher/lower adjusting command (for example due to communication loss or auxiliary-voltage failure of the Follower device) does not result in asynchronicity of the transformers.

The **Master-Follower method** is suitable for transformers of the same design. If transformers of different power are controlled with the **Master-Follower method**, you must be aware that the same tap positions will

result in the same ratios. The relative short-circuit voltages of the transformers must not deviate significantly from each other (max. 10 %).

Logic of the Master-Follower Method

[lo_parallel_voltage_contrl-master-follower, 1, en_US]

Figure 7-135 Logic of the Master-Follower Method

The **Master-Follower method** can be blocked using the automatic function in the systems control. In case of a communication failure the function is also blocked.

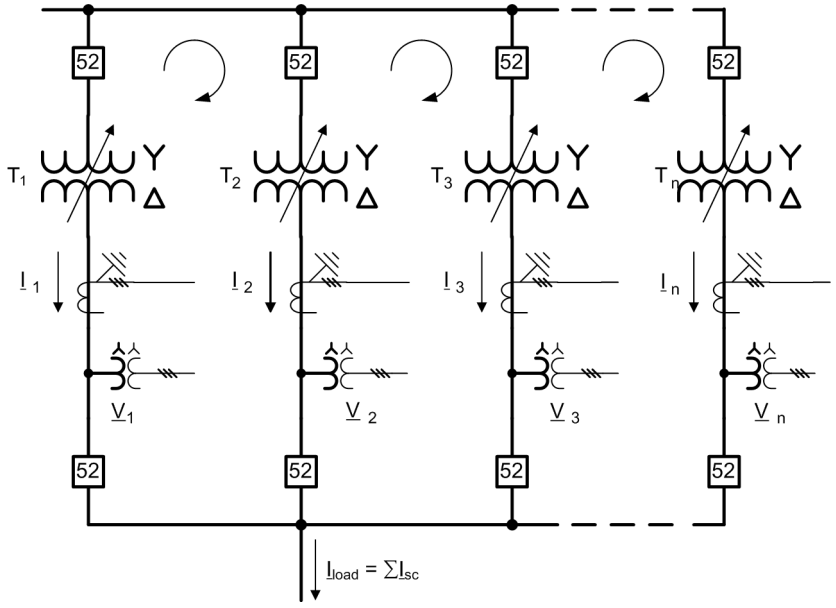
The Master device controls the voltage of the transformer. The Follower device updates the tap position of the Master device. When doing so, the maximum tap-position difference between the transformers is taken into account. If the tap-position difference is exceeded for a predefined time, an error is reported (*Error tap difference*). If the supervision of a group detects that there is more than one Master device, this is reported and the automatic operation is blocked.

Manual Operation Master-Follower

Changing the tap of the tap changer using the Master device leads to an adjustment of the taps by all follower devices within the group.

If a communication error is present, a tap change can be done by the Follower device by switching to manual operation. In the Master device and all Follower devices the **Automatic mode** is blocked.

Method of Minimizing Circulating Reactive Current



If the ratios of the transformers connected in parallel are different (>10 %), Siemens recommends the method of **Minimizing circulating reactive current**. The prerequisite for the method of **Minimizing circulating reactive current** is a data exchange between the ATCC function blocks (one ATCC function for each transformer in the parallel group). The data exchange for ATCC functions in different devices occurs via the GOOSE communication of the IEC 61850 protocol. All data of the devices in a group is exchanged cyclically via GOOSE, both analog and binary signals are exchanged.

The following advantages can be achieved with the method of **Minimizing circulating reactive current** for parallel voltage control:

- Setting the load voltage to a preset value
- Minimizing the circulating reactive current for transformers operated in parallel

Calculation of the Circulating Reactive Current

To calculate the circulating reactive current, the measured values of the individual transformers must be transmitted between the affected voltage controllers. The suitable reference variable for all transformers in a parallel group is the bus voltage. With this, there is a common reference between all devices within one parallel transformer group. The measured bus voltage is the reference value of the devices used.

[dw_CCM_01, 1, en_US]

Figure 7-136 Detection of the Circulating Reactive Current of a Parallel Group

The following formulas are used to calculate the circulating reactive current.

For each device, a direct-axis reactance relating to the control side of the transformer is calculated from the following 3 parameters:

- Rated apparent power S_{rated} of the transformer
- Rated voltage V_{rated} of the transformer
- Short-circuit voltage of the transformer V_{SC} in percent

If the ohmic longitudinal resistance is neglected, the direct-axis reactance of the transformer T_k (k = 1,2,3 ... n in the example) relating to the control side results in:

$$X_k = \frac{V_{rated}^2}{S_{rated}} \cdot \frac{v_k}{100\ \%}$$

[fo_reakccm, 1, en_US]

This direct-axis resistance is transferred to the other voltage controllers as a measured value with GOOSE. This value is displayed as a check. To determine the total load current, from each voltage controller the measured current with magnitude and phase angle is transferred as a GOOSE CMV measured value.
The total load current results in:

$$\bar{I}_L = \sum_{k=1}^{N} \bar{I}_k$$

[fo_summccm, 1, en_US]

The total inductive susceptance, the total susceptance of all transformers results in:

$$B_P = \sum_{k=1}^{N} \frac{1}{X_k}$$

[fo_suszccm, 1, en_US]

The partial load current value of the individual transformers results from the ratio between susceptance and total susceptance multiplied with the total load current. Only the inductive value, namely the imaginary part $Im(\bar{I}_A)$ of the calculated total load current is used.

$$I_{LkImag} = Im(\bar{I}_L) \frac{1}{X_k \cdot B_P}$$

[fo_loadcurccm, 1, en_US]

The circulating reactive current at transformer k is the difference of the current measured at the transformer and the calculated partial load current I_{LkImag}. This is multiplied with -1 so that its positive no-load voltage difference results in a positive circulating reactive current:

$$I_{CRCk} = -1 \cdot \left(Im(\bar{I}_k) - I_{LkImag} \right)$$

[fo_ccmtrafo, 1, en_US]

where:

I_{LkImag}	Calculated inductive part (imaginary part) of the partial load current of transformer k
I_{KBSk}	Circulating reactive current
I_{kImag}	Measured inductive part of the current at transformer k
$\bar{I}_{SC}$	Measured current at the transformer
X	Reactance of the transformer
k	1, 2, 3, ... 8 (number of the transformer)

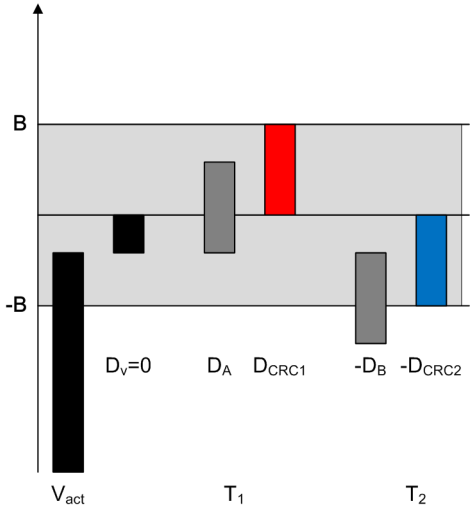
Calculation of the Control Deviation

The control deviation D_{KBSk} is calculated from the calculated circulating reactive current I_{KBSk}:

$$D_{CRCk} = \text{Reactive I control factor}_k \cdot \frac{I_{CRCk} \cdot (X_k + \frac{1}{B_p - B_k}) \cdot \sqrt{3}}{V_{rated}} \cdot 100\ \%$$

[fo_regelabwdcc, 1, en_US]

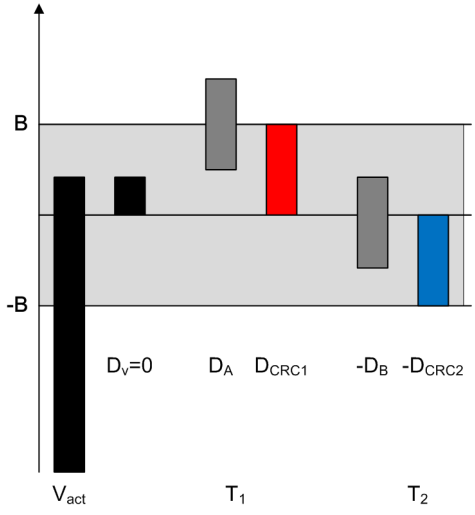
where:



X_k	Reactance of the transformer
B_p	Total susceptance (total susceptance value) of all parallel transformers (sum of the reciprocals of the transformer reactance)
B_k	Susceptance of the transformer (reciprocal of the reactance)
V_{rated}	Rated voltage of the transformer

With the parameter **Reactive I control factor** you can adjust the control deviation D_{KBSk} so that the circulating reactive current caused by a tap difference results in exceeding the control bandwidth. A **Reactive I control factor** which is set too high can affect the control stability. In most cases, control quality and control stability are available with the default setting of 1.

The sum of the control deviation resulting from voltage deviation D_V and the control deviation D_{KBSk}, caused by the circulating reactive current, results in:



$D_k = D_{KBSk} + D_V$

and is compared with the set bandwidth. The following 2 diagrams explain the summations of the control deviation at negative and positive voltage deviation. A possible control deviation initiated by the circulating reactive current, is on transformer T_1 in contrast to transformer T_2. This results for both voltage controllers in a different total deviation.

Negative voltage deviation $-D_V$

Changing to higher tap of T_2 with $D_V + D_{KBS2} < -B$

Positive voltage deviation D_V

Changing to lower tap of T_1 with $D_V + D_{KBS1} > B$

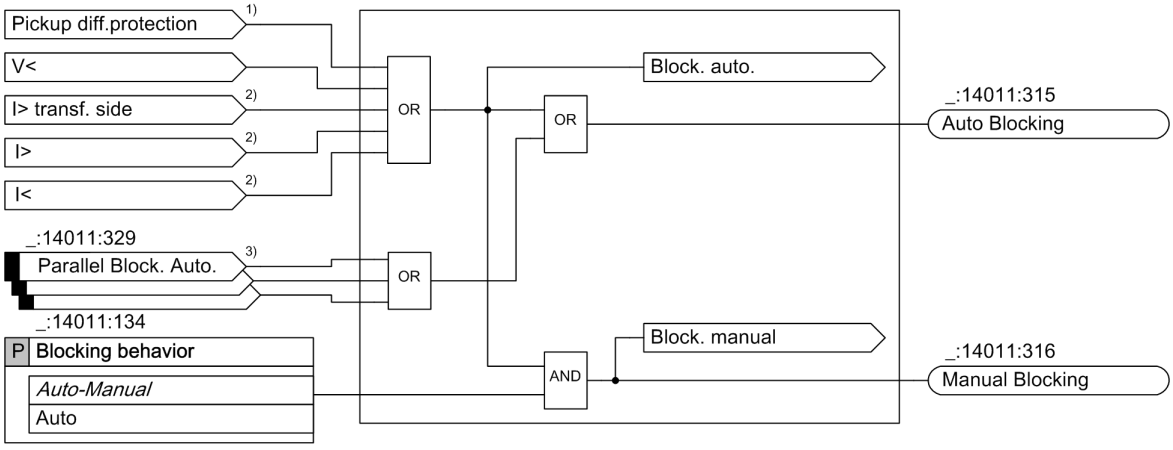
For the calculation of the voltage deviation, the voltages of all voltage controllers are transferred with GOOSE as a measured value and an average value is calculated. The voltage can be monitored. If the data are not plausible the voltage controller is blocked after a time delay which can be set.

Error Behavior

If the value of the circulating reactive current exceeds the set time delay **Circul. current time delay** for a longer time than the threshold value **Circul. current threshold**, the indication *Circul. current blocking* is issued and the voltage control blocked.

If the circulating reactive current value drops below the preset value, the signal is automatically reset. This can be achieved using the manual control of the tap changer.

Blocking the Tap Changer in Case of a Fault



To activate the supervision functions in Follower mode when used with the transformer differential protection, you must set the parameter **Blocking** in the voltage controller function to ***Auto-Manual***.

[scblockVC-240117-01, 1, en_US]

Figure 7-137 Parameter in the Voltage Controller

The blockings prevent tap positions under abnormal network conditions.

[loblokir-090913-01.vsd, 2, en_US]

Figure 7-138 Blocking Logic

1) If transformer differential protection is available
2) If a current measurement is available
3) If parallel proxies are available (max. 7)

In addition to the blockings present with a parallel operation the number of proxies used is taken into account.

Maintenance of Transformers Connected in Parallel

If you want to take the device out of service and disconnect it from the power supply, you must first functionally log off the device. Once you functionally log off the device, all data objects generated in the device (state and measured values) receive the quality attribute **`OperatorBlocked`** = *TRUE*. This also applies to the output from CFC charts.

If objects are transferred via a GOOSE message, the receiver devices can analyze the quality. After a switch off of the transmitting device, the receiver devices detect that the transmitting device has been functionally logged off and did not fail. Now the receiving objects can automatically be set to defined states.

Table 7-31 Decommissioning

Binary input	>Device funct.logoff on 91.507 SPS >Dev. funct.logoff off 91.508 SPS
Controllable/device display	Device logoff 91.319 SPC Logged off via BI 91.313 SPS Logged off via control 91.314 SPS Device logged off 91.315 SPS

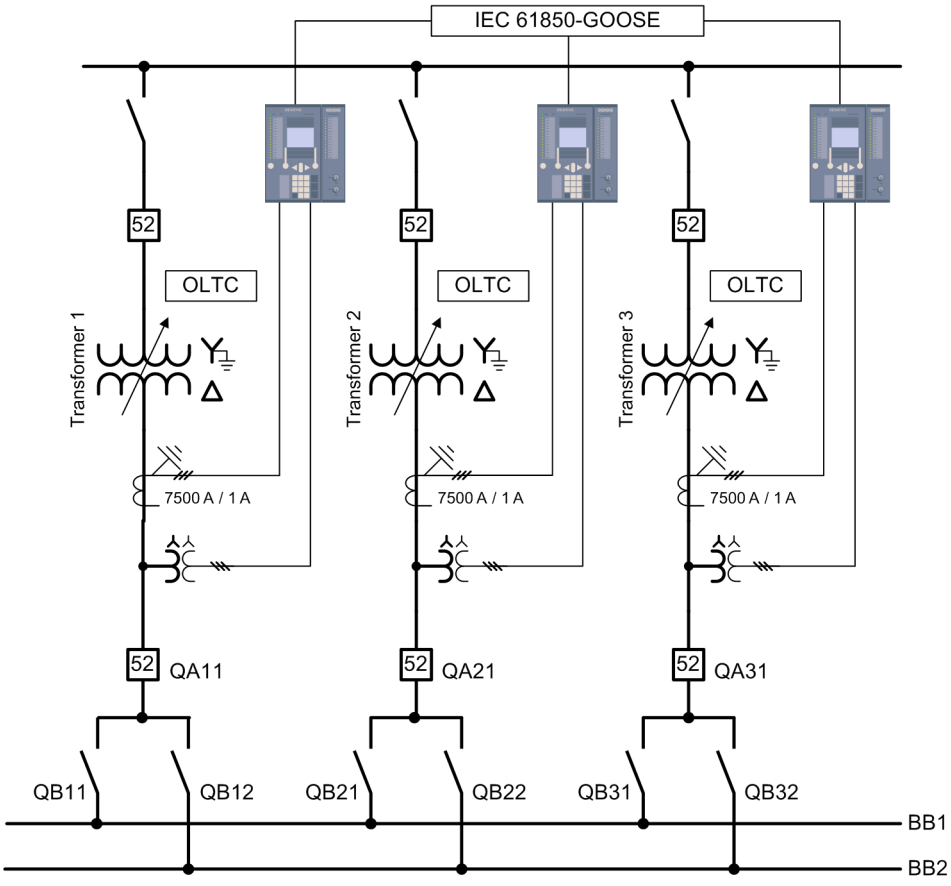
NOTE

Decommissioning the device is only allowed if the **`Parallel mode`** of the voltage controller is set to ***`No mode`***. After the decommissioning you must commission the voltage controller again.

The decommissioning can be done with binary input indications or via the control.

Supervision of the Communication

A communication fault can occur in the following cases:



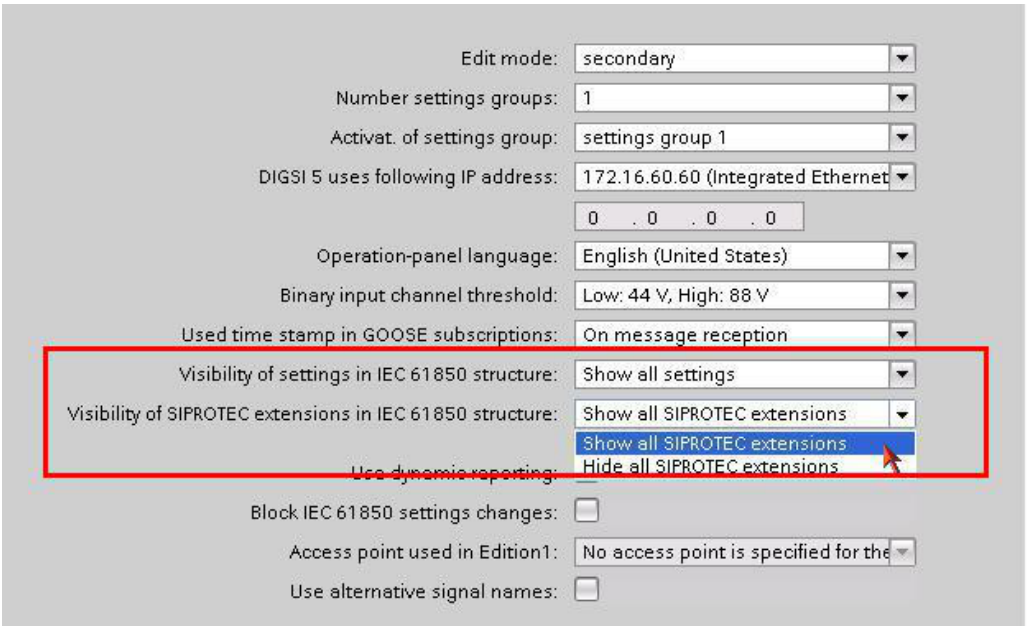
- The connection between 2 SIPROTEC 5 devices is interrupted.
- A hard- or software error is present in the device.
- The supply voltage of one or more devices is not present.

If the receipt of GOOSE messages is disturbed, a GOOSE time-out is signaled and all GOOSE messages arriving are signaled as *invalid*. If **No mode** is set in one of the devices, then the parallel operation is not blocked. If a communication error is present, the parallel mode in the Master and Follower device cannot be determined. In this case the operating mode **automatic operation** in the Master and Follower device is blocked for security reasons. Once the communication error has been cleared, the blocking is removed.

For more information about setting a GOOSE connection between the devices, refer to the following chapter.

7.9.3.10 Creating a GOOSE Later Binding for Parallel Control

To create the GOOSE later binding between the devices for parallel control, proceed as described in the following example:

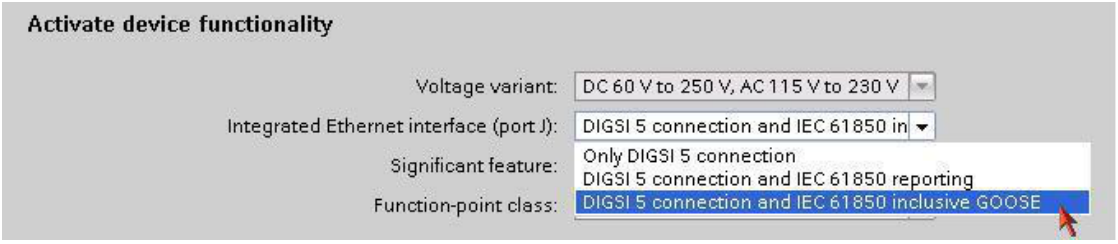


[dw_overview_sys-config_and_iec61850-goose, 1, en_US]

Figure 7-139 Example of a Parallel Control

Step 1

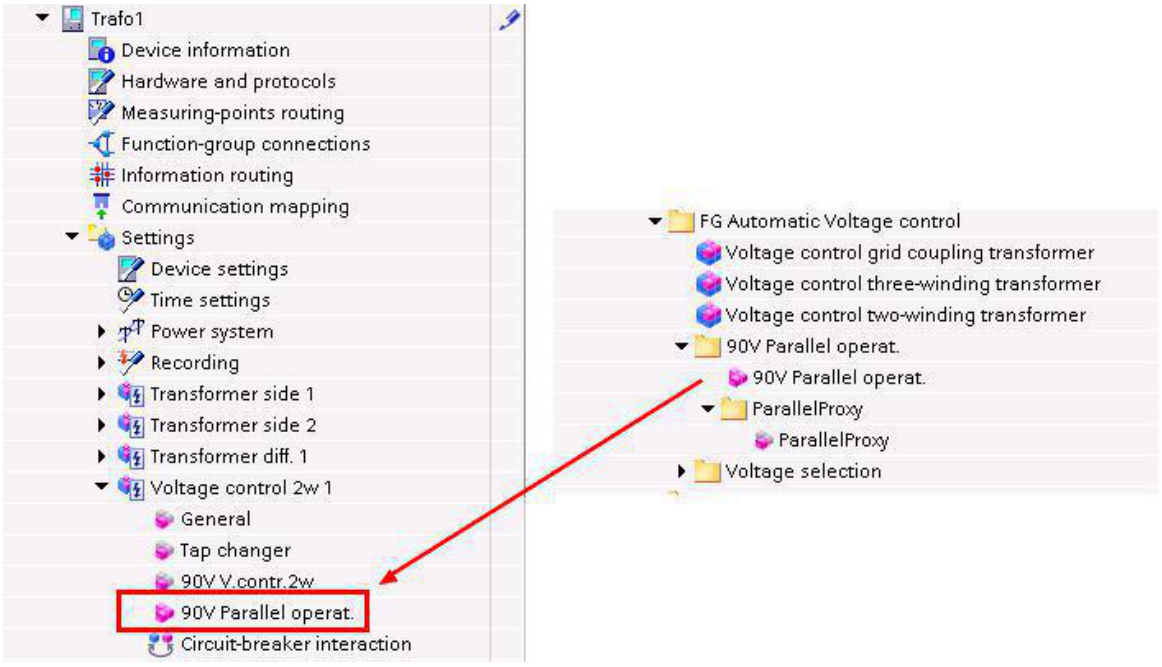
- Create the 1st device for parallel control in the DIGSI 5 project.
- Create the configurations and make the necessary settings for the IEC 61850 structure.



[sc_para_dev_set, 1, en_US]

Figure 7-140 IEC 61850 Structure Settings

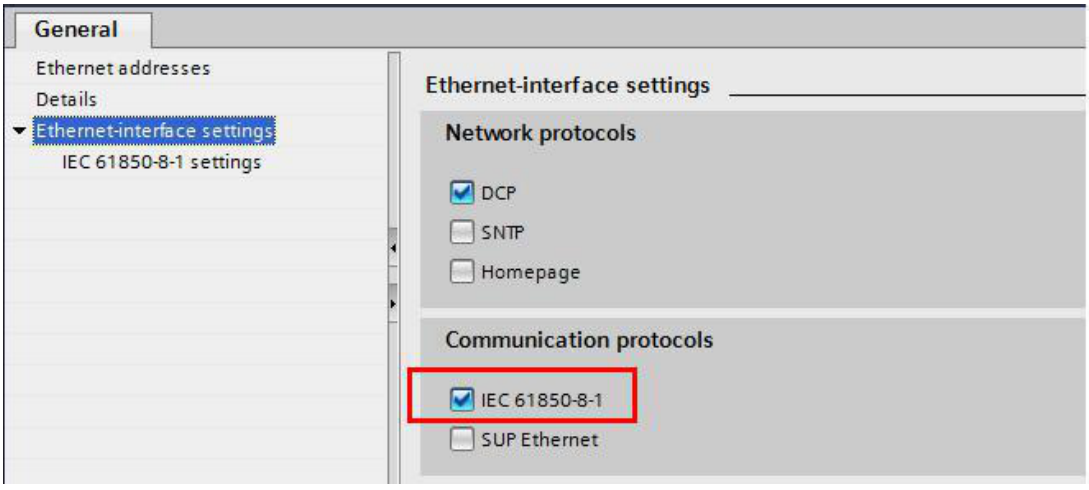
For using Port J for the GOOSE communication:



- Activate the device functionality for Port J.

[sc_para_dev_func, 1, en_US]

Figure 7-141 Setting for the Integrated Ethernet Interface



- Instantiate the voltage controller function for the two-winding transformer and the **`Parallel control`** function and the proxies that are necessary for parallel operation. One **`ParallelProxy`** is required for each transformer to be controlled in parallel, that is, for 3 transformers in the project, it must be additionally instantiate 2 **`ParallelProxies`**.

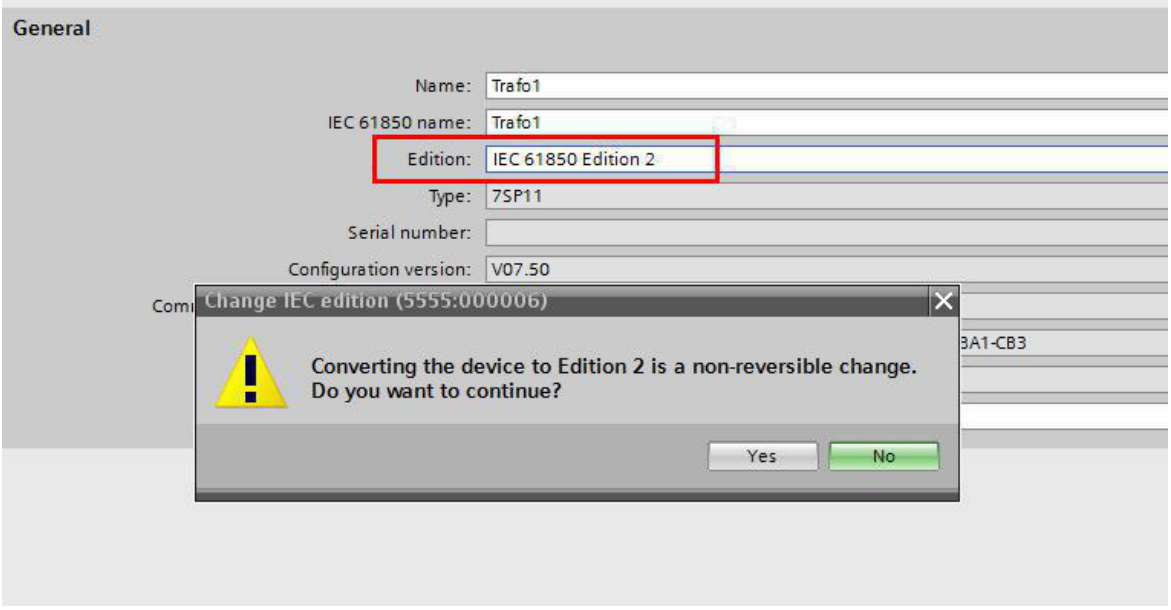
[sc_para_instanz, 1, en_US]

Figure 7-142 Selecting Parallel Control

- Make the necessary communication settings.

[sc_para_com_prot, 1, en_US]

Figure 7-143 Ethernet-interface settings



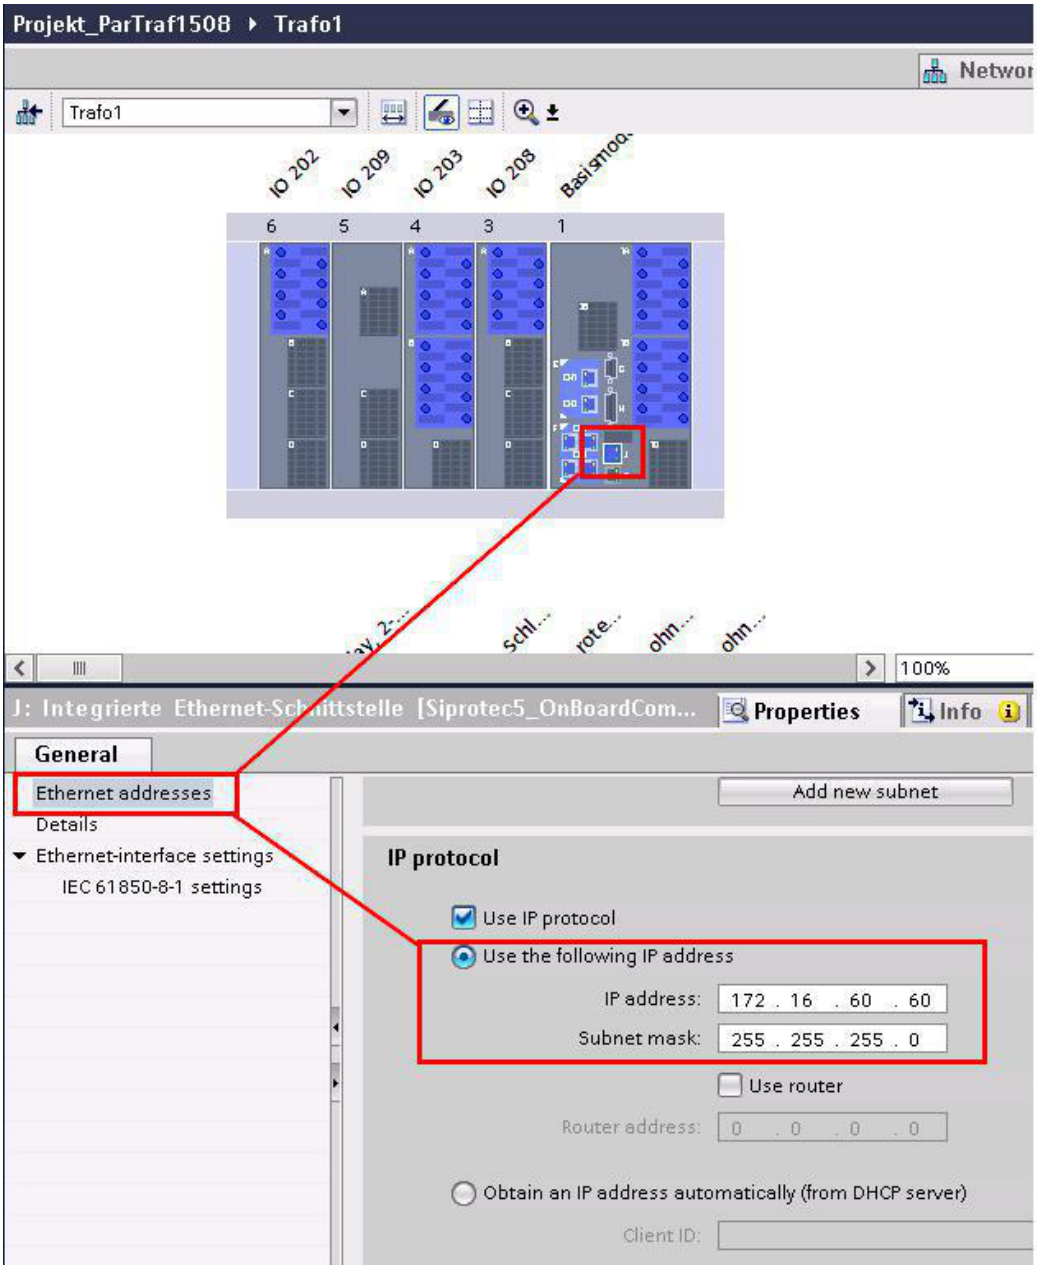
NOTE

Note that you must assign a separate IP address for each device.

NOTE

Note the hardware equipment of the device and the settings for the IEC 61850 communication (IEC 61850 Edition 2 required).

- Under **Device Information** in DIGSI, change IEC 61850 Edition 1 to Edition 2.

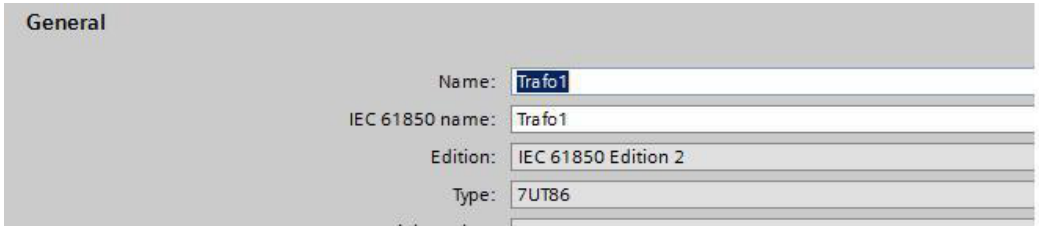


[sc_change_edition, 1, en_US]

Figure 7-144 Changing the IEC 61850 Edition

- Confirm the conversion to IEC 61850 Edition 2 with *Yes*.

Step 2

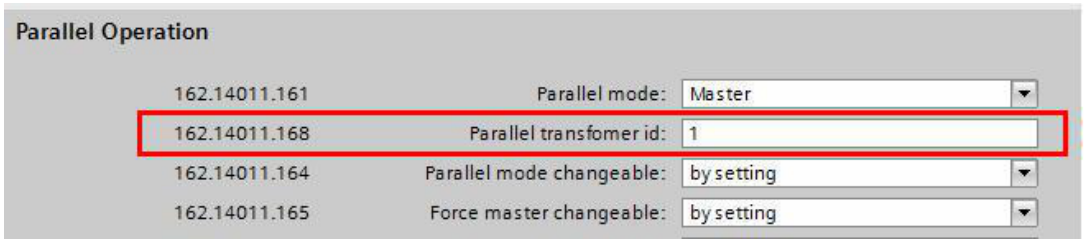


- Copy the 1st device as many times as are needed for the parallel transformers. The copied devices contain the same settings.
- Adapt the IP addresses of the copied devices in the project tree under **Hardware and protocols**.

[sc_para_ether_port], 1, en_US]

Figure 7-145 Adapting the IP Address

- Adapt the entries of the copied devices for the other transformers (device name and IEC 61850 name).



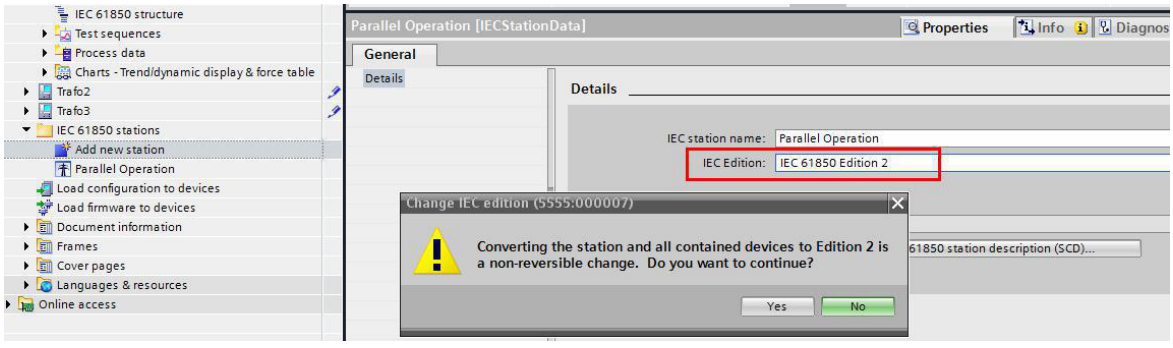
[sc_lbnametrafo, 1, en_US]

Figure 7-146 Adapting the Devices in DIGSI

- Assign a unique transformer ID for the other transformers in the copied devices.

NOTE

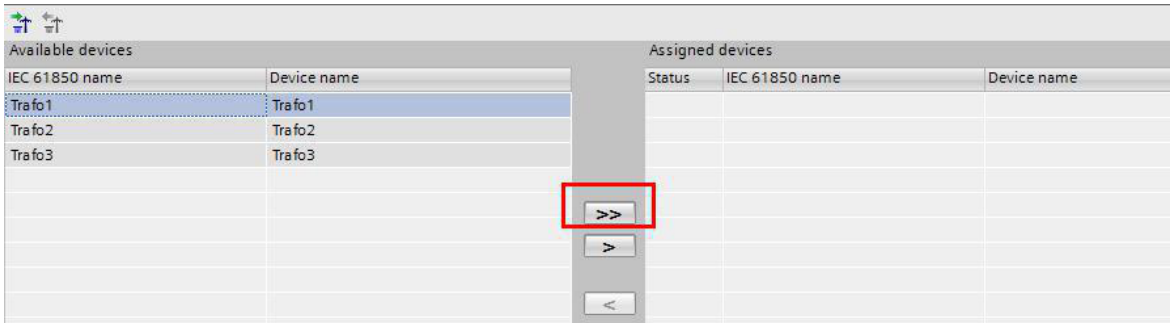
Note that in the Master-Follower method, you must configure one device as the Master device and the additional devices as Follower devices.



[sc_par_trafo_id, 1, en_US]

Figure 7-147 Adapting the Parallel Transformer ID in DIGSI

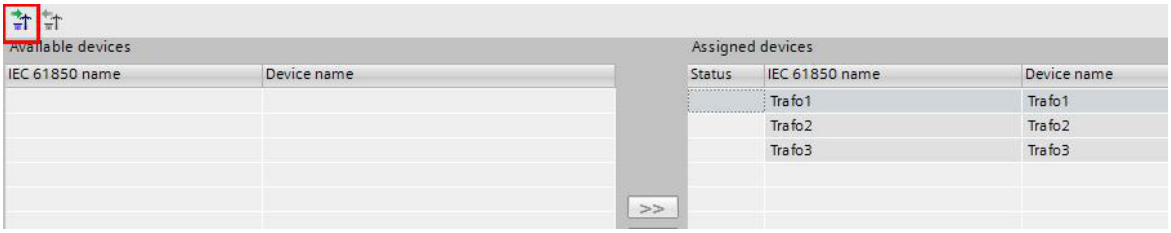
Step 3



- Double-click *Add new station*.
- Double-click the first IEC 61850 station.
- Change the IEC 61850 station name for example in parallel operation.
- Change IEC 61850 Edition 1 to Edition 2.

[sc_par_stat_iec_edi, 1, en_US]

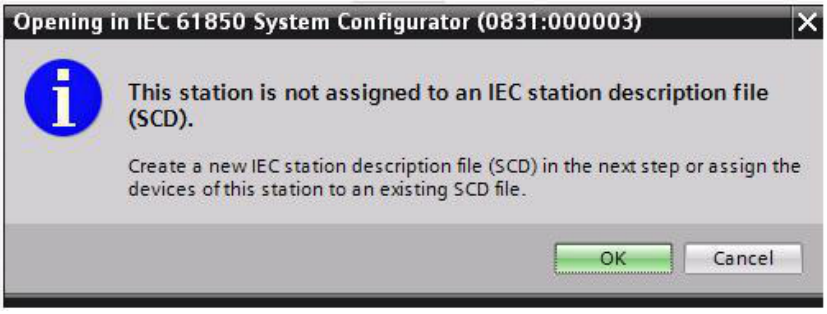
Figure 7-148 Selecting the IEC 61850 Edition



- Confirm the conversion to IEC 61850 Edition 2 with *Yes*.
- Use **>>** to assign the devices to the IEC 61850 station.

[sc_par_assign_syscon, 1, en_US]

Figure 7-149 Assigning the Devices

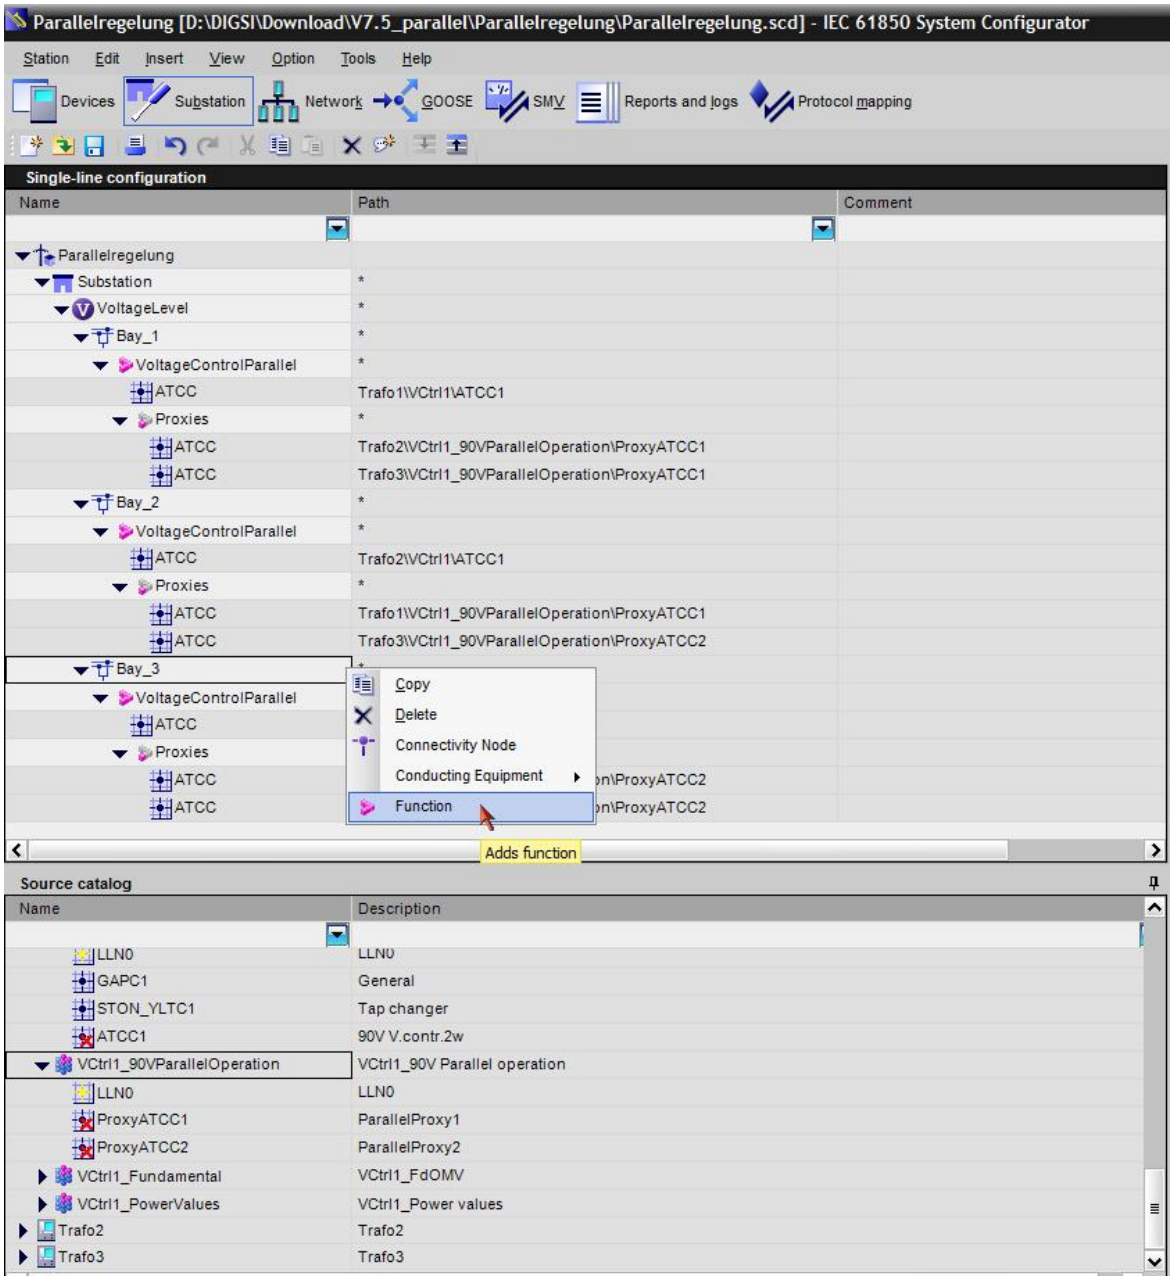


- Export the IEC 61850 station as an ICD file to the IEC 61850 System Configurator.

[sc_par_exp_syscon, 1, en_US]

Figure 7-150 Export to the IEC 61850 System Configurator

If the following dialog appears, confirm with OK and specify a storage location for the SCD file.



[sc_para_assinged, 1, en_US]

Figure 7-151 Export dialog

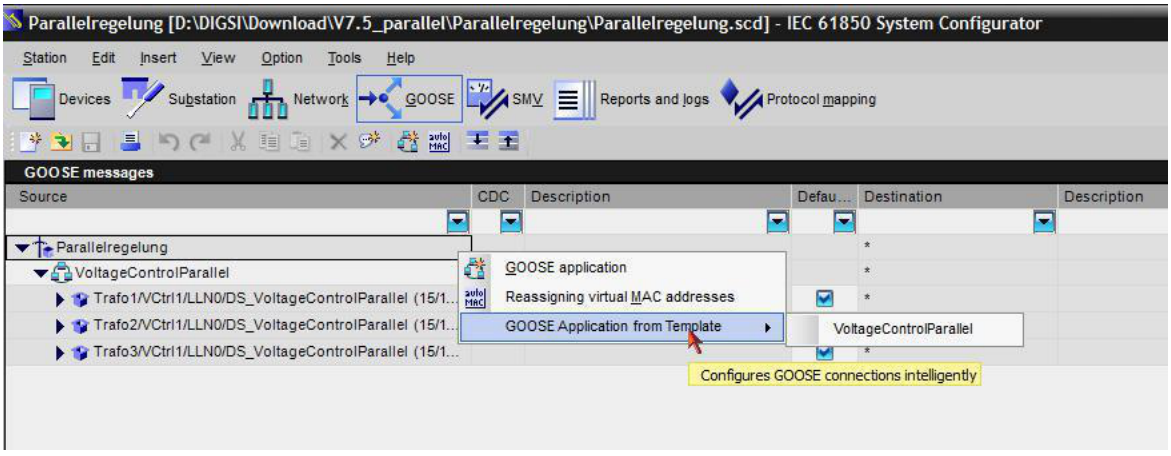
Step 4

- Import the ICD files into the system configurator. After the export to the system configurator, the configurator starts automatically.
- Create a single-line configuration in the system configurator.

[sc_para_single_line_konfig, 1, en_US]

Figure 7-152 Creating a Single-Line Configuration in the System Configurator

- Create a substation. Right-click Parallel operation and select *Substation*.
- Create the individual bays (bays 1-3) and instantiate for each a function and subfunction.
- Rename the *function* to *VoltageControlParallel*.
- Rename the *subfunction* to *Proxies*.



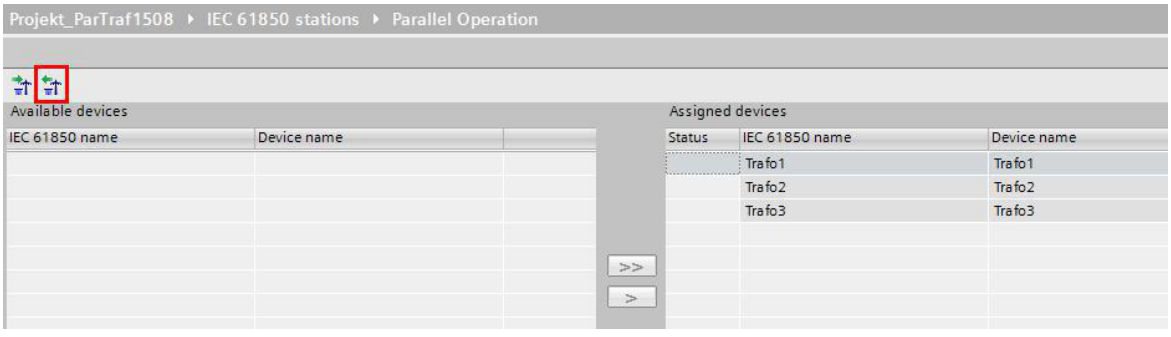
NOTE

If you use the specified function and subfunction names, the GOOSE application will be created without faults.

- Connect the LN *Trafo1\VCtrl1\ATCC1* of the device to the function and the other LN *Trafo2\Ctrl_90VParalleloperation\ProxyATCC1* to the proxies according to *Figure 7-152*.

Step 5

- Create a new GOOSE application and subsequently perform the GOOSE later binding using the application template. With the GOOSE application template, all the links between the devices and the proxies are automatically connected.
- Set all the settings for GOOSE communication between the Master and the Follower devices in the IEC 61850 System Configurator.
- If you have done all the links and settings in the IEC 61850 System Configurator, save the project and close the IEC 61850 System Configurator.



[sc_parasyscon_goose, 1, en_US]

Figure 7-153 Creating the GOOSE Application

Step 6

- Import the SCD file generated and stored in the IEC 61850 System Configurator back to DIGSI.

[sc_para_import, 1, en_US]

Figure 7-154 Import from the IEC 61850 System Configurator into DIGSI

- Load the created configuration to the devices.

7.9.3.11 Functional Measured Values

You can read the current status of the measured values for the two-winding transformer, the parallel control/proxy, the three-winding and grid coupling transformer at any time. The following tables show you the available measured values.

Measured Values, Two-Winding Transformer

Measured Value	Description	Primary	Secondary	% Referenced to
V act.	Current, measured positive-sequence voltage (referenced to phase-to-phase)	kV	V	Target voltage of the primary system referenced to the rated voltage
ΔV act.	Voltage difference between the target voltage and the actual voltage	%	%	Voltage difference referenced to the rated voltage of the controlled winding
I load	Current measured load current (positive-sequence system)	A	A	Load current referenced to the rated value of the function
V max	Maximum positive-sequence voltage ever measured (referenced to phase-to-phase)	kV	V	Maximum voltage of the winding referenced to the rated voltage of the winding
V min	Minimum positive-sequence voltage ever measured (reference to phase-to-phase)	kV	V	Minimum voltage of the winding referenced to the rated voltage of the winding
V target	Calculated target voltage with consideration of Z compensation	kV	V	Target voltage of the winding referenced to the rated voltage of the winding
PhAng	Phase angle of the currently measured load current	°	°	-
I load Σ	Sum of the currently measured load currents. Active when line compensation is activated.	A	A	Load current referenced to the rated current of the function
I circul.	Currently measured circulating reactive current	A	A	Circulating reactive current
Vact.m	Currently measured control voltage	kV	V	Current voltage of the control referenced to the rated voltage of the function
ΔV act V	Voltage difference	%	%	Voltage difference referenced to the rated voltage of the function
ΔV act C	Voltage difference	%	%	Voltage difference referenced to the rated voltage of the function

The function measured values V max and V min can be reset with the input indication *>Reset min./max.*.
For the **two-winding transformer**, you can find the measured values under the following menu entries of the device:

- Main menu → Measurements → Voltage control 2w → 90V V.contr.2w
- Main menu → Measurements → Voltage control 2w → Statistics → 90V V.contr.2w

Measured Values for Parallel Control, Proxy

Measured Value	Description	Primary	Secondary	% Referenced to
V act.	Actual voltage of winding	kV	V	Target voltage of the primary system referenced to the rated voltage of the function
1/X trf.	Susceptance, internal value for GOOSE transmission	1/Ω		

Measured Value	Description	Primary	Secondary	% Referenced to
I load	Load current	A	-	Load current referenced to the rated current of the function
PhAng	Phase angle of the load current relative to the voltage with a power factor of 1.0	°	°	Phase angle of the load current 100 % = 180°

For the **parallel control**, you can find the measured values under the following menu entries of the device:

- Main menu → Measurements → Voltage control 2w → Functional measured values → Parallel operation

Measured Values, Three-Winding Transformer

Measured Value	Description	Primary	Secondary	% Referenced to
Vact.w1	Actual voltage of winding 1	kV	V	Target voltage of the primary system referenced to the rated voltage
Vact.w2	Actual voltage of winding 2	kV	V	Target voltage of the primary system referenced to the rated voltage
ΔV act.	Voltage difference between the target voltage and the actual voltage	%	%	Voltage difference referenced to the rated voltage of the controlled winding
I load w1	Load current of winding 1	A	A	Load current referenced to the rated current of winding 1
I load w2	Load current of winding 2	A	A	Load current referenced to the rated current of winding 2
Vmax 1	Maximum voltage of winding 1	kV	V	Maximum voltage of winding 1 referenced to the rated voltage of winding 1
Vmax 2	Maximum voltage of winding 2	kV	V	Maximum voltage of winding 2 referenced to the rated voltage of winding 2
Vmin 1	Minimum voltage of winding 1	kV	V	Minimum voltage of winding 1 referenced to the rated voltage of winding 1
Vmin 2	Minimum voltage of winding 2	kV	V	Minimum voltage of winding 2 referenced to the rated voltage of winding 2
V tar.w1	Target voltage of winding 1	kV	V	Target voltage of winding 1 referenced to the rated voltage of winding 1
V tar.w2	Target voltage of winding 2	kV	V	Target voltage of winding 2 referenced to the rated voltage of winding 2

The function measured values Vmax 1, Vmax 2, Vmin 1, and Vmin 2 can be reset with the input indication *>Reset min./max.*.

For the **three-winding transformer**, you can find the measured values under the following menu entries of the device:

- Main menu → Measurements → Voltage control 3w → 90V V.contr.3w
- Main menu → Measurements → Voltage control 3w → Statistics → 90V V.contr.3w

Measured Values Grid Coupling Transformer

Measured Value	Description	Primary	Secondary	% Referenced to
Vact.w1	Actual voltage of winding 1	kV	V	Target voltage of the primary system referenced to the rated voltage
Vact.w2	Actual voltage of winding 2	kV	V	Target voltage of the primary system referenced to the rated voltage
ΔV act.	Voltage difference between the target voltage and the actual voltage	%	%	Voltage difference referenced to the rated voltage of the controlled winding
I load w1	Load current of winding 1	A	A	Load current referenced to the rated current of winding 1
I load w2	Load current of winding 2	A	A	Load current referenced to the rated current of winding 2
Vmax 1	Maximum voltage of winding 1	kV	V	Maximum voltage of winding 1 referenced to the rated voltage of winding 1
Vmax 2	Maximum voltage of winding 2	kV	V	Maximum voltage of winding 2 referenced to the rated voltage of winding 2
Vmin 1	Minimum voltage of winding 1	kV	V	Minimum voltage of winding 1 referenced to rated voltage of winding 1
Vmin 2	Minimum voltage of winding 2	kV	V	Minimum voltage of winding 2 referenced to rated voltage of winding 2
V tar.w1	Target voltage of winding 1	kV	V	Target voltage of winding 1 referenced to the rated voltage of winding 1
V tar.w2	Target voltage of winding 2	kV	V	Target voltage of winding 2 referenced to the rated voltage of winding 2

The function measured values Vmax 1, Vmax 2, Vmin 1, and Vmin 2 can be reset with the input indication *>Reset min./max.*.

For the **grid coupling transformer**, you can find the measured values under the following menu entries of the device:

- Main menu → Measurements → Voltage control gc → 90V V.contr.gc
- Main menu → Measurements → Voltage control gc → Statistics → 90V V.contr.gc

Fundamental-Component Values and Power Measured Values

The fundamental-component values and power measured values are always present in the **Two-winding transformer voltage controller**, **Three-winding transformer voltage controller**, and **Grid coupling transformer voltage controller** function groups. Furthermore, you can find the fundamental-component values and power measured values for winding 1 and winding 2 in the **Three-winding transformer voltage controller** and **Grid coupling transformer voltage controller** function groups. These values cannot be deleted.

The following tables show *Table 7-32* and *Table 7-33* the total scope for the case in which a 3-phase voltage measuring point is also connected.

Table 7-32 Possible Fundamental Values for the Voltage Controller Function Group

Fundamental-Component Values		Primary	Secondary	% Referenced to
I_A, I_B, I_C	Phase currents	A	A	Rated operating current of the primary system
I_N	Zero-sequence current	A	A	Rated operating current of the primary system
V_A, V_B,V_C	Phase-to-ground voltages	kV	V	Rated operating voltage of the primary system/√3
V_{AB}, V_{BC}, V_{CA}	Phase-to-phase voltages	kV	V	Rated operating voltage of the primary system
V_N	Measured neutral-point displacement voltage	kV	V	Rated operating voltage of the primary system/√3

Table 7-33 Possible Power Measured Values of the Voltage Controller Function Group

Power Measured Value		Primary	Secondary	% Referenced to
P_{total}	Active power (total power)	MW	W	Active power of the primary system $\sqrt{3} \cdot V_{rated} \cdot I_{rated}$
Q_{total}	Reactive power (total power)	Mvar	var	Reactive power of the primary system $\sqrt{3} \cdot V_{rated} \cdot I_{rated}$
S_{total}	Apparent power (total power)	MVA	VA	Apparent power of the primary system $\sqrt{3} \cdot V_{rated} \cdot I_{rated}$
Cos φ	Active power factor	(abs)	(abs)	100 % corresponds to cos φ = 1

7.9.4 Application and Setting Notes

7.9.4.1 General

The following application and setting notes refer to a two-winding transformer. The additional parameters for a three-winding transformer or a grid coupling transformer are marked correspondingly.

Parameter: Rated current

- Default setting **(_:2311:101) Rated current** = ***1000.00 A***

Parameter: Rated voltage

- Default setting **(_:2311:102) Rated voltage** = ***400.00 kV***

The measured values of the voltage controller can be displayed as primary values, secondary values, or in percent. With the **Rated current** and **Rated voltage** parameters, you set the reference value for the percentage values.

Additional Parameters for the Three-Winding Transformer or the Grid Coupling Transformer
Winding 1 **Parameter:** Rated current • Default setting **(_:2311:101) Rated current** = ***1000.00 A*** **Parameter:** Rated voltage • Default setting **(_:2311:103) Rated voltage** = ***400.00 kV*** **Winding 2** **Parameter:** Rated current • Default setting **(_:2311:102) Rated current** = ***1000.00 A*** **Parameter:** Rated voltage • Default setting **(_:2311:104) Rated voltage** = ***400.00 kV*** The measured values of the voltage controller can be displayed as primary values, secondary values, or in percent. With the **Rated current** and **Rated voltage** parameters, you set the reference value for the percentage values.

Tap Changer

The parameters of the tap changer inside the voltage controller correspond to those of the tap changer in chapter *7.8.2 Application and Setting Notes*.

For the tap changer inside the voltage controller, the parameters for the control model are copies of those from the voltage controller. This concerns the parameters:

- Checking the switching authority
- Control model
- SBO[62] Time-out
- Feedback.monitor.time

General

Parameter: Mode

- Default setting **(_:14011:1) Mode** = ***on***

With the **Mode** parameter, you switch the voltage controller in ***on***, ***off***, or in ***test*** operation.

Parameter: Operating mode

- Default setting **(_:14011:101) Operating mode** = ***Manual***

With the **Operating mode** parameter, you specify whether the voltage controller operates in ***Auto*** or in ***Manual*** mode.

Parameter: Minimal voltage

- Default setting **(_:14011:104) Minimal voltage** = ***5 %***

With the **Minimal voltage** parameter, you specify the threshold value at which the voltage controller operates. If the value is below the set threshold value, the entire measurement is not displayed and the binary output *Auto inactive* is activated.

62 In the IEC 61850 standard, reservation is known as Select Before Operate (SBO).

Three-Winding Transformer only:

Parameter: Winding selection

- Default setting **(_:15601:157) Winding selection** = ***Winding 1***

With the **Winding selection** parameter, you specify whether the voltage controller controls the voltage of ***Winding 1*** or ***Winding 2***. With the ***WithMaxLoad*** parameter, the voltage to be controlled is selected automatically depending on the load current. With this method, you can toggle using the parameter **Winding selection** or the controllable *Automatic winding selection*.

If the controllable *Automatic winding selection* is set to **Off** or is not set, you can influence the winding to be controlled using the following 2 options:

- Using the **Winding selection** parameter
- Using the *Manual winding selection* controllable

The function value *Active winding* shows the winding selection.

Grid Coupling Transformer only:

Parameter: Winding selection

- Default setting **(_:16351:161) Winding selection** = ***Winding 1***

With the **Winding selection** parameter, you specify whether the voltage controller controls the voltage of ***Winding 1*** or ***Winding 2***.

You may select the winding to be controlled using the **Winding selection** parameter or the *Manual winding selection* controllable. The function value *Active winding* shows the winding selection.

7.9.4.2 Controlling

Parameter: Check switching authority

- Default setting **(_:107) Check switching authority** = ***yes***

With the **Check switching authority** parameter, you specify whether the switching authority (**On-site**, **Remote**) is checked during an adjusting command.

Parameter: Control model

- Default setting **(_:109) Control model** = ***SBO w. enh. security***

This parameter **Control model** specifies the control model according to IEC 61850-7-2 that corresponds to the behavior of the data (SBO – Select Before Operate).

You can select one of the following settings:

- ***direct w. normal secur.***
- ***SBO w. normal secur.***
- ***direct w. enh. security***
- ***SBO w. enh. security***

Parameter: SBO time-out

- Default setting **(_:110) SBO time-out** = ***30.00 s***

This parameter specifies the time for detecting the time-out of the SBO command. The range of values extends from 0.01 s to 1800.00 s. This is the time that can elapse between command acceptance and command execution (command model as per IEC 61850-7-2).

Parameter: Feedback monitoring time

- Default setting **(_:111) Feedback monitoring time** = ***10.00 s***

Reaching a new tap position after the adjusting command is monitored via the feedback-monitoring time. If a new tap position is not reached, the command is canceled after this time.

7.9.4.3 Voltage Controller

Parameter: Measured value

- Default setting **(_:14011:100) Measured value** = ***positive-seq. voltage***

With the parameter **Measured value**, you select the control voltage with which the voltage controller operates. Depending on the connection type, you can select the following settings between measured and calculated voltage.

positive-seq. voltage
VA measured
VB measured
VC measured
VAB measured
VBC measured
VCA measured
VAB calculated
VBC calculated
VCA calculated

Parameter: Number of target voltage

- Default setting **(_:14011:156) Number of target voltage** = ***1***

With this parameter, you specify the number of available **target voltages** (**1** to **4**). You can select a target voltage from those available using the function key, communication, or binary input.

NOTE

Keep in mind that the parameter **Number of target voltage** cannot be influenced by way of the settings group switching.

You can specify the **target voltages** (**1** to **4**) in primary, secondary, or in percent.

For the activation of the target voltage 1 to 4 via a binary input, you need a CFC chart.

Parameter: Target voltage 1

- Default setting **(_:14011:112) Target voltage 1** = ***110.000 V***

With the **Target voltage 1**parameter, you specify the voltage to be reached by the voltage controller.

Parameter: Target voltage 2

- Default setting **(_:14011:157) Target voltage 2** = ***110.000 V***

With the **Target voltage 2** parameter, you specify the 2nd voltage to be reached by the voltage controller.

Parameter: Target voltage 3

- Default setting **(_:14011:158) Target voltage 3** = ***110.000 V***

With the **Target voltage 3** parameter, you specify the 3rd voltage to be reached by the voltage controller.

Parameter: Target voltage 4

- Default setting **(_:14011:159) Target voltage 4** = ***110.000 V***

With the **Target voltage 4** parameter, you specify the 4th voltage to be reached by the voltage controller.

Three-Winding Transformer only:

Parameter: Number of target voltage

- Default setting **(_:15601:164) Number of target voltage** = *1*

With this parameter, you specify the number of available **target voltages** (**1 W1/2** to **4 W1/2**). You can select a target voltage from those using the function key, communication, or binary input.

Note:

Keep in mind that the parameter **Number of target voltage** cannot be influenced by way of the settings group switching.

You can specify the **target voltages** (**1 W1/2** to **4 W1/2**) in primary, secondary, or in percent.

For the activation of the target voltage 1 to 4 via a binary input, you need a CFC chart.

Parameter: Target voltage 1 w1

- Default setting **(_:15601:112) Target voltage 1 w1** = *110.000 V*

Parameter: Target voltage 1 w2

- Default setting **(_:15601:146) Target voltage 1 w2** = *110.000 V*

Parameter: Target voltage 2 w1

- Default setting **(_:15601:165) Target voltage 2 w1** = *110.000 V*

Parameter: Target voltage 2 w2

- Default setting **(_:15601:168) Target voltage 2 w2** = *110.000 V*

Parameter: Target voltage 3 w1

- Default setting **(_:15601:166) Target voltage 3 w1** = *110.000 V*

Parameter: Target voltage 3 w2

- Default setting **(_:15601:169) Target voltage 3 w2** = *110.000 V*

Parameter: Target voltage 4 w1

- Default setting **(_:15601:167) Target voltage 4 w1** = *110.000 V*

Parameter: Target voltage 4 w2

- Default setting **(_:15601:170) Target voltage 4 w2** = *110.000 V*

Grid Coupling Transformer only:

Parameter: Number of target voltage

- Default setting **(_:16351:164) Number of target voltage** = *1*

With this parameter, you specify the number of available **target voltages** (**1 W1/2** to **4 W1/2**). You can select a target voltage from those using the function key, communication, or binary input.

Note:

Keep in mind that the parameter **Number of target voltage** cannot be influenced by way of the settings group switching.

You can specify the **target voltages** (**1 W1/2** to **4 W1/2**) in primary, secondary, or in percent.

For the activation of the target voltage 1 to 4 via a binary input, you need a CFC chart.

Parameter: Target voltage 1 w1

- Default setting **(_:16351:112) Target voltage 1 w1** = *110.000 V*

Parameter: Target voltage 1 w2

- Default setting **(_:16351:146) Target voltage 1 w2** = *110.000 V*

Parameter: Target voltage 2 w1

- Default setting **(_:16351:165) Target voltage 2 w1** = *110.000 V*

Parameter: Target voltage 2 w2

- Default setting **(_:16351:168) Target voltage 2 w2** = *110.000 V*

Parameter: Target voltage 3 w1

- Default setting **(_:16351:166) Target voltage 3 w1** = *110.000 V*

Parameter: Target voltage 3 w2

- Default setting **(_:16351:169) Target voltage 3 w2** = *110.000 V*

Parameter: Target voltage 4 w1

- Default setting **(_:16351:167) Target voltage 4 w1** = *110.000 V*

Parameter: Target voltage 4 w2

- Default setting **(_:16351:170) Target voltage 4 w2** = *110.000 V*

Parameter: Bandwidth

- Default setting **(_:113) Bandwidth** = *1.0 %*

With the **Bandwidth** parameter, you specify the voltage range where no control action higher or lower is to occur at the **Target voltage 1**. If the actual voltage is outside the bandwidth referenced to the **Target voltage 1**, a correction is made.

Calculation of the **Bandwidth**:

NOTE

When calculating the **Bandwidth** B, keep the maximum accepted voltage deviation in the electrical power system and the tap voltage of the tap changer on the secondary side of the transformer in mind. Select the bandwidths so that it is not passed through within an increment.

NOTE

Instable Controlling (Hunting)

The tolerance band is defined by the double bandwidth. If you select the bandwidth – and thus the admissible control deviation D – such that the tolerance band is smaller than the increment of the transformer, then, with the next increment operation, the voltage controller adjusts over the other side of the band after exceeding the tolerance band. In this case, stable controlling is not possible. This operation is also referred to as ***Hunting***. Also note that the load of the tap changer, – that is the number of increments performed – increases the lower the bandwidth.

On the secondary side, the increment ΔV_{sec} is not linear. The largest $\Delta V_{max,sec}$ in an increment results with the increment to the highest stage (smallest ratio) and with maximum power-system voltage on the primary side.

$$\Delta V_{max,sec} = \left[\frac{V_{rated,sec}}{V_{N,prim}} - \frac{V_{rated,sec}}{V_{(N-1),prim}}\right] \cdot V_{max,prim}$$

[fobdnvrz-150816, 1, en_US]

If the control deviation and the bandwidth are thus correlated, this results in a minimal bandwidth that is to be set:

$$B \geq 0.6 \cdot \frac{\Delta V_{max,sec}}{V_{rated,obj}} \cdot 100\ \%$$

[fospnvrz-150816, 1, en_US]

$V_{rated,sec}$	Secondary rated voltage of the transformer
$V_{N,prim}$	Primary tap voltage of the transformer of stage N
$V_{(N-1),prim}$	Primary tap voltage of the transformer of stage N-1
$V_{max,prim}$	Maximum primary voltage of the transformer
$V_{max,sec}$	Maximum secondary voltage of the transformer

Parameter: T1 characteristic

- Default setting **(_:114) T1 characteristic** = ***Linear***

Parameter: T1 delay

- Default setting **(_:115) T1 delay** = ***40 s***

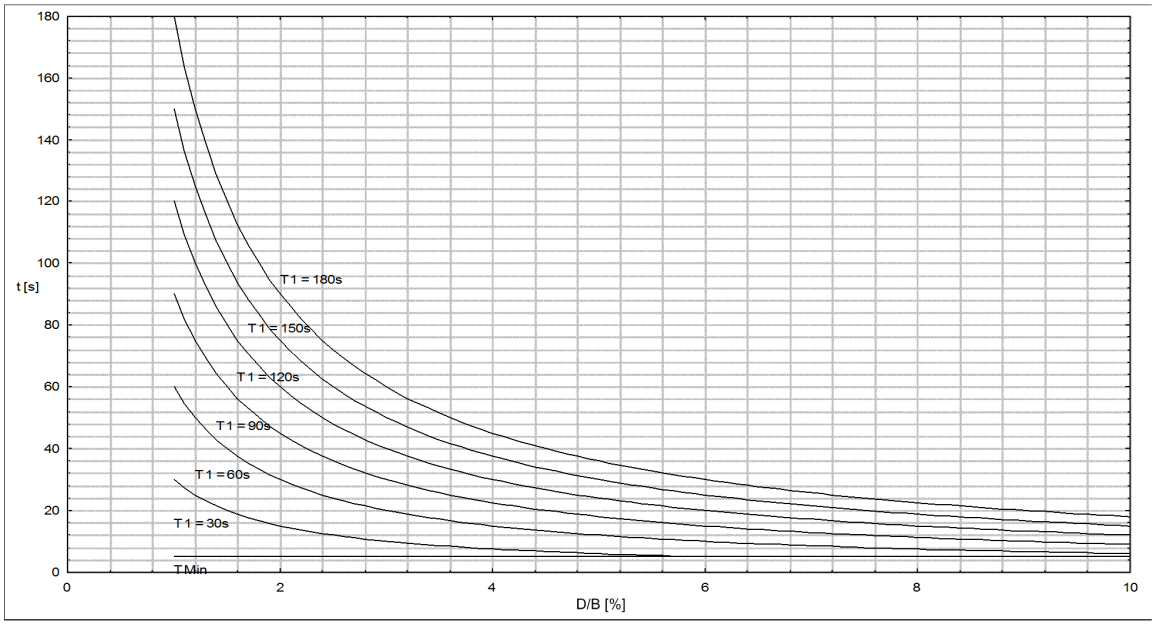
You can adjust the control action so that the smallest number of adjusting commands possible is necessary. To do so, use **T1 characteristic** to set the control response and **T1 delay** to set a time delay.

In the ***Linear*** setting (linear control response), the control response is independent of the voltage deviation. A constant time delay applies here.

In the ***Inverse*** setting (inverse control response), the time delay is a function of the voltage deviation referenced to **Target voltage 1**. The greater the control deviation, the faster the control response. The control quality improves, but the switching frequency increases. If the voltage control is blocked during the time delay, the accumulated time delay **T1 delay** is reset.

The effective time delay is the result of:

$$t_{1_delay} = \frac{T_1 \cdot B}{|D|}$$



[fovrzzet-211013, 2, en_US]

T_1 – Parameter **T1 delay**

$$D = \frac{V_{act} - V_{target}}{V_{rated}} 100\ \%$$

[fokonisk-211013, 2, en_US]

D = Control deviation

[dwrglchr-160913-01.vsd, 2, en_US]

Figure 7-155 Inverse Control Characteristic

Parameter: T1 Inverse Min

- Default setting **(_:116) T1 Inverse Min** = ***5 s***

With the **T1 Inverse Min** parameter, you define the minimum time delay for the control action. This time applies only to the control response ***Inverse*** and the response cannot be shorter.

Parameter: T2 delay

- Default setting **(_:117) T2 delay** = ***5 s***

With the **T2 delay** parameter, you set the time the tap changer has to wait from one tap position to the next. During this time, several adjusting commands can be sent to the tap changer in one direction, which permits a correction of the actual voltage. The time delay T2 has an independent characteristic. The time T2 is generally set shorter than the time T1. If the time T2 is switched off by a setting equal to 0, the delay T1 is always active. If the voltage control is blocked during the time delay, the accumulated time delays **T1 delay** and **T2 delay** are reset.

Parameter: Fast step up

- Default setting **(_:118) Fast step up** = ***off***

Parameter: Fast step up limit

- Default setting **(_:119) Fast step up limit** = ***-6.0 %***

Parameter: Fast step up T delay

- Default setting **(_:120) Fast step up T delay** = ***2.0 s***

With this parameter, you specify the time delay of the fast step-up mode. If the actual voltage is less than the value of the limit for the fast step-up mode (_:119), the fast step up mode is activated. A fast step-up mode is not activated if the value drops below the voltage limit for only a brief period within the time delay. If the voltage control is blocked during the time delay, the accumulated time delay **Fast step up T delay** is reset.

Parameter: Fast step down

- Default setting **(_:121) Fast step down** = ***on***

Parameter: Fast step down limit

- Default setting **(_:122) Fast step down limit** = ***6.0 %***

Parameter: Fast step down T delay

- Default setting **(_:123) Fast step down T delay** = ***0.0 s***

With this parameter, you specify the time delay of the fast step-down mode. If the actual voltage is greater than the value of the limit for the fast step-down mode (_:122), the fast step-down mode is activated. A fast step-down mode is not activated if the voltage limit is exceeded for only a brief period within the time delay. If the voltage control is blocked during the time delay, the accumulated time delay **Fast step down T delay** is reset.

Parameter: Function monitoring

- Default setting **(_:124) Function monitoring** = ***15 min***

You can delay the pickup of the function monitor. With the **Function monitoring** = ***0 min*** parameter, the function monitor is switched off.

Grid Coupling Transformer only:
Parameter: Power-flow supervision • Default setting **(_:16351:162) Power-flow supervision** = ***on*** With the **Power-flow supervision** parameter, you monitor the power flow. You can switch the parameter on or off.

Parameter: Regulate with T2 at start

- Default setting **(_:14011:155) Regulate with T2 at start** = ***on***
