3.22.3 Real multiplication MULR

3.22.3.1 Function block

Figure 174: Function block

3.22.3.2 Functionality

The real multiplication function MULR multiplies the real input REAL_IN1 by the real input REAL_IN2 together. MULR executes the equation

REAL_OUT = REAL_IN1 x REAL_IN2

If the value of the product is outside the range, then the output quality is set as bad and VALID is set to FALSE. The minimum negative product value is restricted to -2097152.000 and the maximum positive product value is restricted to 2097152.000.

3.22.3.3 Signals

3.22.4 Real subtraction SUBR

3.22.4.1 Function block

Figure 175: Function block

3.22.4.2 Functionality

The real subtraction function SUBR subtracts input REAL_IN2 from REAL_IN1. SUBR executes the equation

REAL_OUT = REAL_IN1 – REAL_IN2

If the value of the difference is outside the range, then the output quality is set as bad and VALID is set to FALSE. The minimum negative difference value is restricted to –2097152.000 and the maximum positive difference value is restricted to 2097152.000.

3.22.4.3 Signals

3.22.5 Real equal comparator EQR

3.22.5.1 Function block

Figure 176: Function block

3.22.5.2 Functionality

The real equal comparator function EQR compares the real input REAL_IN1 with the real input REAL_IN2 and activates the binary output OUT if REAL_IN1 is within the region of REAL_IN2 + TOLR and REAL_IN2 –TOLR, that is, if REAL_IN1 ≥ (REAL_IN2 – TOLR) and REAL_IN1 ≤ (REAL_IN2 + TOLR), OUT = 1, else OUT = 0.

If inputs REAL_IN1 or REAL_IN2 are outside the range, then OUT is set to 0.

Figure 177: Region of EQR comparison

EQR requires a positive value for TOLR, otherwise it may not function properly. The TOLR value can be set using SETRGAPC.

EQR function blocks do not have the hysteresis feature. Oscillating outputs should be avoided when comparing analog signals that have closely varying values.

3.22.5.3 Signals

Table 323: EQR Input signals

3.22.6 Real not equal comparator NER

3.22.6.1 Function block

Figure 178: Function block

3.22.6.2 Functionality

The real not equal comparator function NER compares the real input REAL_IN1 with the real input REAL_IN2 and activates the binary output OUT if REAL_IN1 is outside the region of REAL_INT2 + TOLR and REAL_IN2 - TOLR. That is, if REAL_IN1 < (REAL_IN2 - TOLR) or REAL_IN1 > (REAL_IN2 + TOLR), OUT= 1, else OUT = 0.

If inputs REAL_IN1 or REAL_IN2 are outside the range, then OUT is set to 0.

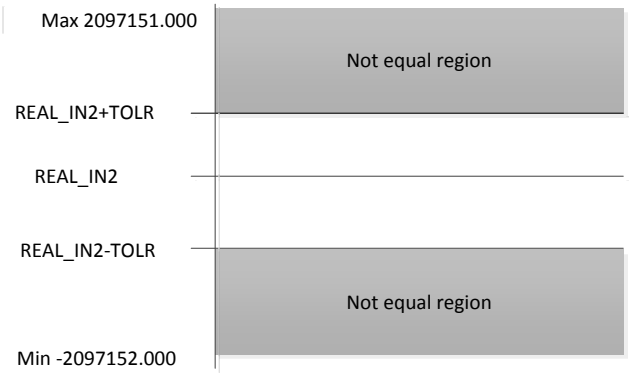

Figure 179: Region of NER comparison

NER requires a positive value for TOLR, otherwise it may not function properly. The TOLR value can be set using SETRGAPC.

NER function blocks do not have the hysteresis feature. Oscillating outputs should be avoided when comparing analog signals that have closely varying values.

3.23 Factory settings restoration

In case of configuration data loss or any other file system error that prevents the protection relay from working properly, the whole file system can be restored to the original factory state. All default settings and configuration files stored in the factory are restored. For further information on restoring factory settings, see the operation manual.

3.24 Load profile LDPRLRC (ANSI LOADPROF)

3.24.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Load profile recorder	LDPRLRC	LOADPROF	LOADPROF

3.24.2 Function block

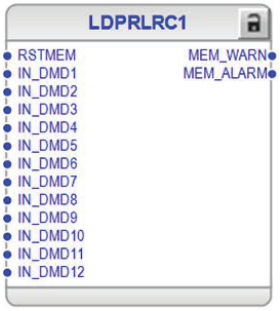

Figure 188: Function block

3.24.3 Functionality

The protection relay is provided with a load profile recorder. The load profile feature stores the historical load data captured at a periodical time interval (demand interval). Up to 12 load quantities can be selected for recording and storing in a nonvolatile memory. The value range for the recorded load quantities is about eight times the nominal value, and values higher than that saturate. The recording time depends on a settable demand interval parameter and the amount of quantities selected. The record output is in the COMTRADE format.

3.24.3.1 Quantities

Table 341: Signals supported by the load profile recorder

Function	Signal	Description
CMMXU	I_DMD_A	Demand value of IL1 current
	I_DMD_B	Demand value of IL2 current
	I_DMD_C	Demand value of IL3 current

Table continues on the next page

Function	Signal	Description
PEMMXU	S_DMD	Demand value of apparent power
	P_DMD	Demand value of active power
	Q_DMD	Demand value of reactive power
	PF_DMD	Demand value of power factor
RESCMMXU	I_DMD_RES	Demand value of residual current
VMMXU	U_DMD_AB	Demand value of U12 voltage
	U_DMD_BC	Demand value of U23 voltage
	U_DMD_CA	Demand value of U31 voltage
	U_DMD_A	Demand value of UL1 voltage
	U_DMD_B	Demand value of UL2 voltage
	U_DMD_C	Demand value of UL3 voltage
RESVMMXU	U_DMD_RES	Demand value of residual voltage
VAMMXU	U_DMD	Demand value of phase voltage

If the data source for the selected quantity is removed, for example, with Application Configuration in PCM600, the load profile recorder stops recording it and the previously collected data are cleared.

3.24.3.2 Length of record

The recording capability is about 7.4 years when one quantity is recorded and the demand interval is set to 180 minutes. The recording time scales down proportionally when a shorter demand time is selected or more quantities are recorded. The recording lengths in days with different settings used are presented in *Table 342*. When the recording buffer is fully occupied, the oldest data are overwritten by the newest data.

Table 342: Recording capability in days with different settings

	Demand interval						
	1 minute	5 minutes	10 minutes	15 minutes	30 minutes	60 minutes	180 minutes
Amount of quantities	**Recording capability in days**						
1	15.2	75.8	151.6	227.4	454.9	909.7	2729.2
2	11.4	56.9	113.7	170.6	341.1	682.3	2046.9

Table continues on the next page

	Demand interval						
3	9.1	45.5	91.0	136.5	272.9	545.8	1637.5
4	7.6	37.9	75.8	113.7	227.4	454.9	1364.6

10	3.8	19.0	37.9	56.9	113.7	227.4	682.3
11	3.5	17.5	35.0	52.5	105.0	209.9	629.8
12	3.2	16.2	32.5	48.7	97.5	194.9	584.8

3.24.3.3 Uploading of record

The protection relay stores the load profile COMTRADE files to the C:\LDP\COMTRADE folder. The files can be uploaded with the PCM600 tool or any appropriate computer software that can access the C:\LDP\COMTRADE folder.

The load profile record consists of two COMTRADE file types: the configuration file (.CFG) and the data file (.DAT). The file name is same for both file types.

To ensure that both the uploaded file types are generated from the same data content, the files need to be uploaded successively. Once either of the files is uploaded, the recording buffer is halted to give time to upload the other file.

Data content of the load profile record is sequentially updated. Therefore, the size attribute for both COMTRADE files is "0".

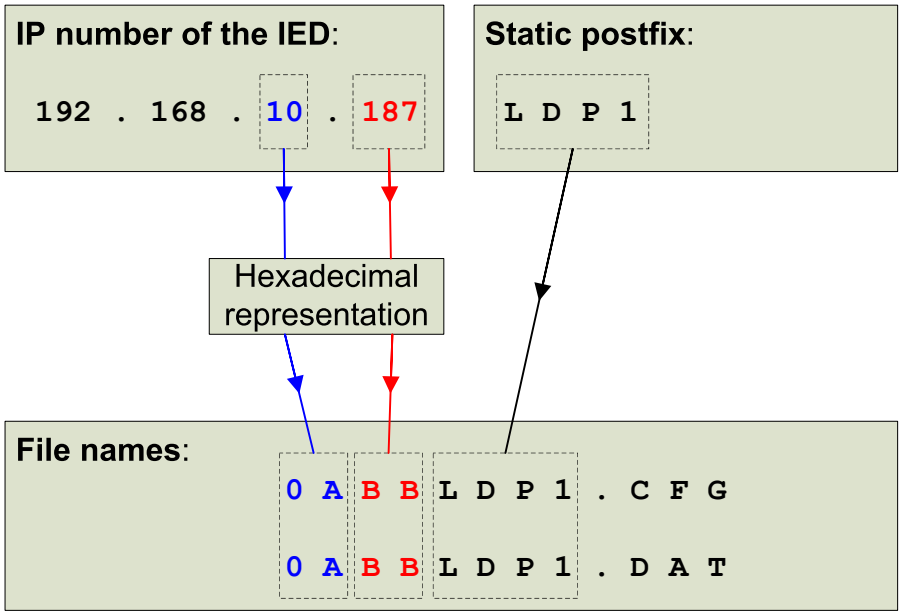

Figure 189: Load profile record file naming

3.24.3.4 Clearing of record

The load profile record can be cleared with *Reset load profile rec* via HMI, communication or the ACT input in PCM600. Clearing of the record is allowed only on the engineer and administrator authorization levels.

The load profile record is automatically cleared if the quantity selection parameters are changed or any other parameter which affects the content of the COMTRADE configuration file is changed. Also, if data source for selected quantity is removed, for example, with ACT, the load profile recorder stops recording and previously collected data are cleared.

3.24.4 Configuration

The load profile record can be configured with the PCM600 or any tool supporting the IEC 61850 standard.

The load profile record can be enabled or disabled with the *Operation* setting under the **Configuration/Load Profile Record** menu.

Any demand output can be connected to any of the quantity channels of the load profile record. The mapping is done in Application Configuration in PCM600.

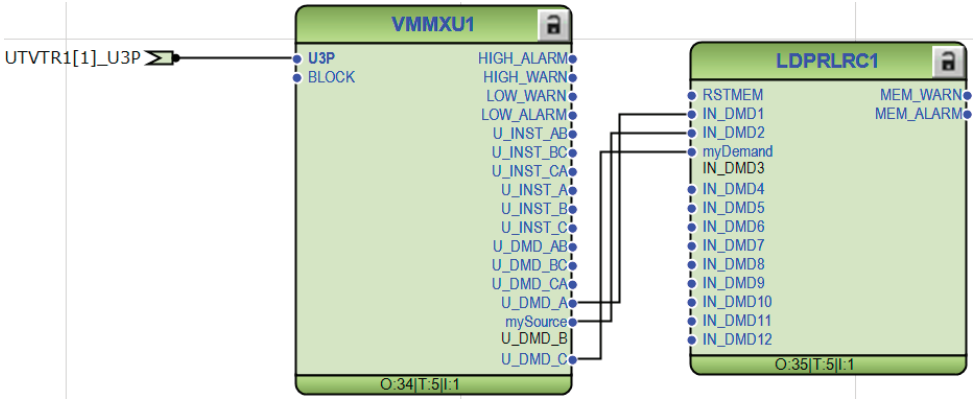

Figure 190: Example of a load profile record ACT configuration

The memory consumption of load profile record is supervised, and indicated with two signals `MEM_WARN` and `MEM_ALARM`, which could be used to notify the customer that recording should be backlogged by reading the recorded data from the protection relay. The levels for MEM_WARN and MEM_ALARM are set by two parameters *Mem.warn level* and *Mem. Alarm level*.

The IP number of the protection relay and the content of the Bay name setting are both included in the COMTRADE configuration file for identification purposes.

3.24.5 Signals

3.24.5.1 LDPRLRC Output signals

3.25 Ethernet channel supervision functions

The protection relay offers a bandwidth rate limiting functionality to limit the Ethernet/TCP network traffic. The main purpose of this feature is the possibility to divide network segments for different multicast frame types and also to limit the network congestion and traffic towards the protection relay processing during network attacks (such as a Denial of Service attack) or in case of network configuration issues.

See the cyber security deployment guideline for the Ethernet filter and rate limiter functionality.

3.25.1 Redundant Ethernet channel supervision RCHLCCH

3.25.1.1 Function block

Figure 191: Function block

3.25.1.2 Functionality

Redundant Ethernet channel supervision RCHLCCH represents LAN A and LAN B redundant Ethernet channels.

3.25.1.3 Signals

Table 346: RCHLCCH Output signals

Name	Values (Range)	Description
CHLIV	BOOLEAN	Status of redundant Ethernet channel LAN A When *Redundant mode* is set to "HSR" or "PRP", value is TRUE if the protection relay is receiving redundancy supervision frames. Otherwise the value is FALSE.
REDCHLIV	BOOLEAN	Status of redundant Ethernet channel LAN B When *Redundant mode* is set to "HSR" or "PRP", value is TRUE if the protection relay is receiving redundancy supervision frames. Otherwise the value is FALSE.
LNKLIV	BOOLEAN	Link status of redundant port LAN A Valid only when *Redundant mode* is set to "HSR" or "PRP". Value is "Up" or "Down".
REDLNKLIV	BOOLEAN	Link status of redundant port LAN B Valid only when *Redundant mode* is set to "HSR" or "PRP". Value is "Up" or "Down".

3.25.1.4 Settings

Table 347: RCHLCCH Settings

Parameter	Values (Range)	Unit	Step	Default	Description
Redundant mode	Off PRP HSR				Mode selection for Ethernet switch on redundant communication modules. The "None" mode is used with normal and Self-healing Ethernet topologies.
Filter Mode A_B	Off SMV GOOSE GOOSE & SMV			Off	Filtering selection for message types
Goose rate limiter A_B	0.512...90.000			10.000	Goose rate limit (Mbps)
SMV rate limit A_B	0.512...90.000			70.000	Sampled measured values rate limit (Mbps)
Def. rate limit A_B	0.512...90.000			8.000	Default rate limit (Mbps)

3.25.1.5 Monitored data

Monitored data is available in four locations.

- **Monitoring** > **Communication** > **Ethernet** > **Activity** > **CHLIV_A**
- **Monitoring** > **Communication/** > **Ethernet** > **Activity** > **REDCHLIV_B**
- **Monitoring** > **Communication** > **Ethernet** > **Link statuses** > **LNKLIV_A**
- **Monitoring** > **Communication** > **Ethernet** > **Link statuses** > **REDLNKLIV_B**

3.25.1.6 Diagnostics

Diagnostics data is available in **Monitoring** > **Communication** > **Ethernet** > **Diagnostics** > **A_B**.

Table 348: Diagnostic parameters for the redundant Ethernet channels LAN A and LAN B

Parameter	Values (Range)	Unit	Step	Default	Description
Reset counters	FALSE / TRUE			FALSE	Reset counters command
GOOSE limit count	0...1000000			0	Goose rate limit exceed count
SMV limit count	0...1000000			0	Sampled measured values limit exceed count
Ucast limit count	0...1000000			0	Unicast rate limit exceed count
Def. limit count	0...1000000			0	Default rate limit exceed count
GOOSE limit alarm	FALSE / TRUE			FALSE	Goose rate limit exceed alarm
SMV limit alarm	FALSE / TRUE			FALSE	Sampled measured values limit alarm
Ucast limit alarm	FALSE / TRUE			FALSE	Unicast rate limit exceed alarm
Def. limit alarm	FALSE / TRUE			FALSE	Default rate limit exceed alarm

3.25.2 Ethernet channel supervision SCHLCCH

3.25.2.1 Function block

Figure 192: Function block

3.25.2.2 Functionality

Ethernet channel supervision SCHLCCH represents X1/LAN, X2/LAN and X3/LAN Ethernet channels.

An unused Ethernet port can be set "Off" with the setting **Configuration** > **Communication** > **Ethernet** > **Rear port(s)** > **Port x Mode**. This setting closes the port from software, disabling the Ethernet communication in that port. Closing an unused Ethernet port enhances the cyber security of the relay.

3.25.2.3 Signals

Table 349: SCHLCCH1 Output signals

Name	Type	Description
CH1LIV	BOOLEAN	Status of Ethernet channel X1/LAN When *Redundant mode* is set to "None" or port is not one of the redundant ports (LAN A or LAN B), value is TRUE if the port is receiving Ethernet frames. Otherwise the value is FALSE.
LNK1LIV	BOOLEAN	Link status of Ethernet port X1/LAN Value is "Up" or "Down".

Table 350: SCHLCCH2 Output signals

Name	Type	Description
CH2LIV	BOOLEAN	Status of Ethernet channel X2/LAN When *Redundant mode* is set to "None" or port is not one of the redundant ports (LAN A or LAN B), value is TRUE if the port is receiving Ethernet frames. Otherwise the value is FALSE.
LNK2LIV	BOOLEAN	Link status of Ethernet port X2/LAN Value is "Up" or "Down".

Table 351: SCHLCCH3 Output signals

Name	Type	Description
CH3LIV	BOOLEAN	Status of Ethernet channel X3/LAN When *Redundant mode* is set to "None" or port is not one of the redundant ports (LAN A or LAN B), value is TRUE if the port is receiving Ethernet frames. Otherwise the value is FALSE.
LNK3LIV	BOOLEAN	Link status of Ethernet port X3/LAN Value is "Up" or "Down".

3.25.2.4 Settings

Table 352: SCHLCCH Settings

Parameter [1]	Values (Range)	Unit	Step	Default	Description
Port n Mode	Off On Dedicated channel [2]			On	Mode selection for rear port(s). If port is not used, it can be set to "Off". Port cannot be set to "Off" when *Redundant mode* is "HSR" or "PRP" and port is one of the redundant ports (LAN A or LAN B).
Filter Mode Xn	Off SMV GOOSE GOOSE & SMV			Off	Selection for message filtering
Goose rate limiter Xn	0.512...90.000			10.000	Goose rate limit (Mbps)
SMV rate limit Xn	0.512...90.000			70.000	Sampled measured values rate limit (Mbps)
Def. rate limit Xn	0.512...90.000			8.000	Default rate limit (Mbps)

3.25.2.5 Monitored data

Monitored data is available in six locations.

- **Monitoring** > **Communication** > **Ethernet** > **Activity** > **CH1LIV**
- **Monitoring** > **Communication** > **Ethernet** > **Activity** > **CH2LIV**
- **Monitoring/** > **Communication** > **Ethernet** > **Activity** > **CH3LIV**

3.26 External HMI wake-up EIHMI

3.26.1 Function block

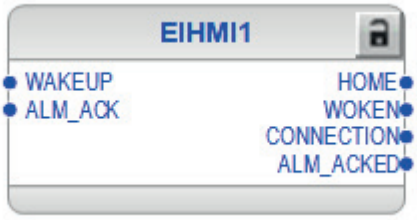

Figure 193: Function block

3.26.2 Functionality

The external HMI wake-up function EIHMI is a control block that is used to control certain parts of the HMI with Application Configuration in PCM600.

Some data can be bound to control options to enable the required features: remote HMI wake-up, remote acknowledgment of alarms, information when the device has been woken up, indication when the Home button on the HMI is activated and indication when alarms are being acknowledged either remotely or from the HMI.

All functionalities described here are applicable only to paired HMI devices.

3.26.3 Operation principle

The input signal WAKEUP is used to wake the HMI from a low-power state and restore the display's backlight if it has been dimmed or turned off. The display’s backlight can be controlled with parameter *Backlight timeout* under **Configuration** > **HMI**. The HMI remains in normal operation mode as long as there is user input from the HMI or a wake-up signal before the time set with *Backlight timeout* elapses.

The signal used to wake up the HMI is boolean rising edge. The wake-up can be triggered only after the connected signal has been in FALSE state for longer than a single function cycle.

The input signal ALM_ACK is used to acknowledge all active and fleeting alarms. These alarms are displayed on the HMI's alarms page and mini-alarms widget.

The signal used to acknowledge the alarms is boolean rising edge. Acknowledge alarms can be triggered only after the connected signal has been in the FALSE state for longer than a single function cycle. The actual acknowledgement takes effect only after the ALM_ACKED output has been in the FALSE state for longer than 100 ms.

The output signal HOME is activated when the capacitive Home button is activated on the HMI unit. This generates a boolean TRUE value pulse that persists for a

second until the output is reset to FALSE. The output remains in this state until the Home button is pressed again.

The output signal WOKEN is activated whenever the HMI device is woken from a low-power state. This generates a one-second boolean TRUE value pulse. After one second, the output is reset to FALSE. A new output can be triggered once the HMI has entered the low-power state.

The output CONNECTION is activated whenever the paired HMI is connected to the protection relay. If the communication between the protection relay and the HMI is severed, this output resets itself to FALSE until communication has been restored.

When an SHMI is connected and paired with the protection relay, the CONNECTION output is activated when the user navigates from the SHMI navigation page to the HMI view. The CONNECTION output is deactivated when the user returns to the navigation view or the connection between the relay and the SHMI is lost. The output can be used to visually indicate that the SHMI is connected to the relay in the panel, and it works as an LHMI for the relay.

The output ALM_ACKED is activated when any alarms are acknowledged either by the boolean rising edge on the ALM_ACK input or by acknowledging alarms from the HMI. This generates a one-second boolean TRUE value pulse. After one second, the output is reset to FALSE until some alarms are acknowledged. There is at least a 100 ms FALSE state between each pulse. If alarms are acknowledged from the HMI during the TRUE state or within 100 ms after resetting to FALSE, additional pulses are not be produced.

PCM600 parameters

EIHMI contains three paths to populate parameters visible in Parameter Setting in PCM600.

- **Configuration** > **HMI**
- **Monitoring** > **Detached LHMI**
- **Information** > **HW modules** > **EIHMI1**

3.26.4 Application

Substation HMI wake-up (door sensor)

In this example, substation HMI devices need to be woken up when a person enters the substation to see that everything works as expected.

A switch signal is directly connected to the binary input, which activates the paired HMI.

Depending on the hardware solution, this hardware signal can be distributed to all affected protection relays on the substation. Optionally, the processed signal can be routed in horizontal communication through process bus communications, that is, GOOSE, to other protection relays.

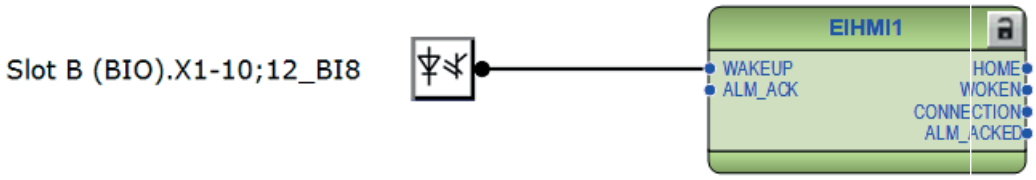

Figure 194: Binary input connection

Do not keep the HMI backlight always on as it may cause premature and unnecessary wear of the display panel.

3.26.5 Signals

Table 354: EIHMI Input signals

Name	Type	Default	Description

Three-phase non-directional overcurrent protection, instantaneous stage	PHIPTOC	3I>>>	50P

4.1.1.2 Function block

Figure 197: Function block

4.1.1.3 Functionality

The three-phase non-directional overcurrent protection function PHxPTOC is used as one-phase, two-phase or three-phase non-directional overcurrent and short-circuit protection.

The function starts when the current exceeds the set limit. The operate time characteristics for low stage PHLPTOC and high stage PHHPTOC can be selected to be either definite time (DT) or inverse definite minimum time (IDMT). The instantaneous stage PHIPTOC always operates with the DT characteristic.

In the DT mode, the function operates after a predefined operate time and resets when the fault current disappears. The IDMT mode provides current-dependent timer characteristics.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.1.1.4 Analog input configuration

PHxPTOC has one analog group input which must be properly configured.

Table 362: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PHxPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

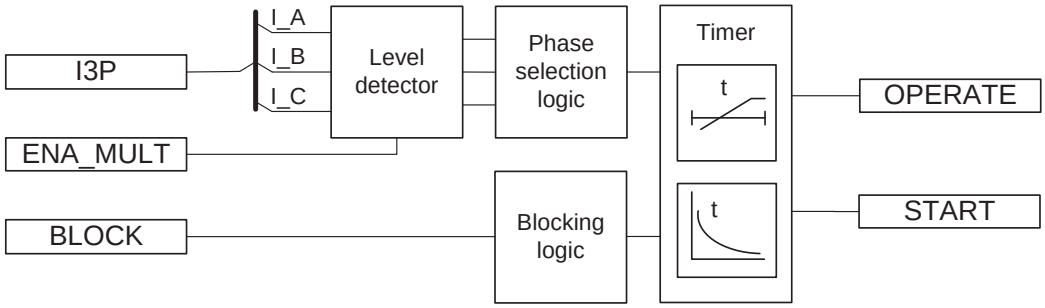

Figure 198: Functional module diagram

Level detector

The measured phase currents are compared phasewise to the set *Start value*. If the measured value exceeds the set *Start value*, the level detector reports the exceeding of the value to the phase selection logic. If the `ENA_MULT` input is active, the *Start value* setting is multiplied by the *Start value Mult* setting.

The protection relay does not accept the *Start value* or *Start value Mult* setting if the product of these settings exceeds the *Start value* setting range.

The start value multiplication is normally done when the inrush detection function (INRPHAR) is connected to the ENA_MULT input.

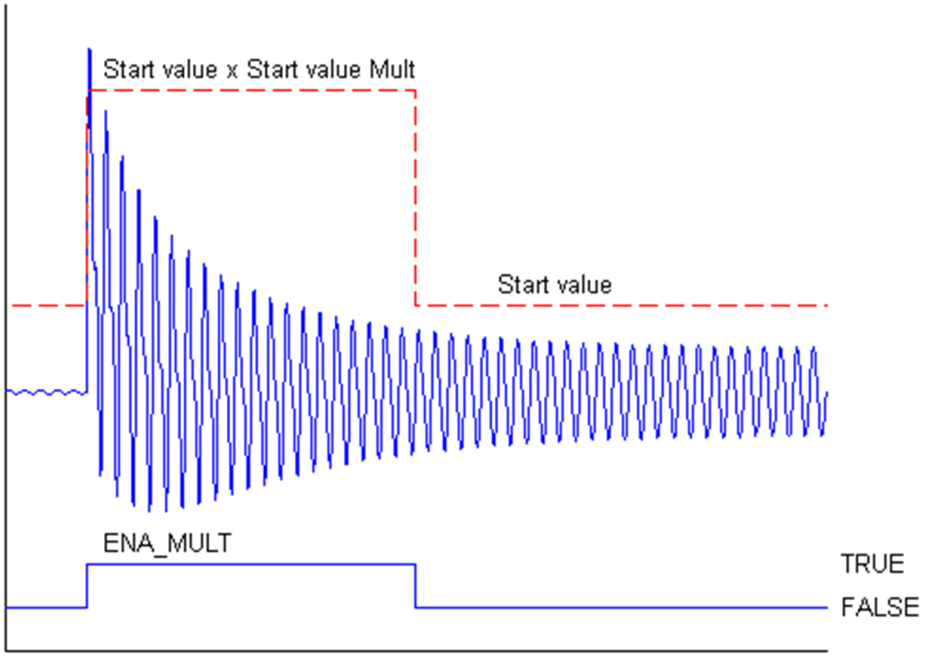

Figure 199: Start value behavior with ENA_MULT input activated

Phase selection logic

If the fault criteria are fulfilled in the level detector, the phase selection logic detects the phase or phases in which the measured current exceeds the setting. If the phase information matches the *Num of start phases* setting, the phase selection logic activates the timer module.

Timer

Once activated, the timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate"

causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operate and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.1.1.6 Measurement modes

The function operates on four alternative measurement modes: "RMS", "DFT", "Peak-to-Peak" and "P-to-P + backup". Additionally, there is “Wide P-to-P” measurement mode in some products variants. The measurement mode is selected with the setting *Measurement mode*.

Table 363: Measurement modes supported by PHxPTOC stages

Measurement mode	PHLPTOC	PHHPTOC	PHIPTOC
RMS	x	x	
DFT	x	x	
Peak-to-Peak	x	x	
P-to-P + backup			x
Wide P-to-P	x [2]		

For a detailed description of the measurement modes, see *Chapter 11.6 Measurement modes* in this manual.

4.1.1.7 Timer characteristics

PHxPTOC supports both DT and IDMT characteristics. The user can select the timer characteristics with the *Operating curve type* and *Type of reset curve* settings. When the DT characteristic is selected, it is only affected by the *Operate delay time* and *Reset delay time* settings.

The protection relay provides 16 IDMT characteristics curves, of which seven comply with the IEEE C37.112 and six with the IEC 60255-3 standard. Two curves follow the special characteristics of ABB praxis and are referred to as RI and RD. One curve is for rectifier bridge protection. In addition to this, a user programmable curve can be used if none of the standard curves are applicable. The DT characteristics can be chosen by selecting the *Operating curve type* values "ANSI Def. Time" or "IEC Def. Time". The functionality is identical in both cases.

The timer characteristics supported by different stages comply with the list in the IEC 61850-7-4 specification, indicate the characteristics supported by different stages:

Table 364: Timer characteristics supported by different stages

Operating curve type	PHLPTOC	PHHPTOC
(1) ANSI Extremely Inverse	x	x
(2) ANSI Very Inverse	x	
(3) ANSI Normal Inverse	x	x
(4) ANSI Moderately Inverse	x	
(5) ANSI Definite Time	x	x
(6) Long Time Extremely Inverse	x	
(7) Long Time Very Inverse	x	
(8) Long Time Inverse	x	
(9) IEC Normal Inverse	x	x
(10) IEC Very Inverse	x	x
(11) IEC Inverse	x	
(12) IEC Extremely Inverse	x	x
(13) IEC Short Time Inverse	x	
(14) IEC Long Time Inverse	x	
(15) IEC Definite Time	x	x
(17) User programmable	x	x
(18) RI type	x	
(19) RD type	x	
(20) UK rectifier	x	

[2] Available only in REG615 standard configurations C and D

PHIPTOC supports only definite time characteristic.

For a detailed description of timers, see *Chapter 11 General function block features* in this manual.

Table 365: Reset time characteristics supported by different stages

Reset curve type	PHLPTOC	PHHPTOC	Note
(1) Immediate	x	x	Available for all operate time curves
(2) Def time reset	x	x	Available for all operate time curves
(3) Inverse reset	x	x	Available only for ANSI and user programmable curves

The *Type of reset curve* setting does not apply to PHIPTOC or when the DT operation is selected. The reset is purely defined by the *Reset delay time* setting.

4.1.1.8 Application

PHxPTOC is used in several applications in the power system. The applications include but are not limited to:

- Selective overcurrent and short-circuit protection of feeders in distribution and subtransmission systems
- Backup overcurrent and short-circuit protection of power transformers and generators
- Overcurrent and short-circuit protection of various devices connected to the power system, for example shunt capacitor banks, shunt reactors and motors
- General backup protection

PHxPTOC is used for single-phase, two-phase and three-phase non-directional overcurrent and short-circuit protection. Typically, overcurrent protection is used for clearing two and three-phase short circuits. Therefore, the user can choose how many phases, at minimum, must have currents above the start level for the function to operate. When the number of start-phase settings is set to "1 out of 3", the operation of PHxPTOC is enabled with the presence of high current in one-phase.

When the setting is "2 out of 3" or "3 out of 3", single-phase faults are not detected. The setting "3 out of 3" requires the fault to be present in all three phases.

Many applications require several steps using different current start levels and time delays. PHxPTOC consists of three protection stages.

- Low PHLPTOC
- High PHHPTOC
- Instantaneous PHIPTOC

PHLPTOC is used for overcurrent protection. The function contains several types of time-delay characteristics. PHHPTOC and PHIPTOC are used for fast clearance of very high overcurrent situations.

Transformer overcurrent protection

The purpose of transformer overcurrent protection is to operate as main protection, when differential protection is not used. It can also be used as coarse back-up protection for differential protection in faults inside the zone of protection, that is, faults occurring in incoming or outgoing feeders, in the region of transformer terminals and tank cover. This means that the magnitude range of the fault current can be very wide. The range varies from 6xI_n to several hundred times I_n, depending on the impedance of the transformer and the source impedance of the feeding network. From this point of view, it is clear that the operation must be both very fast and selective, which is usually achieved by using coarse current settings.

The purpose is also to protect the transformer from short circuits occurring outside the protection zone, that is through-faults. Transformer overcurrent protection also provides protection for the LV-side busbars. In this case the magnitude of the fault current is typically lower than 12xI_n depending on the fault location and transformer impedance. Consequently, the protection must operate as fast as possible taking into account the selectivity requirements, switching-in currents, and the thermal and mechanical withstand of the transformer and outgoing feeders.

Traditionally, overcurrent protection of the transformer has been arranged as shown in *Figure 200*. The low-set stage PHLPTOC operates time-selectively both in transformer and LV-side busbar faults. The high-set stage PHHPTOC operates instantaneously making use of current selectivity only in transformer HV-side faults. If there is a possibility, that the fault current can also be fed from the LV-side up to the HV-side, the transformer must also be equipped with LV-side overcurrent protection. Inrush current detectors are used in start-up situations to multiply the current start value setting in each particular protection relay where the inrush current can occur. The overcurrent and contact based circuit breaker failure protection CCBRBRF is used to confirm the protection scheme in case of circuit breaker malfunction.

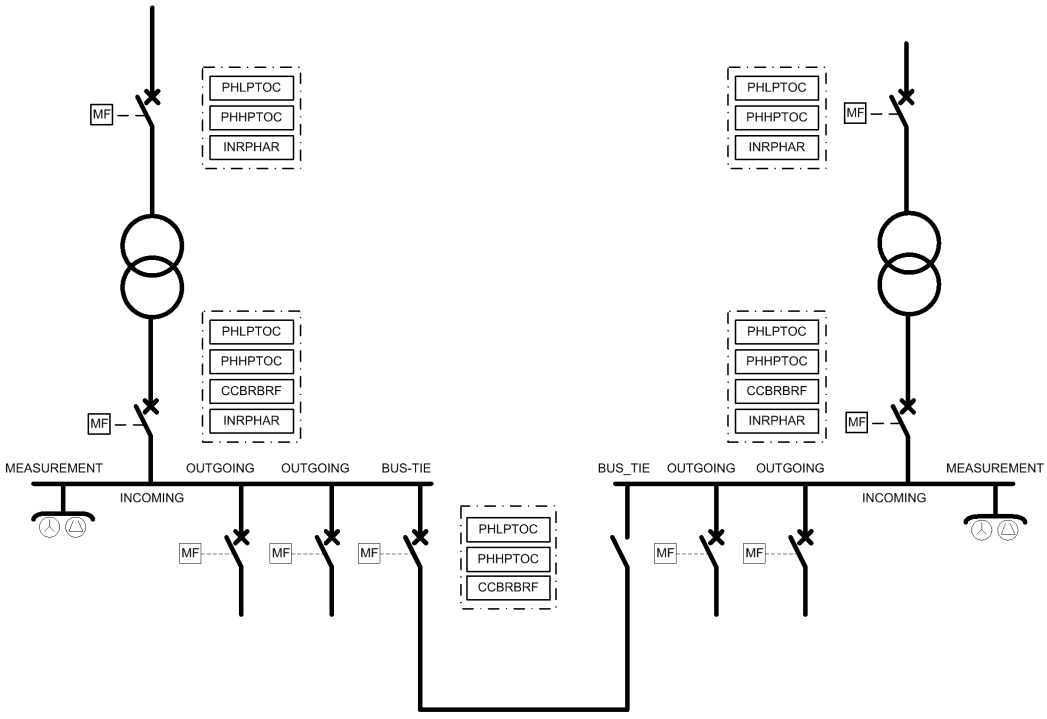

Figure 200: Example of traditional time selective transformer overcurrent protection

The operating times of the main and backup overcurrent protection of the above scheme become quite long, this applies especially in the busbar faults and also in the transformer LV-terminal faults. In order to improve the performance of the above scheme, a multiple-stage overcurrent protection with reverse blocking is proposed. *Figure 202* shows this arrangement.

Overcurrent protection with line differential protection

The line differential protection relay has also four separate overcurrent functions which can be used as the backup protection of line differential function for lines and cables. There are three stages available with definite or inverse time characteristics and an instantaneous stage.

The differential protection is available only if the communication between the units is working properly and no CT failure situation is detected. If a communication failure exists, the protect area or unit is left out from the primary protection scheme. Therefore it is practical to use overcurrent protection as a local backup functionality.

In the standard configuration of the protection relay, the backup overcurrent protection is implemented with four overcurrent stages so that under normal conditions, that is, when the line differential communication is healthy, only two lowest stages are available for the remote backup protection. In case a line differential communication failure exists, two more stages are released for rapid local backup overcurrent and short circuit protection. These stages are blocked in normal situation and automatically unblocked when the communication failure is detected. The setting of the overcurrent stages for local backup protection has to be considered carefully in order to achieve the best possible protection performance under abnormal conditions.

Two situations, case A and B, are shown in *Figure 201*. In case A, the communication media is valid and therefore the line differential protection is in operation. In this case, the two lowest stages of overcurrent protection are in operation simultaneously. In case B, a communication failure causes a situation where the line differential function is not able to work properly. Unblocking of the two highest overcurrent protection stages releases these functions to protect the line against overcurrents and short-circuits.

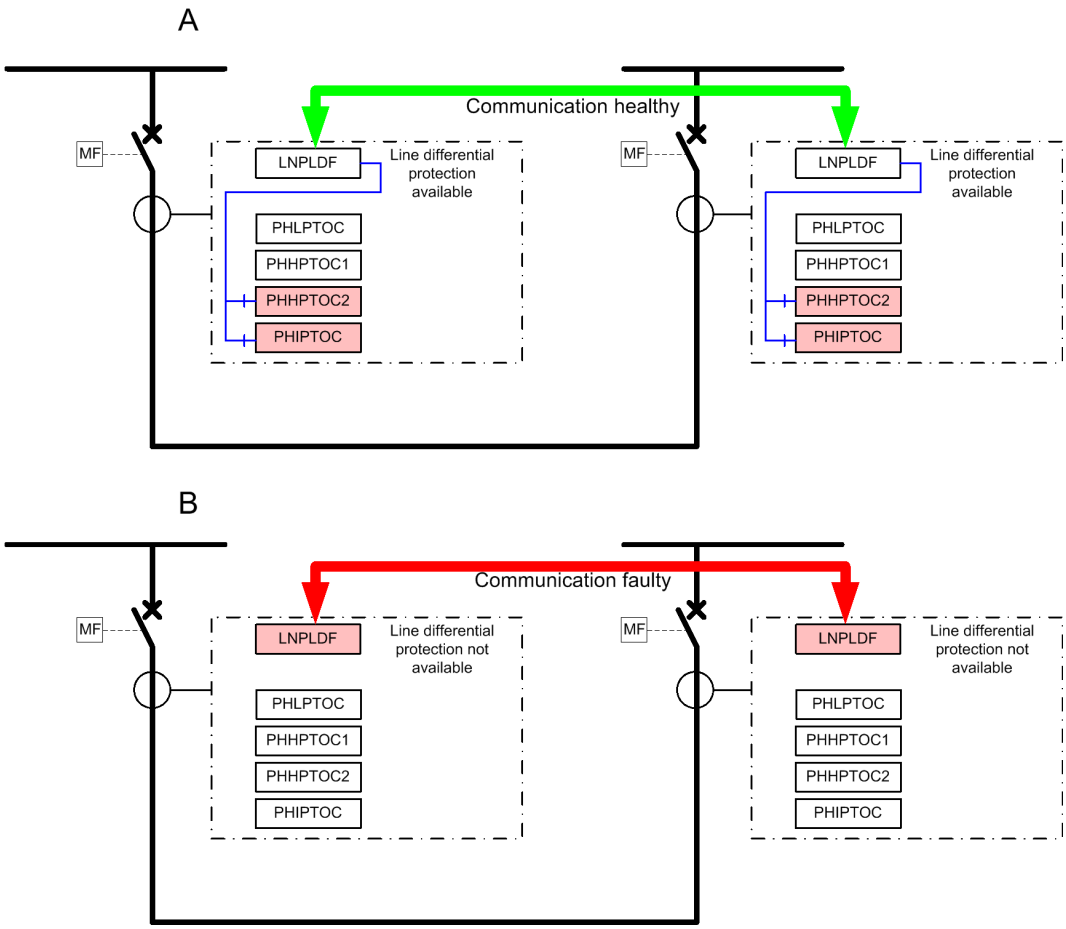

Figure 201: Backup overcurrent protection for line differential applications

Transformer and busbar overcurrent protection with reverse blocking principle

By implementing a full set of overcurrent protection stages and blocking channels between the protection stages of the incoming feeders, bus-tie and outgoing feeders, it is possible to speed up the operation of overcurrent protection in the busbar and transformer LV-side faults without impairing the selectivity. Also, the security degree of busbar protection is increased, because there is now a dedicated, selective and fast busbar protection functionality which is based on the blockable overcurrent protection principle. The additional time selective stages on the transformer HV and LV-sides provide increased security degree of backup protection for the transformer, busbar and also for the outgoing feeders.

Depending on the overcurrent stage in question, the selectivity of the scheme in *Figure 202* is based on the operating current, operating time or blockings between successive overcurrent stages. With blocking channels, the operating time of the protection can be drastically shortened if compared to the simple time selective protection. In addition to the busbar protection, this blocking principle is applicable for the protection of transformer LV terminals and short lines. The functionality and performance of the proposed overcurrent protections can be summarized as seen in the table.

Table 366: Proposed functionality of numerical transformer and busbar overcurrent protection. DT = definite time, IDMT = inverse definite minimum time

O/C-stage	Operating char.	Selectivity mode	Operation speed	Sensitivity
HV/3I>	DT/IDMT	time selective	low	very high
HV/3I>>	DT	blockable/time selective	high/low	high
HV/3I>>>	DT	current selective	very high	low
LV/3I>	DT/IDMT	time selective	low	very high
LV/3I>>	DT	time selective	low	high
LV/3I>>>	DT	blockable	high	high

In case the bus-tie breaker is open, the operating time of the blockable overcurrent protection is approximately 100 ms (relaying time). When the bus-tie breaker is closed, that is, the fault current flows to the faulted section of the busbar from two directions, the operation time becomes as follows: first the bus-tie relay unit trips the tie breaker in the above 100 ms, which reduces the fault current to a half. After this the incoming feeder relay unit of the faulted bus section trips the breaker in approximately 250 ms (relaying time), which becomes the total fault clearing time in this case.

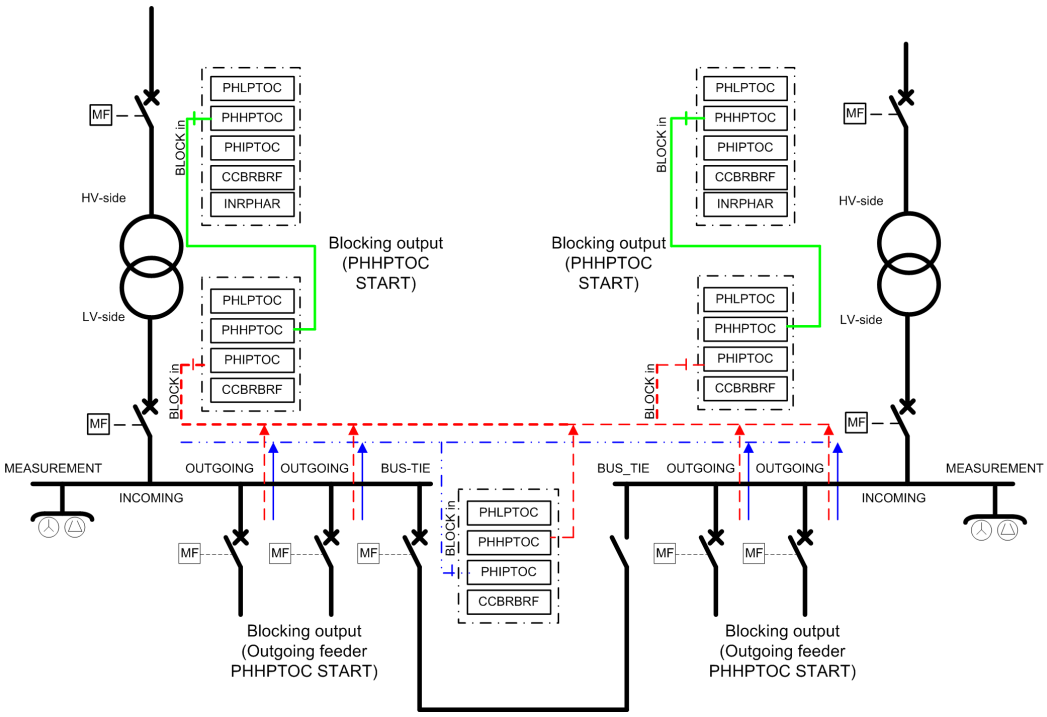

Figure 202: Numerical overcurrent protection functionality for a typical sub-transmission/distribution substation (feeder protection not shown). Blocking output = digital output signal from the start of a protection stage, Blocking in = digital input signal to block the operation of a protection stage

The operating times of the time selective stages are very short, because the grading margins between successive protection stages can be kept short. This is mainly due to the advanced measuring principle allowing a certain degree of CT saturation, good operating accuracy and short retardation times of the numerical units. So, for

example, a grading margin of 150 ms in the DT mode of operation can be used, provided that the circuit breaker interrupting time is shorter than 60 ms.

The sensitivity and speed of the current-selective stages become as good as possible due to the fact that the transient overreach is very low. Also, the effects of switching inrush currents on the setting values can be reduced by using the protection relay's logic, which recognizes the transformer energizing inrush current and blocks the operation or multiplies the current start value setting of the selected overcurrent stage with a predefined multiplier setting.

Finally, a dependable trip of the overcurrent protection is secured by both a proper selection of the settings and an adequate ability of the measuring transformers to reproduce the fault current. This is important in order to maintain selectivity and also for the protection to operate without additional time delays. For additional information about available measuring modes and current transformer requirements, see *Chapter 11.6 Measurement modes* in this manual.

Radial outgoing feeder overcurrent protection

The basic requirements for feeder overcurrent protection are adequate sensitivity and operation speed taking into account the minimum and maximum fault current levels along the protected line, selectivity requirements, inrush currents and the thermal and mechanical withstand of the lines to be protected.

In many cases the above requirements can be best fulfilled by using multiple-stage overcurrent units. *Figure 203* shows an example of this. A brief coordination study has been carried out between the incoming and outgoing feeders.

The protection scheme is implemented with three-stage numerical overcurrent protection, where the low-set stage PHLPTOC operates in IDMT-mode and the two higher stages PHHPTOC and PHIPTOC in DT-mode. Also the thermal withstand of the line types along the feeder and maximum expected inrush currents of the feeders are shown. Faults occurring near the station where the fault current levels are the highest are cleared rapidly by the instantaneous stage in order to minimize the effects of severe short circuit faults. The influence of the inrush current is taken into consideration by connecting the inrush current detector to the start value multiplying input of the instantaneous stage. By this way the start value is multiplied with a predefined setting during the inrush situation and nuisance tripping can be avoided.

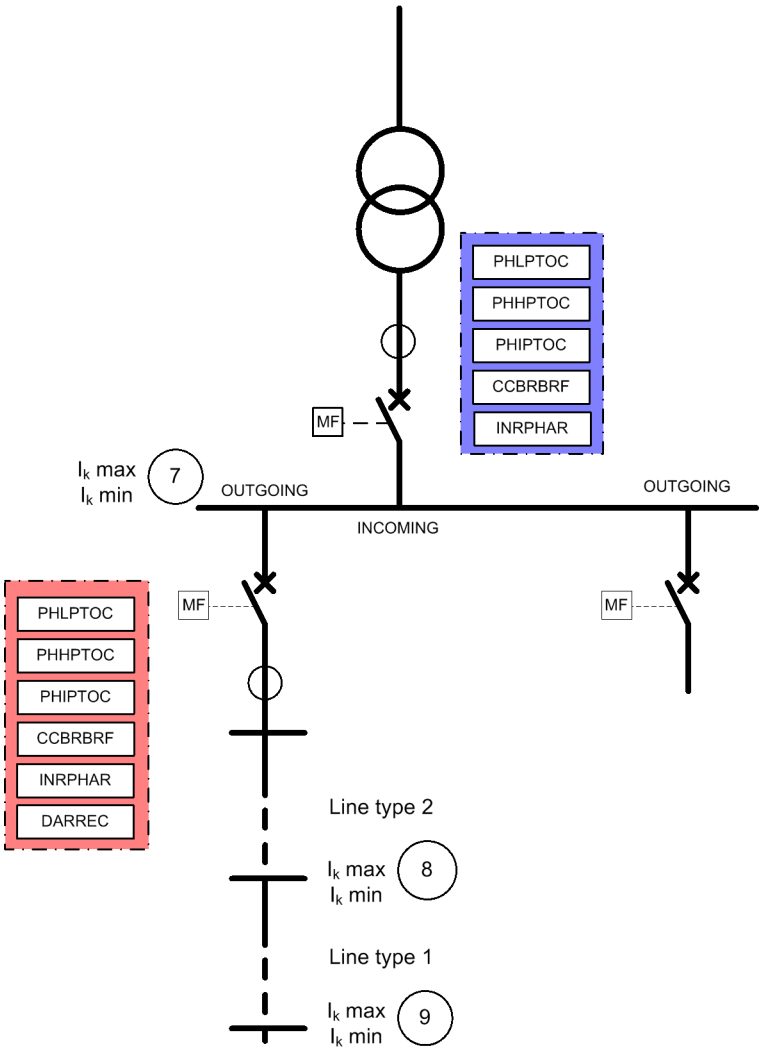

Figure 203: Functionality of numerical multiple-stage overcurrent protection

The coordination plan is an effective tool to study the operation of time selective operation characteristics. All the points mentioned earlier, required to define the overcurrent protection parameters, can be expressed simultaneously in a coordination plan. In *Figure 204*, the coordination plan shows an example of operation characteristics in the LV-side incoming feeder and radial outgoing feeder.

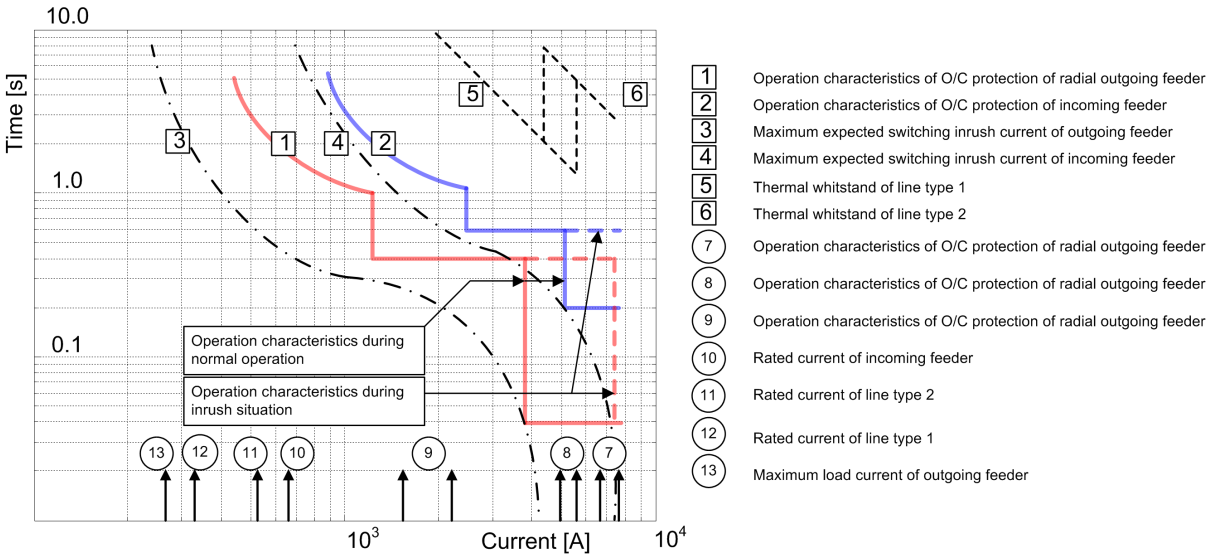

Figure 204: Example coordination of numerical multiple-stage overcurrent protection

4.1.2 Three-phase directional overcurrent protection DPHxPDOC (ANSI 67P/51P-1, 67P/51P-2)

[1] *Measurement mode* = default (depends on stage), current before fault = 0.0 × I_n, f_n = 50 Hz, fault current in one phase with nominal frequency injected from random phase angle, results based on statistical distribution of 1000 measurements.
[2] Measured with static signal output (SSO).
[3] Includes the delay of the signal output contact (SO).
[4] *Maximum Start value* = 2.5 × I_n, *Start value* multiples in the range of 1.5...20.

4.1.2.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase directional overcurrent protection, low stage	DPHLPDOC	3I> ->	67P/51P-1
Three-phase directional overcurrent protection, high stage	DPHHPDOC	3I>> ->	67P/51P-2

4.1.2.2 Function block

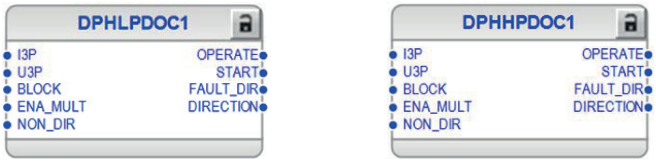

Figure 205: Function block

4.1.2.3 Functionality

The three-phase directional overcurrent protection function DPHxPDOC is used as one-phase, two-phase or three-phase directional overcurrent and short-circuit protection for feeders.

DPHxPDOC starts up when the value of the current exceeds the set limit and directional criterion is fulfilled. The operate time characteristics for low stage DPHLPDOC and high stage DPHHPDOC can be selected to be either definite time (DT) or inverse definite minimum time (IDMT).

In the DT mode, the function operates after a predefined operate time and resets when the fault current disappears. The IDMT mode provides current-dependent timer characteristics.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.1.2.4 Analog channel configuration

DPHxPDOC has two analog group inputs which must be properly configured.

Table 389: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 390: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of DPHxPDOC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

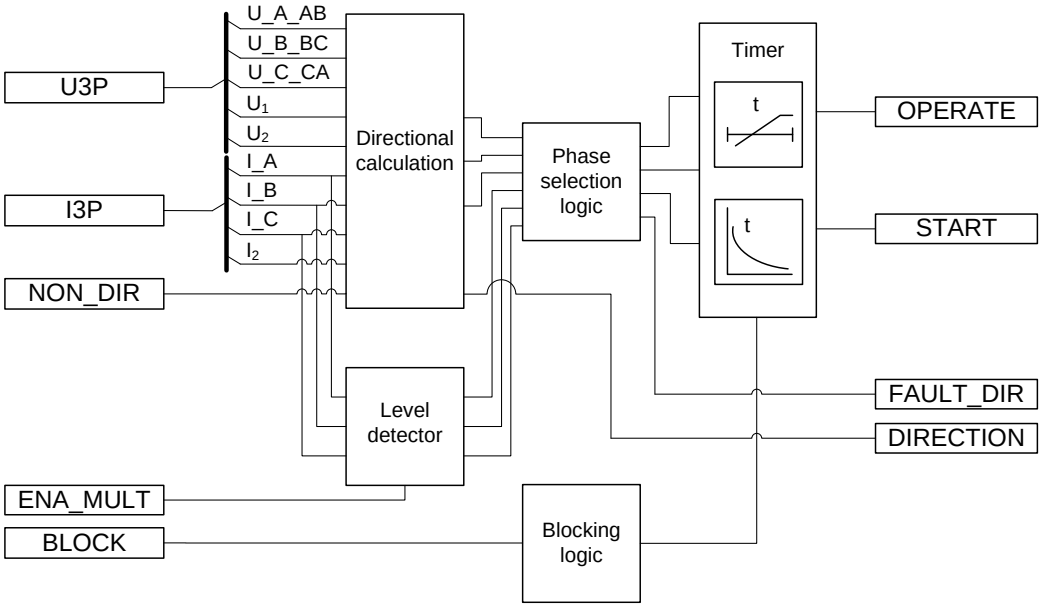

Figure 206: Functional module diagram

Directional calculation

The directional calculation compares the current phasors to the polarizing phasor. A suitable polarization quantity can be selected from the different polarization quantities, which are the positive sequence voltage, negative sequence voltage, self-polarizing (faulted) voltage and cross-polarizing voltages (healthy voltages). The polarizing method is defined with the *Pol quantity* setting.

Table 391: Polarizing quantities

Polarizing quantity	Description
Pos. seq. volt	Positive sequence voltage
Neg. seq. volt	Negative sequence voltage
Self pol	Self polarization
Cross pol	Cross polarization

The directional operation can be selected with the *Directional mode* setting. The user can select either "Non-directional", "Forward" or "Reverse" operation. By setting the value of *Allow Non Dir* to "True", the non-directional operation is allowed when the directional information is invalid.

The *Characteristic angle* setting is used to turn the directional characteristic. The value of *Characteristic angle* should be chosen in such a way that all the faults in the operating direction are seen in the operating zone and all the faults in the opposite direction are seen in the non-operating zone. The value of *Characteristic angle* depends on the network configuration.

Reliable operation requires both the operating and polarizing quantities to exceed certain minimum amplitude levels. The minimum amplitude level for the operating quantity (current) is set with the *Min operate current* setting. The minimum amplitude level for the polarizing quantity (voltage) is set with the *Min operate voltage* setting. If the amplitude level of the operating quantity or polarizing quantity is below the set level, the direction information of the corresponding phase is set to "Unknown".

The polarizing quantity validity can remain valid even if the amplitude of the polarizing quantity falls below the value of the *Min operate voltage* setting. In this case, the directional information is provided by a special memory function for a time defined with the *Voltage Mem time* setting.

DPHxPDOC is provided with a memory function to secure a reliable and correct directional protection relay operation in case of a close short circuit or an earth fault characterized by an extremely low voltage. At sudden loss of the polarization quantity, the angle difference is calculated on the basis of a fictive voltage. The fictive voltage is calculated using the positive phase sequence voltage measured before the fault occurred, assuming that the voltage is not affected by the fault. The memory function enables the function to operate up to a maximum of three seconds after a total loss of voltage. This time can be set with the *Voltage Mem time* setting. The voltage memory cannot be used for the "Negative sequence voltage" polarization because it is not possible to substitute the positive sequence voltage for negative sequence voltage without knowing the network unsymmetry level. This is the reason why the fictive voltage angle and corresponding direction information are frozen immediately for this polarization mode when the need for a voltage memory arises and these are kept frozen until the time set with *Voltage Mem time* elapses.

The value for the *Min operate voltage* setting should be carefully selected since the accuracy in low signal levels is strongly affected by the measuring device accuracy.

When the voltage falls below *Min operate voltage* at a close fault, the fictive voltage is used to determine the phase angle. The measured voltage is applied again as soon as the voltage rises above *Min operate voltage* and hysteresis. The fictive voltage is also discarded if the measured voltage stays below *Min operate voltage* and hysteresis for longer than *Voltage Mem time* or if the fault current disappears

while the fictive voltage is in use. When the voltage is below *Min operate voltage* and hysteresis and the fictive voltage is unusable, the fault direction cannot be determined. The fictive voltage can be unusable for two reasons:

- The fictive voltage is discarded after *Voltage Mem time*
- The phase angle cannot be reliably measured before the fault situation.

DPHxPDOC can be forced to the non-directional operation with the NON_DIR input. When the NON_DIR input is active, DPHxPDOC operates as a non-directional overcurrent protection, regardless of the *Directional mode* setting.

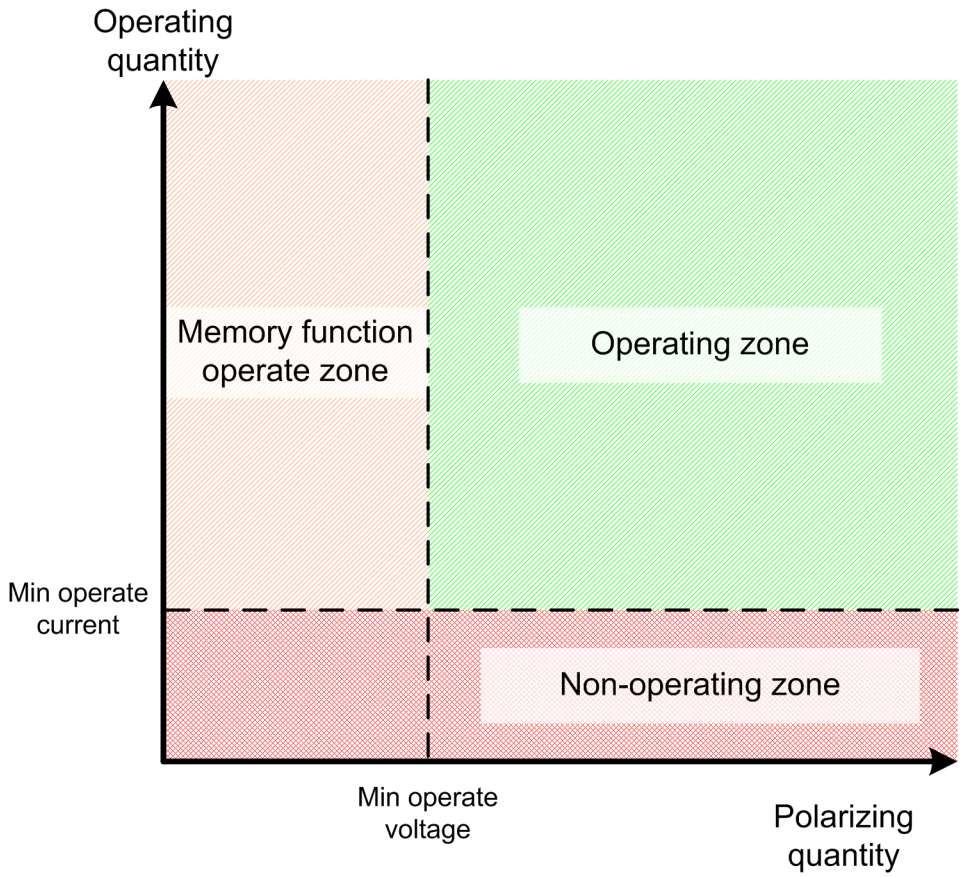

Figure 207: Operating zones at minimum magnitude levels

The DIRECTION output indicates on which operating sector the current is measured. The value combines phase-specific directions which are available in monitored data as DIR_A, DIR_B and DIR_C.

Level detector

The measured phase currents are compared phasewise to the set *Start value*. If the measured value exceeds the set *Start value*, the level detector reports the exceeding of the value to the phase selection logic. If the ENA_MULT input is active, the *Start value* setting is multiplied by the *Start value Mult* setting.

The protection relay does not accept the *Start value* or *Start value Mult* setting if the product of these settings exceeds the *Start value* setting range.

The start value multiplication is normally done when the inrush detection function (INRPHAR) is connected to the ENA_MULT input.

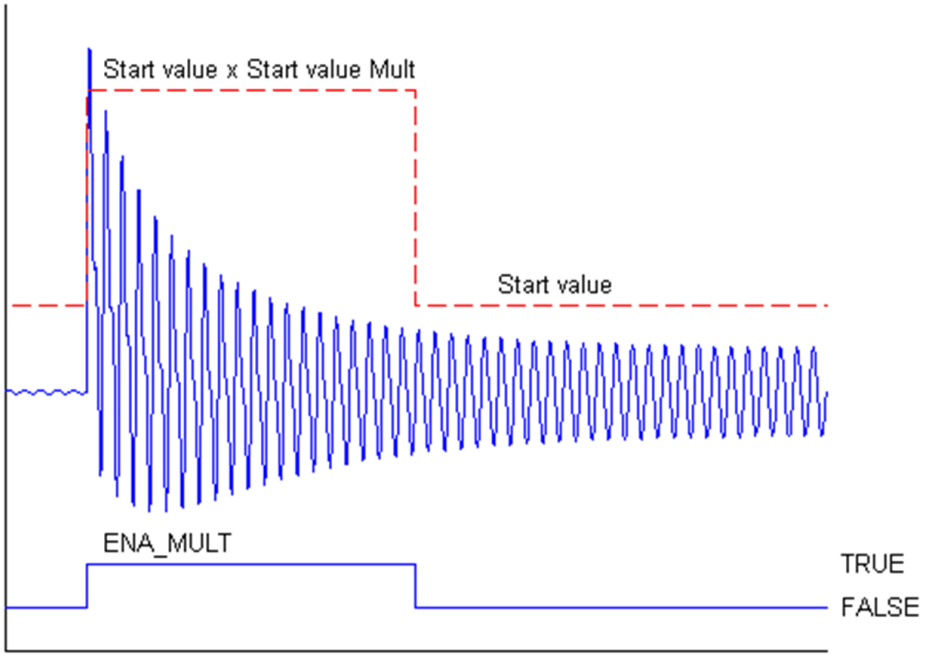

Figure 208: Start value behavior with ENA_MULT input activated

Phase selection logic

If the fault criteria are fulfilled in the level detector and the directional calculation, the phase selection logic detects the phase or phases in which the measured current exceeds the setting. If the phase information matches the *Num of start phases* setting, the phase selection logic activates the timer module.

FAULT_DIR gives the detected direction of the fault during fault situations, that is, when the START output is active.

Timer

Once activated, the timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and Curve parameter E.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic

is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operate and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.1.2.6 Measurement modes

The function operates on three alternative measurement modes: “RMS”, “DFT” and “Peak-to-Peak” . The measurement mode is selected with the *Measurement mode* setting.

Table 392: Measurement modes supported by DPHxPDOC stages

Measurement mode	DPHLPDOC	DPHHPDOC
RMS	x	x
DFT	x	x
Peak-to-Peak	x	x

4.1.2.7 Directional overcurrent characteristics

The forward and reverse sectors are defined separately. The forward operation area is limited with the *Min forward angle* and *Max forward angle* settings. The reverse operation area is limited with the *Min reverse angle* and *Max reverse angle* settings.

The sector limits are always given as positive degree values.

In the forward operation area, the *Max forward angle* setting gives the counterclockwise sector and the *Min forward angle* setting gives the corresponding clockwise sector, measured from the *Characteristic angle* setting.

In the backward operation area, the *Max reverse angle* setting gives the counterclockwise sector and the *Min reverse angle* setting gives the corresponding clockwise sector, a measurement from the *Characteristic angle* setting that has been rotated 180 degrees.

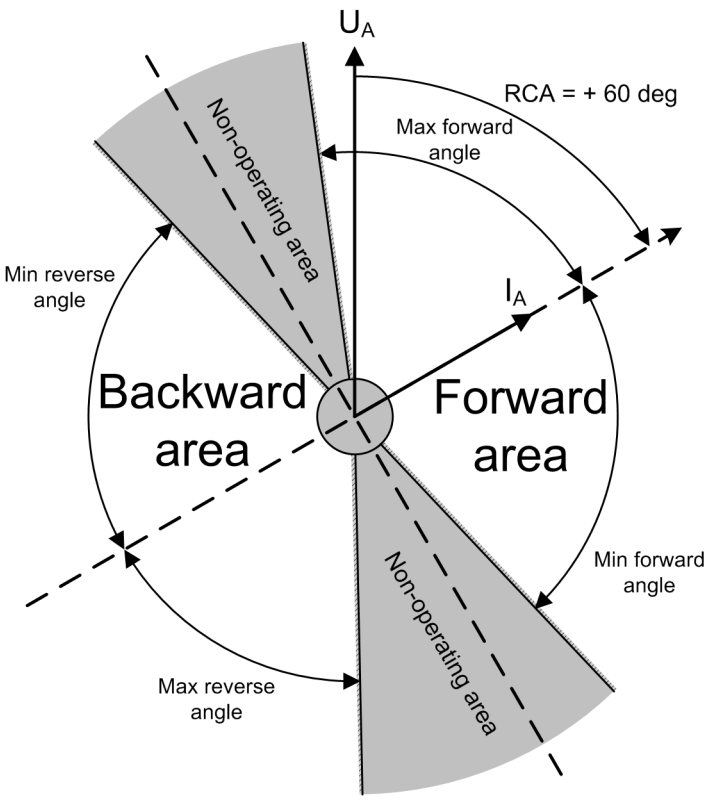

Figure 209: Configurable operating sectors

Table 393: Momentary per phase direction value for monitored data view

Criterion for per phase direction information	The value for DIR_A/_B/_C
The ANGLE_X is not in any of the defined sectors, or the direction cannot be defined due too low amplitude	0 = unknown
The ANGLE_X is in the forward sector	1 = forward

Table continues on the next page

Criterion for per phase direction information	The value for DIR_A/_B/_C
The ANGLE_X is in the reverse sector	2 = backward
(The ANGLE_X is in both forward and reverse sectors, that is, when the sectors are overlapping)	3 = both

Table 394: Momentary phase combined direction value for monitored data view

Criterion for phase combined direction information	The value for DIRECTION
The direction information (DIR_X) for all phases is unknown	0 = unknown
The direction information (DIR_X) for at least one phase is forward, none being in reverse	1 = forward
The direction information (DIR_X) for at least one phase is reverse, none being in forward	2 = backward
The direction information (DIR_X) for some phase is forward and for some phase is reverse	3 = both

FAULT_DIR gives the detected direction of the fault during fault situations, that is, when the START output is active.

Self-polarizing as polarizing method

Table 395: Equations for calculating angle difference for self-polarizing method

Faulted phases	Used fault current	Used polarizing voltage	Angle difference
A	$\underline{I}_A$	$\underline{U}_A$	$ANGLE_A = \varphi(\underline{U}_A) - \varphi(\underline{I}_A) - \varphi_{RCA}$ (Equation 9)
B	$\underline{I}_B$	$\underline{U}_B$	$ANGLE_B = \varphi(\underline{U}_B) - \varphi(\underline{I}_B) - \varphi_{RCA}$ (Equation 10)
C	$\underline{I}_C$	$\underline{U}_C$	$ANGLE_C = \varphi(\underline{U}_C) - \varphi(\underline{I}_C) - \varphi_{RCA}$ (Equation 11)
A - B	$\underline{I}_A$-$\underline{I}_B$	$\underline{U}_{AB}$	$ANGLE_A = \varphi(\underline{U}_{AB}) - \varphi(\underline{I}_A - \underline{I}_B) - \varphi_{RCA}$ (Equation 12)
B - C	$\underline{I}_B$-$\underline{I}_C$	$\underline{U}_{BC}$	$ANGLE_B = \varphi(\underline{U}_{BC}) - \varphi(\underline{I}_B - \underline{I}_C) - \varphi_{RCA}$ (Equation 13)
C - A	$\underline{I}_C$-$\underline{I}_A$	$\underline{U}_{CA}$	$ANGLE_C = \varphi(\underline{U}_{CA}) - \varphi(\underline{I}_C - \underline{I}_A) - \varphi_{RCA}$ (Equation 14)

In an example case of the phasors in a single-phase earth fault where the faulted phase is phase A, the angle difference between the polarizing quantity U_A and operating quantity I_A is marked as ϕ. In the self-polarization method, there is no need to rotate the polarizing quantity.

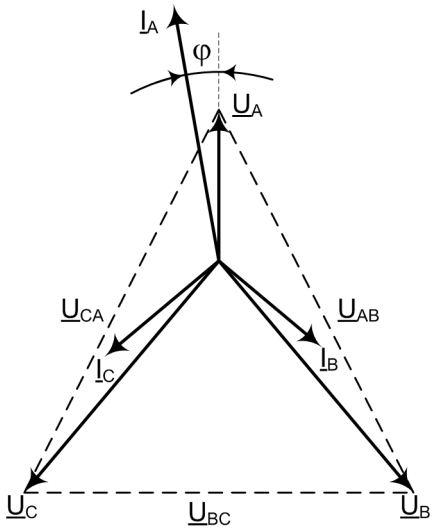

Figure 210: Single-phase earth fault, phase A

In an example case of a two-phase short-circuit failure where the fault is between phases B and C, the angle difference is measured between the polarizing quantity U_{BC} and operating quantity $\underline{I}_B - \underline{I}_C$ in the self-polarizing method.

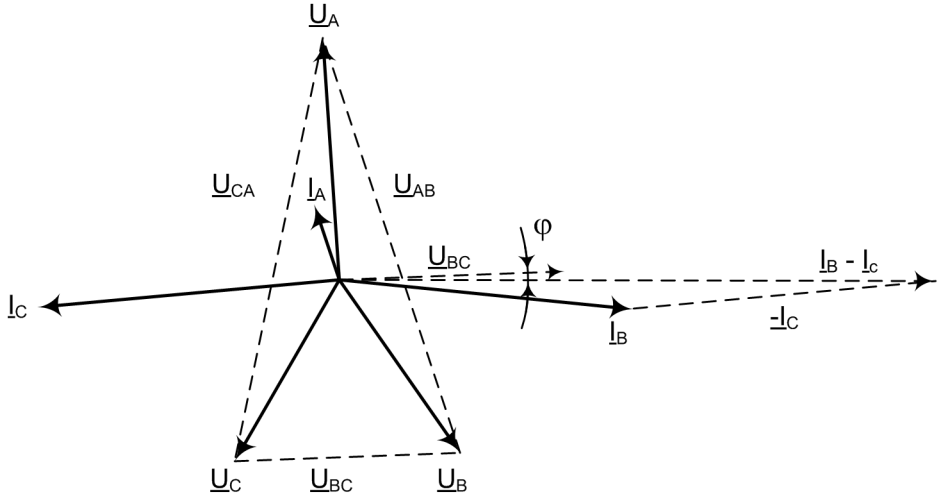

Figure 211: Two-phase short circuit, short circuit is between phases B and C

Cross-polarizing as polarizing quantity

Table 396: Equations for calculating angle difference for cross-polarizing method

Faulted phases	Used fault current	Used polarizing voltage	Angle difference
A	$\underline{I}_A$	$\underline{U}_{BC}$	$ANGLE_A = \varphi(\underline{U}_{BC}) - \varphi(\underline{I}_A) - \varphi_{RCA} + 90^o$ (Equation 15)
B	$\underline{I}_B$	$\underline{U}_{CA}$	$ANGLE_B = \varphi(\underline{U}_{CA}) - \varphi(\underline{I}_B) - \varphi_{RCA} + 90^o$ (Equation 16)
C	$\underline{I}_C$	$\underline{U}_{AB}$	$ANGLE_C = \varphi(\underline{U}_{AB}) - \varphi(\underline{I}_C) - \varphi_{RCA} + 90^o$ (Equation 17)
A - B	$\underline{I}_A$-$\underline{I}_B$	$\underline{U}_{BC}$-$\underline{U}_{CA}$	$ANGLE_A = \varphi(\underline{U}_{BC} - \underline{U}_{CA}) - \varphi(\underline{I}_A - \underline{I}_B) - \varphi_{RCA} + 90^o$ (Equation 18)
B - C	$\underline{I}_B$-$\underline{I}_C$	$\underline{U}_{CA}$-$\underline{U}_{AB}$	$ANGLE_B = \varphi(\underline{U}_{CA} - \underline{U}_{AB}) - \varphi(\underline{I}_B - \underline{I}_C) - \varphi_{RCA} + 90^o$ (Equation 19)
C - A	$\underline{I}_C$-$\underline{I}_A$	$\underline{U}_{AB}$-$\underline{U}_{BC}$	$ANGLE_C = \varphi(\underline{U}_{AB} - \underline{U}_{BC}) - \varphi(\underline{I}_C - \underline{I}_A) - \varphi_{RCA} + 90^o$ (Equation 20)

The angle difference between the polarizing quantity U_{BC} and operating quantity I_A is marked as ϕ in an example of the phasors in a single-phase earth fault where the faulted phase is phase A. The polarizing quantity is rotated with 90 degrees. The characteristic angle is assumed to be ~ 0 degrees.

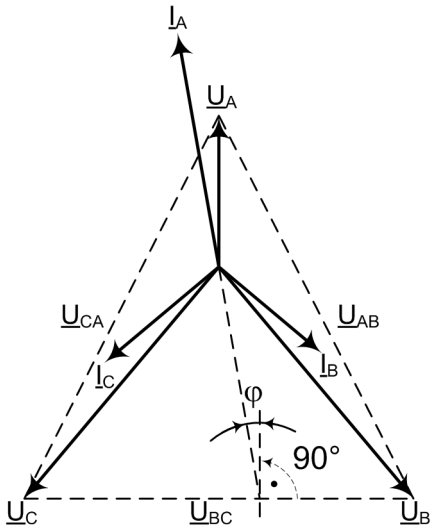

Figure 212: Single-phase earth fault, phase A

In an example of the phasors in a two-phase short-circuit failure where the fault is between the phases B and C, the angle difference is measured between the polarizing quantity $\underline{U}_{AB}$ and operating quantity $\underline{I}_B$ - $\underline{I}_C$ marked as ϕ.

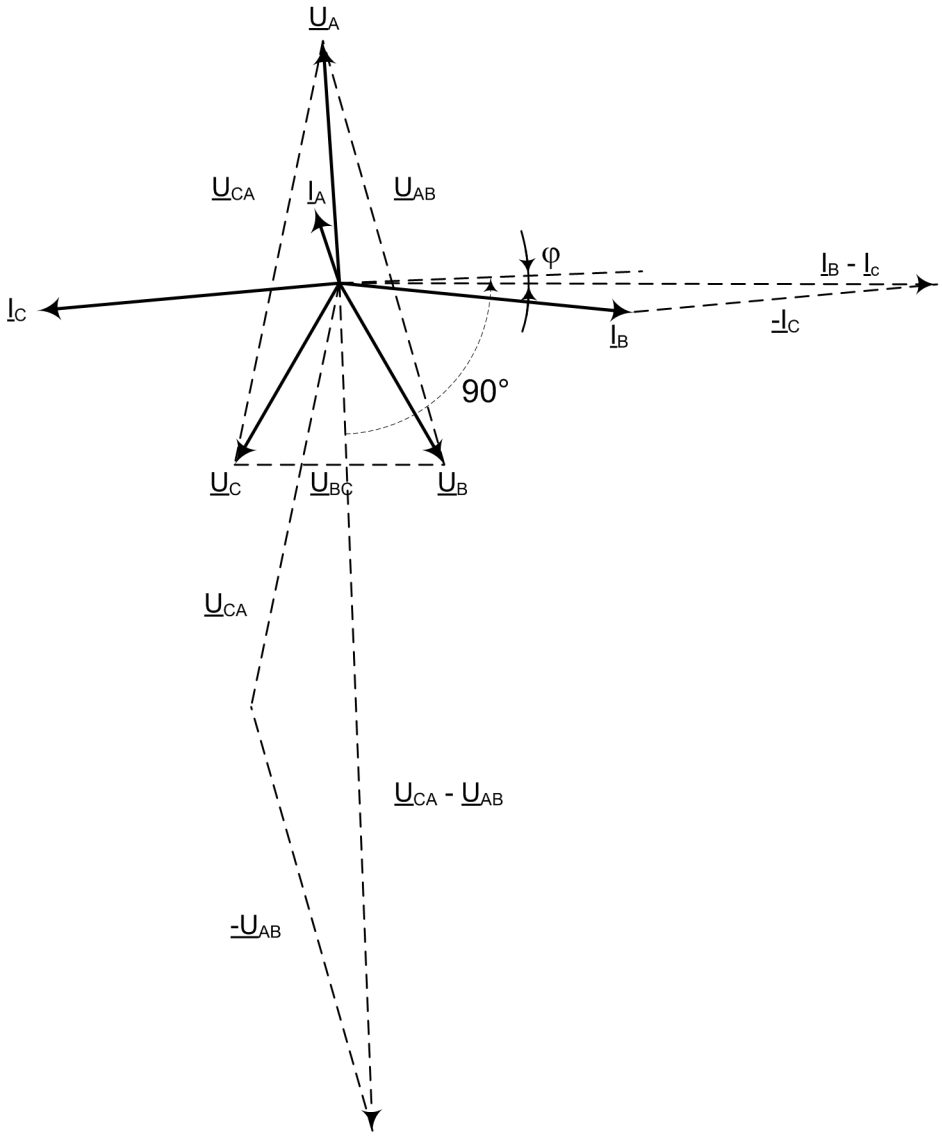

Figure 213: Two-phase short circuit, short circuit is between phases B and C

The equations are valid when network rotating direction is counter-clockwise, that is, ABC. If the network rotating direction is reversed, 180 degrees is added to the calculated angle difference. This is done automatically with a system parameter *Phase rotation*.

Negative sequence voltage as polarizing quantity

When the negative voltage is used as the polarizing quantity, the angle difference between the operating and polarizing quantity is calculated with the same formula for all fault types:

$$ANGLE_X = \varphi(-\underline{U}_2) - \varphi(\underline{I}_2) - \varphi_{RCA}$$

(Equation 21)

This means that the actuating polarizing quantity is - $\underline{U}_2$.

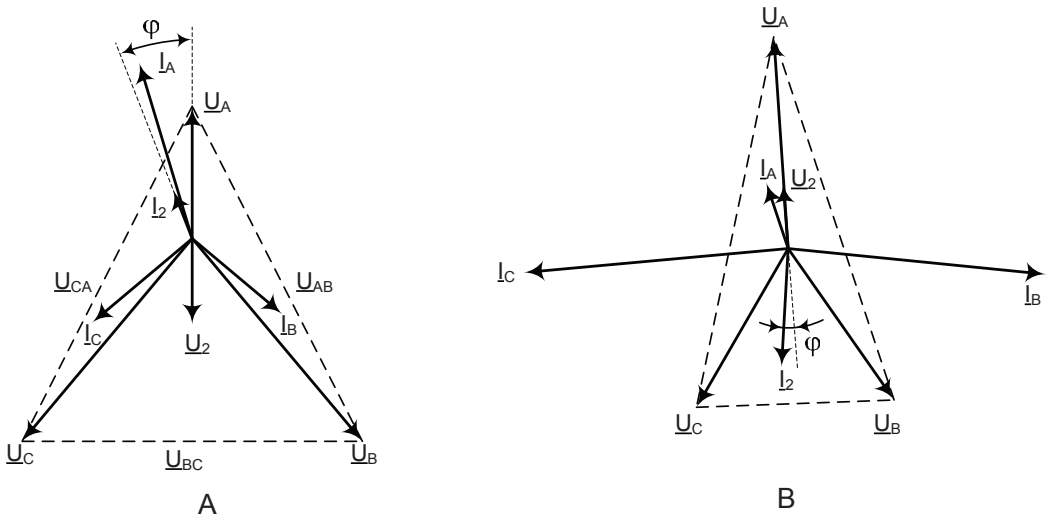

Figure 214: Phasors in a single-phase earth fault, phases A-N, and two-phase short circuit, phases B and C, when the actuating polarizing quantity is the negative-sequence voltage -U2

Positive sequence voltage as polarizing quantity

Table 397: Equations for calculating angle difference for positive-sequence quantity polarizing method

Faulted phases	Used fault current	Used polarizing voltage	Angle difference
A	$\underline{I}_A$	$\underline{U}_1$	$ANGLE_A = \varphi(\underline{U}_1) - \varphi(\underline{I}_A) - \varphi_{RCA}$ (Equation 22)
B	$\underline{I}_B$	$\underline{U}_1$	$ANGLE_B = \varphi(\underline{U}_1) - \varphi(\underline{I}_B) - \varphi_{RCA} - 120^\circ$ (Equation 23)
C	$\underline{I}_C$	$\underline{U}_1$	$ANGLE_C = \varphi(\underline{U}_1) - \varphi(\underline{I}_C) - \varphi_{RCA} + 120^\circ$ (Equation 24)
A - B	$\underline{I}_A$-$\underline{I}_B$	$\underline{U}_1$	$ANGLE_A = \varphi(\underline{U}_1) - \varphi(\underline{I}_A - \underline{I}_B) - \varphi_{RCA} + 30^\circ$ (Equation 25)

Table continues on the next page

Faulted phases	Used fault current	Used polarizing voltage	Angle difference
B - C	$\underline{I}_B$-$\underline{I}_C$	$\underline{U}_1$	$ANGLE_B = \varphi(\underline{U}_1) - \varphi(\underline{I}_B - \underline{I}_C) - \varphi_{RCA} - 90^\circ$ (Equation 26)
C - A	$\underline{I}_C$-$\underline{I}_A$	$\underline{U}_1$	$ANGLE_C = \varphi(\underline{U}_1) - \varphi(\underline{I}_C - \underline{I}_A) - \varphi_{RCA} + 150^\circ$ (Equation 27)

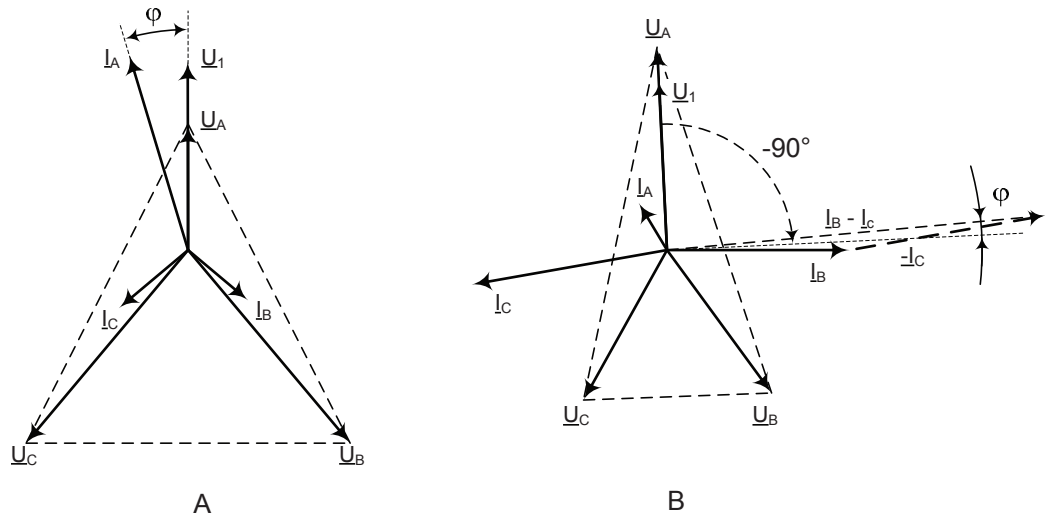

Figure 215: Phasors in a single-phase earth fault, phase A to ground, and a two-phase short circuit, phases B-C, are short-circuited when the polarizing quantity is the positive-sequence voltage U 1

Network rotation direction

Typically, the network rotating direction is counter-clockwise and defined as "ABC". If the network rotating direction is reversed, meaning clockwise, that is, "ACB", the equations for calculating the angle difference needs to be changed. The network rotating direction is defined with a system parameter *Phase rotation*. The change in the network rotating direction affects the phase-to-phase voltages polarization method where the calculated angle difference needs to be rotated 180 degrees. Also, when the sequence components are used, which are, the positive sequence voltage or negative sequence voltage components, the calculation of the components are affected but the angle difference calculation remains the same. When the phase-to-ground voltages are used as the polarizing method, the network rotating direction change has no effect on the direction calculation.

The network rotating direction is set in the protection relay using the parameter in the HMI menu **Configuration** > **System** > **Phase rotation**. The default parameter value is "ABC".

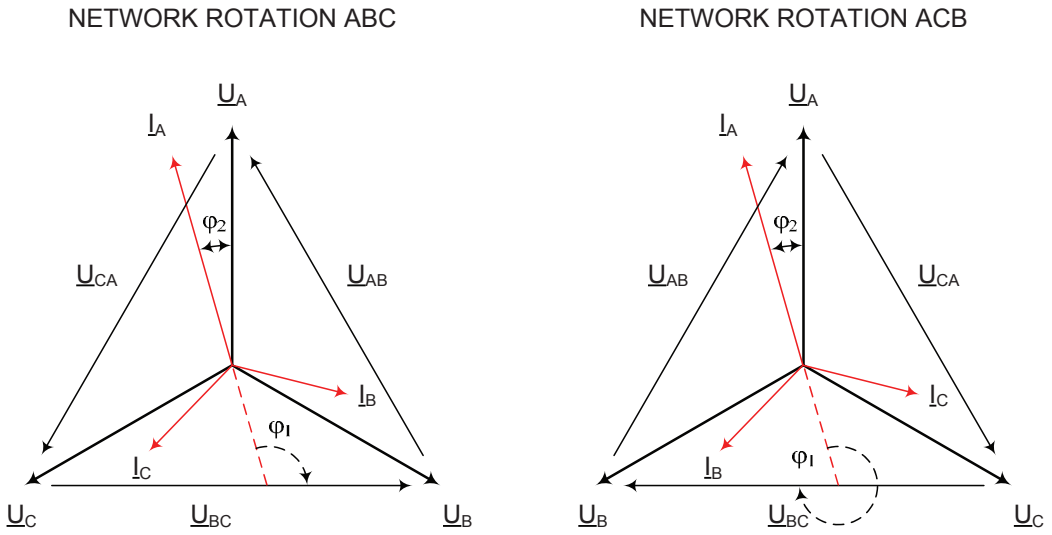

Figure 216: Examples of network rotating direction

4.1.2.8 Application

DPHxPDOC is used as short-circuit protection in three-phase distribution or sub transmission networks operating at 50 or 60 Hz.

In radial networks, phase overcurrent protection relays are often sufficient for the short circuit protection of lines, transformers and other equipment. The current-time characteristic should be chosen according to the common practice in the network. It is recommended to use the same current-time characteristic for all overcurrent protection relays in the network. This includes the overcurrent protection of transformers and other equipment.

The phase overcurrent protection can also be used in closed ring systems as short circuit protection. Because the setting of a phase overcurrent protection system in closed ring networks can be complicated, a large number of fault current calculations are needed. There are situations with no possibility to have the selectivity with a protection system based on overcurrent protection relays in a closed ring system.

In some applications, the possibility of obtaining the selectivity can be improved significantly if DPHxPDOC is used. This can also be done in the closed ring networks and radial networks with the generation connected to the remote in the system thus giving fault current infeed in reverse direction. Directional overcurrent protection relays are also used to have a selective protection scheme, for example in case of parallel distribution lines or power transformers fed by the same single source. In ring connected supply feeders between substations or feeders with two feeding sources, DPHxPDOC is also used.

Parallel lines or transformers

When the lines are connected in parallel and if a fault occurs in one of the lines, it is practical to have DPHxPDOC to detect the direction of the fault. Otherwise, there is a risk that the fault situation in one part of the feeding system can de-energize the whole system connected to the LV side.

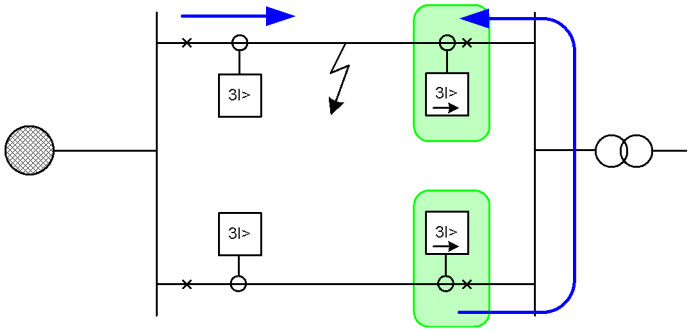

Figure 217: Overcurrent protection of parallel lines using directional protection relays

DPHxPDOC can be used for parallel operating transformer applications. In these applications, there is a possibility that the fault current can also be fed from the LV-side up to the HV-side. Therefore, the transformer is also equipped with directional overcurrent protection.

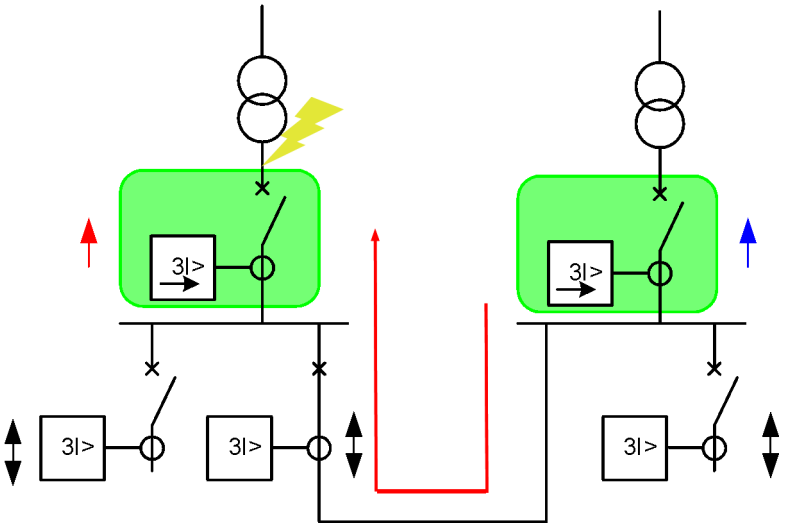

Figure 218: Overcurrent protection of parallel operating transformers

Closed ring network topology

The closed ring network topology is used in applications where electricity distribution for the consumers is secured during network fault situations. The power is fed at least from two directions which means that the current direction can be varied. The time grading between the network level stages is challenging without unnecessary delays in the time settings. In this case, it is practical to use the directional overcurrent protection relays to achieve a selective protection scheme. Directional overcurrent functions can be used in closed ring applications. The arrows define the operating direction of the directional functionality. The double arrows define the non-directional functionality where faults can be detected in both directions.

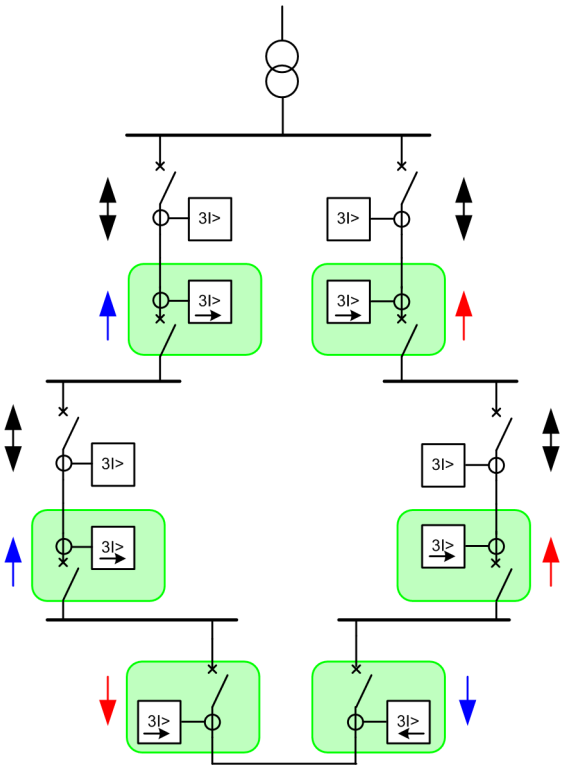

Figure 219: Closed ring network topology where feeding lines are protected with directional overcurrent protection relays

4.1.3 Three-phase voltage-dependent overcurrent protection PHPVOC (ANSI 51V)

4.1.3.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase voltage-dependent overcurrent protection	PHPVOC	3I(U)>	51V

4.1.3.2 Function block

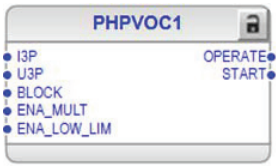

Figure 220: Function block

4.1.3.3 Functionality

The three-phase voltage-dependent overcurrent protection function PHPVOC is used for single-phase, two-phase or three-phase voltage-dependent time overcurrent protection of generators against overcurrent and short circuit conditions.

PHPVOC starts when the input phase current exceeds a limit which is dynamically calculated based on the measured terminal voltages. The operating characteristics can be selected to be either inverse definite minimum time IDMT or definite time DT.

PHPVOC contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.1.3.4 Analog channel configuration

PHPVOC has two analog group inputs which all must be properly configured.

Table 414: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 415: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PHPVOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

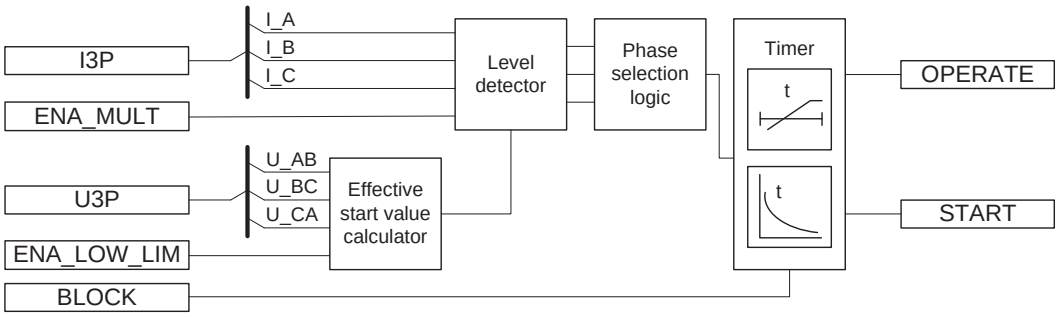

Figure 221: Functional module diagram

Effective start value calculator

The normal starting current above which the overcurrent protection starts is set through the *Start value* setting. The Effective start value of the current may need to be changed during certain conditions like magnetizing inrush or when the terminal voltages drop due to a fault. Hence, the effective start value calculator module dynamically calculates the effective start value above which the overcurrent protection starts.

Four methods of calculating the effective start value are provided in PHPVOC. These can be chosen with the *Control mode* setting to be either "Voltage control", "Input control", "Volt & Input Ctrl" or "No Volt dependency".

The calculated effective start value per phase, `EFF_ST_VAL_A`, `EFF_ST_VAL_B`, `EFF_ST_VAL_C`, is available in the Monitored data view and is used by the Level detector module.

All three phase-to-phase voltages should be available for the function to operate properly.

Voltage control mode

In the Voltage control mode, the Effective start value is calculated based on the magnitude of input voltages U_AB, U_BC and U_CA. The voltage dependency is phase sensitive, which means that the magnitude of one input voltage controls the start value of only the corresponding phase, that is, the magnitude of voltage inputs U_AB, U_BC and U_CA independently control the current start values of phases A, B and C.

Two voltage control characteristics, voltage step and voltage slope, can be achieved with the *Voltage high limit* and *Voltage low limit* settings.

The voltage step characteristic is achieved when the *Voltage high limit* setting is equal to the *Voltage low limit* setting. The effective start value is calculated based on the equations.

Voltage level	Effective start value (I> effective)
U < *Voltage high limit*	*Start value low*
U ≥ *Voltage high limit*	*Start value*

In this example, U represents the measured input voltage. This voltage step characteristic is graphically represented in *Figure 222*.

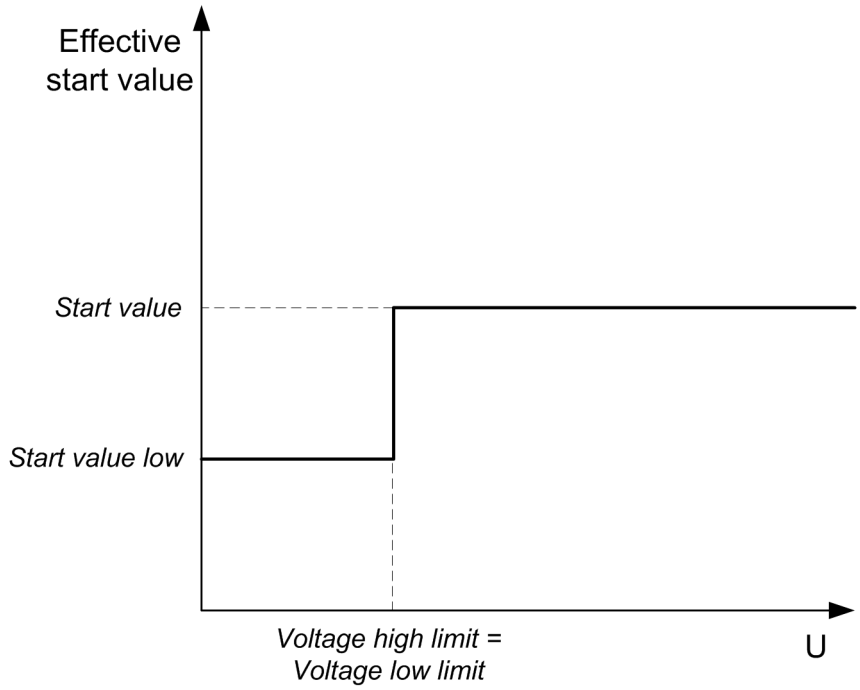

Figure 222: Effective start value for voltage step characteristic

The voltage slope characteristic is achieved by assigning different values to *Voltage high limit* and *Voltage low limit*. The effective start value calculation is based on the equations.

Voltage level	Effective start value (I> effective)
U < *Voltage low limit*	*Start value low*
U ≥ *Voltage high limit*	*Start value*

If *Voltage low limit* ≤ U < *Voltage high limit*,

I>(*effective*) = I> - [((I> - A) / (C – D)) * (C – U)]

(Equation 28)

A	set *Start value low*
I>	set *Start value*
C	set *Voltage high limit*
D	set *Voltage low limit*

Here U represents the measured input voltage. The voltage slope characteristic is graphically represented.

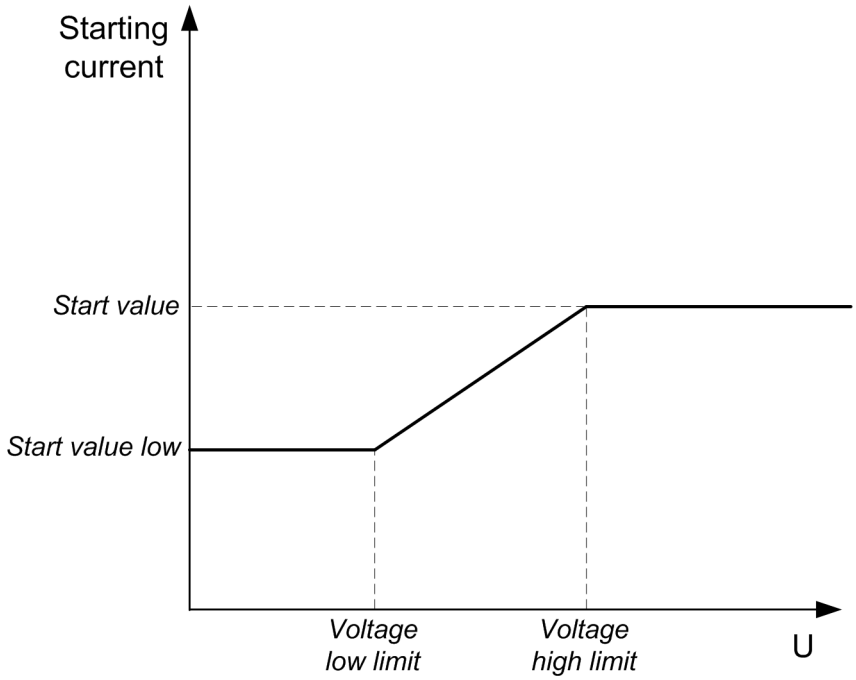

Figure 223: Effective start value or voltage slope characteristic

To achieve the voltage slope characteristics, *Voltage high limit* must always be set to a value greater than *Voltage low limit*.

If *Voltage high limit* is lower than *Voltage low limit*, the voltage step characteristic is active with *Voltage low limit* being the cutoff value.

The value of the setting *Start value* should always be greater than the setting *Start value low*. Otherwise, *Start value low* is used as the effective start value.

External input control mode

The External input control mode is used to enable voltage control from an external application. If *Control mode* is set to the "Input Control" mode, the effective start value for all phases is influenced by the status of the binary input `ENA_U_MULT`.

If ENA_U_MULT is TRUE :
Effective start value = Start value low

(Equation 29)

If ENA_U_MULT is FALSE :
Effective start value = Start value

(Equation 30)

Voltage and input control mode

If *Control mode* is set to "Voltage and input Ctrl", both the "Voltage control" and "Input control" modes are used. However, the “Input control” functionality is dominant over the “Voltage control” mode when ENA_LOW_LIM is active.

No voltage dependency mode

When *Control mode* is set to "No Volt dependency", the effective start value has no voltage dependency and the function acts as a normal time overcurrent function with effective start value being equal to the *Start value* setting.

Level detector

The measured phase currents are compared phasewise to the calculated effective start value. If the measured value exceeds the calculated effective start value, the Level detector reports the exceeding value to the phase selection logic. If the ENA_MULT input is active, the effective start value is multiplied by the *Start value Mult* setting.

Do not set the multiplier *Start value Mult* setting higher than necessary. If the value is too high, the function may not operate at all during an inrush followed by a fault, no matter how severe the fault is.

The start value multiplication is normally done when the inrush detection function INRPHAR is connected to the ENA_MULT input.

Phase selection logic

If the fault criteria are fulfilled in the level detector, the phase selection logic detects the phase or phases in which the measured current exceeds the setting. If the phase information matches the *Num of start phases* setting, the phase selection logic activates the Timer module.

Timer

Once activated, the Timer module activates the START output.

Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user programmable IDMT curve is selected, the operation time characteristics are defined by the settings *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

In a drop-off situation, that is, when a fault suddenly disappears before the operating delay is exceeded, the timer reset state is activated. The functionality of the Timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The *Time multiplier* is used for scaling the IDMT operate and reset times.

The *Minimum operate time* setting defines the minimum desired operating time for IDMT operation. The setting is applicable only when the IDMT curves are used.

Though the *Time multiplier* and *Minimum operate time* settings are common for different IDMT curves, the operating time essentially depends upon the type of IDMT curve chosen.

The Timer calculates the start duration value START_DUR which indicates the percentage ratio of the start situation and the set operating time. This output is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.1.3.6 Application

The three-phase voltage-dependent overcurrent protection is used as a backup protection for the generators and system from damage due to the phase faults which are not cleared by primary protection and associated breakers.

In case of a short circuit, the sustained fault current of the generator, determined by the machine synchronous reactance, could be below the full-load current. If the generator excitation power is fed from the generator terminals, a voltage drop caused by a short circuit also leads to low fault current. The primary protection, like normal overcurrent protection, might not detect this kind of fault situation. In some cases, the automatic voltage regulator AVR can help to maintain high fault

currents by controlling the generator excitation system. If the AVR is out of service or if there is an internal fault in the operation of AVR, the low fault currents can go unnoticed and therefore a voltage-depended overcurrent protection should be used for backup.

Two voltage control characteristics, voltage step and voltage slope, are available in PHPVOC. The choice is made based on the system conditions and the level of protection to be provided.

Voltage step characteristic is applied to generators used in industrial systems. Under close-up fault conditions when the generator terminal voltages drop below the settable threshold value, a new start value of the current, well below the normal load current, is selected. The control voltage setting should ensure that PHPVOC does not trip under the highest loading conditions to which the system can be subjected. Choosing too high a value for the control voltage may allow an undesired operation of the function during wide-area disturbances. When the terminal voltage of the generator is above the control voltage value, the normal start value is used. This ensures that PHPVOC does not operate during normal overloads when the generator terminal voltages are maintained near the normal levels.

Voltage slope characteristic is often used as an alternative to impedance protection on small to medium (5...150 MVA) size generators to provide backup to the differential protection. Other applications of the voltage slope characteristic protection exist in networks to provide better coordination and fault detection than plain overcurrent protection. The voltage slope method provides an improved sensitivity of overcurrent operation by making the overcurrent start value proportional to the terminal voltage. The current start value varies correspondingly with the generator terminal voltages between the set voltage high limit and voltage low limit, ensuring the operation of PHPVOC despite the drop in fault current value.

The operation of PHPVOC should be time-graded with respect to the main protection scheme to ensure that PHPVOC does not operate before the main protection.

4.1.3.7 Signals

PHPVOC Input signals

Table 416: PHPVOC Input signals

Name	Type	Default	Description

[2] Includes the delay of the signal output contact

4.1.4.3 Functionality

The accidental energization protection function GAEPVOC for the synchronous generator is an overcurrent protection function which is enabled only when the generator is at a standstill or in turning gear. The function is used to protect the generator rotor from damage due to rapid heating.

A number of field conditions, such as generator operating errors, breaker head flashovers, control circuit malfunctions, false actuation of breaker, or a combination of these can cause accidental energization of the generators. The generator under this condition suddenly causes a relatively heavy load to the surrounding network, which might lead to power balance instability.

Since the generator starts behaving as an asynchronous motor, this three-phase current develops higher current in the rotor, which may thermally damage the generator in a few seconds. A very high thermal stress in both the stator winding and the rotor has been produced by this situation.

The prime mover can also suffer from mechanical damage in moving parts like turbine blades or gearing teeth. Lack of oil may damage the bearings as lube pumps are not in operation when the generator is at a standstill. The turning gear oil pumps are not in operation either and the accidental energization may significantly damage the turning gear.

4.1.4.4 Analog channel configuration

GAEPVOC has two analog group inputs which must be properly configured.

Table 424: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 425: Special conditions

Condition	Description
U3P connected real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.4.5 Operation principle

The function can be enabled and disabled with the *Operation setting*. The corresponding parameter values are "on" and "off".

The operation of GAEPVOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

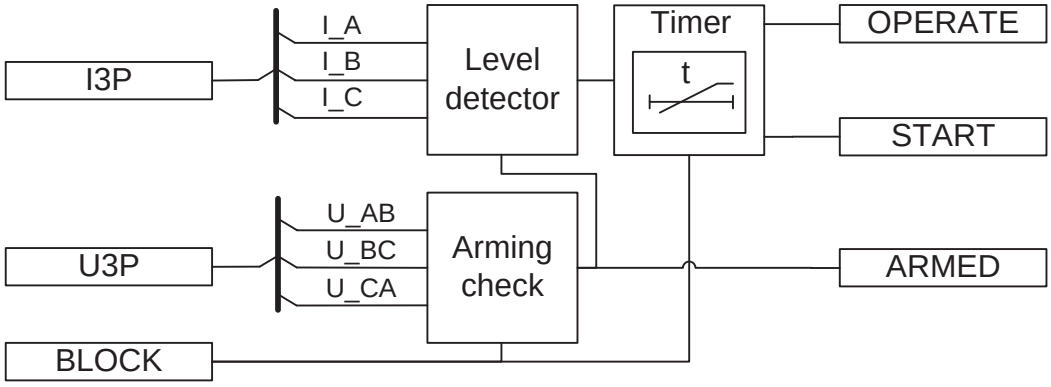

Figure 225: Functional module diagram

Arming check

The fundamental frequency component of the three measured phase-to-phase generator side voltages are compared with setting *Arm set voltage*. If all measured voltages are below the set *Arm set voltage* for longer than *Arm delay time*, the ARMED signal is set to TRUE and simultaneously Level detector is enabled.

The value of *Arm set voltage* must be set lower than any emergency low voltage condition that can occur when the system is under extreme stress conditions. When the generator returns to service and the voltage exceeds the *Disarm set voltage* setting, the scheme is automatically removed from service (Level detector disabled) after a time delay (*Disarm delay time setting*) and the ARMED output is set to FALSE. GAEPVOC must only be activated when the generator is out-of-service and disabled when the generator is online.

The setting value of *Arm set voltage* should be less than the setting value of *Disarm set voltage*.

Activation of BLOCK input resets the ARMED output to FALSE state.

Level detector

The measured peak-to-peak values of three phase currents are compared with the set *Start value*. If the measured values exceed *Start value*, an enable signal is sent to Timer.

Timer

Once activated, Timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If a drop-off situation occurs, the Timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, Timer resets.

The activation of the BLOCK input resets Timer and blocks the START and OPERATE outputs.

Timer calculates the start duration value START_DUR which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

4.1.4.6 Application

Accidental energization protection or dead machine protection is necessary as part of the generator protection application. In case of operating error, breaker head flashovers, control circuit malfunctions or a combination of these, the generator may be accidentally energized while offline. High currents might cause mechanical and thermal stress to the generator and cables, and other related power station equipment.

Three-phase thermal protection for feeders, cables and distribution transformers	T1PTTR	3Ith>F	49F

4.1.5.2 Function block

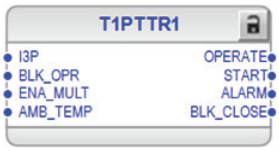

Figure 226: Function block

4.1.5.3 Functionality

The increased utilization of power systems closer to the thermal limits has generated a need for a thermal overload function also for power lines.

A thermal overload is in some cases not detected by other protection functions, and the introduction of the three-phase thermal protection for feeders, cables and distribution transformers function T1PTTR allows the protected circuit to operate closer to the thermal limits.

An alarm level gives an early warning to allow operators to take action before the line trips. The early warning is based on the three-phase current measuring function using a thermal model with first order thermal loss with the settable time constant. If the temperature rise continues the function will operate based on the thermal model of the line.

Re-energizing of the line after the thermal overload operation can be inhibited during the time the cooling of the line is in progress. The cooling of the line is estimated by the thermal model.

4.1.5.4 Analog channel configuration

T1PTTR has one analog group input which must be properly configured.

Table 433: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of T1PTTR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

The function uses ambient temperature which can be measured locally or remotely. Local measurement is done by the protection relay. Remote measurement uses analog GOOSE to connect `AMB_TEMP` input.

If the quality of remotely measured temperature is invalid or communication channel fails the function uses ambient temperature set in *Env temperature Set*.

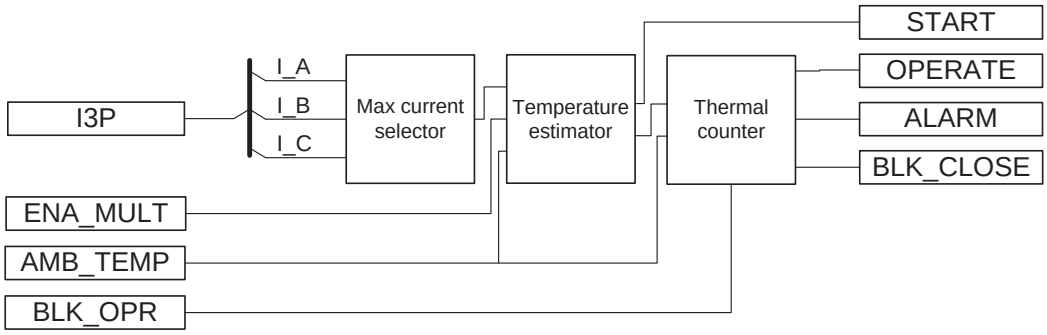

Figure 227: Functional module diagram

Max current selector

The max current selector of the function continuously checks the highest measured TRMS phase current value. The selector reports the highest value to the temperature estimator.

Temperature estimator

The final temperature rise is calculated from the highest of the three-phase currents according to the expression:

$$\Theta_{final} = \left(\frac{I}{I_{ref}} \right)^2 \cdot T_{ref}$$

(Equation 31)

I	the highest phase current
I_{ref}	set *Current reference*
T_{ref}	set *Temperature rise*

The ambient temperature is added to the calculated final temperature rise estimation, and the ambient temperature value used in the calculation is also available in the monitored data as TEMP_AMB in degrees. If the final temperature estimation is higher than the set *Maximum temperature*, the START output is activated.

Current reference and *Temperature rise* setting values are used in the final temperature estimation together with the ambient temperature. It is suggested to set these values to the maximum steady state current allowed for the line or cable under emergency operation for a few hours per years. Current values with the corresponding conductor temperatures are given in cable manuals. These values are given for conditions such as ground temperatures, ambient air temperature, the way of cable laying and ground thermal resistivity.

Thermal counter

The actual temperature at the actual execution cycle is calculated as:

$$\Theta_n = \Theta_{n-1} + \left(\Theta_{final} - \Theta_{n-1} \right) \cdot \left(1 - e^{-\frac{\Delta t}{\tau}} \right)$$

(Equation 32)

Θ_n	calculated present temperature
Θ_{n-1}	calculated temperature at previous time step
Θ_{final}	calculated final temperature with actual current
Δt	time step between calculation of actual temperature
t	thermal time constant for the protected device (line or cable), set *Time constant*

The actual temperature of the protected component (line or cable) is calculated by adding the ambient temperature to the calculated temperature, as shown above. The ambient temperature can be given a constant value or it can be measured. The calculated component temperature can be monitored as it is exported from the function as a real figure.

When the component temperature reaches the set alarm level *Alarm value*, the output signal ALARM is set. When the component temperature reaches the set trip level *Maximum temperature*, the OPERATE output is activated. The OPERATE signal pulse length is fixed to 100 ms.

There is also a calculation of the present time to operation with the present current. This calculation is only performed if the final temperature is calculated to be above the operation temperature:

$$t_{operate} = -\tau \cdot \ln\left(\frac{\Theta_{final} - \Theta_{operate}}{\Theta_{final} - \Theta_{n}}\right)$$

(Equation 33)

Caused by the thermal overload protection function, there can be a lockout to reconnect the tripped circuit after operating. The lockout output BLK_CLOSE is activated at the same time when the OPERATE output is activated and is not reset until the device temperature has cooled down below the set value of the *Reclose temperature* setting. The *Maximum temperature* value must be set at least two degrees above the set value of *Reclose temperature*.

The time to lockout release is calculated, that is, the calculation of the cooling time to a set value. The calculated temperature can be reset to its initial value (the *Initial temperature* setting) via a control parameter that is located under the clear menu. This is useful during testing when secondary injected current has given a calculated false temperature level.

$$t_{lockout_release} = -\tau \cdot \ln\left(\frac{\Theta_{final} - \Theta_{lockout_release}}{\Theta_{final} - \Theta_{n}}\right)$$

(Equation 34)

Here the final temperature is equal to the set or measured ambient temperature.

In some applications, the measured current can involve a number of parallel lines. This is often used for cable lines where one bay connects several parallel cables. By setting the *Current multiplier* parameter to the number of parallel lines (cables), the actual current on one line is used in the protection algorithm. To activate this option, the ENA_MULT input must be activated.

The ambient temperature can be measured with the RTD measurement. The measured temperature value is then connected, for example, from the AI_VAL3 output of the X130 RTD function to the AMB_TEMP input of T1PTTR.

The *Env temperature Set* setting is used to define the ambient temperature if the ambient temperature measurement value is not connected to the AMB_TEMP input. The *Env temperature Set* setting is also used when the ambient temperature measurement connected to T1PTTR is set to “Not in use” in the X130 RTD function.

The temperature calculation is initiated from the value defined with the *Initial temperature* setting parameter. This is done in case the protection relay is powered up, the function is turned "Off" and back "On" or reset through the Clear menu. The temperature is also stored in the nonvolatile memory and restored in case the protection relay is restarted.

The thermal time constant of the protected circuit is given in seconds with the *Time constant* setting. Please see cable manufacturers manuals for further details.

T1PTTR thermal model complies with the IEC 60255-149 standard.

4.1.5.6 Application

The lines and cables in the power system are constructed for a certain maximum load current level. If the current exceeds this level, the losses will be higher than expected. As a consequence, the temperature of the conductors will increase. If the temperature of the lines and cables reaches too high values, it can cause a risk of damages by, for example, the following ways:

- The sag of overhead lines can reach an unacceptable value.
- If the temperature of conductors, for example aluminium conductors, becomes too high, the material will be destroyed.
- In cables the insulation can be damaged as a consequence of overtemperature, and therefore phase-to-phase or phase-to-earth faults can occur.

In stressed situations in the power system, the lines and cables may be required to be overloaded for a limited time. This should be done without any risk for the above-mentioned risks.

The thermal overload protection provides information that makes temporary overloading of cables and lines possible. The thermal overload protection estimates the conductor temperature continuously. This estimation is made by using a thermal model of the line/cable that is based on the current measurement.

If the temperature of the protected object reaches a set warning level, a signal is given to the operator. This enables actions in the power system to be done before dangerous temperatures are reached. If the temperature continues to increase to the maximum allowed temperature value, the protection initiates a trip of the protected line.

[1] Overload current > 1.2 × Operate level temperature

4.1.6.2 Function block

Figure 228: Function block

4.1.6.3 Functionality

The three-phase thermal overload protection, two time constants, protection function T2PTTR protects the transformer mainly from short-time overloads. The transformer is protected from long-time overloads with the oil temperature detector included in its equipment.

The alarm signal gives an early warning to allow the operators to take action before the transformer trips. The early warning is based on the three-phase current measuring function using a thermal model with two settable time constants. If the temperature rise continues, T2PTTR operates based on the thermal model of the transformer.

After a thermal overload operation, the re-energizing of the transformer is inhibited during the transformer cooling time. The transformer cooling is estimated with a thermal model.

4.1.6.4 Analog channel configuration

T2PTTR has one analog group input which must be properly configured.

Table 442: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.6.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of T2PTTR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

The function uses ambient temperature which can be measured locally or remotely. Local measurement is done by the protection relay. Remote measurement uses analog GOOSE to connect AMB_TEMP input.

If the quality of remotely measured temperature is invalid or communication channel fails the function uses ambient temperature set in *Env temperature Set*.

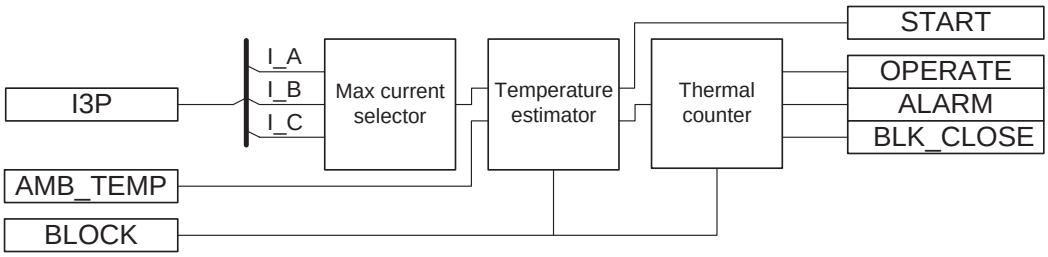

Figure 229: Functional module diagram

Max current selector

The max current selector of the function continuously checks the highest measured TRMS phase current value. The selector reports the highest value to the thermal counter.

Temperature estimator

The final temperature rise is calculated from the highest of the three-phase currents according to the expression:

$$\Theta_{final} = \left(\frac{I}{I_{ref}} \right)^2 \cdot T_{ref}$$

(Equation 35)

I	highest measured phase current
I_{ref}	the set value of the *Current reference* setting
T_{ref}	the set value of the *Temperature rise* setting (temperature rise (°C) with the steady-state current I_{ref}

The ambient temperature value is added to the calculated final temperature rise estimation. If the total value of temperature is higher than the set operate temperature level, the START output is activated.

The *Current reference* setting is a steady-state current that gives the steady-state end temperature value *Temperature rise*. It gives a setting value corresponding to the rated power of the transformer.

The *Temperature rise* setting is used when the value of the reference temperature rise corresponds to the *Current reference* value. The temperature values with the corresponding transformer load currents are usually given by transformer manufacturers.

Thermal counter

T2PTTR applies the thermal model of two time constants for temperature measurement. The temperature rise in degrees Celsius (°C) is calculated from the highest of the three-phase currents according to the expression:

$$\Delta\Theta = \left[p * \left(\frac{I}{I_{ref}} \right)^2 * T_{ref} \right] \cdot \left(1 - e^{-\frac{\Delta t}{\tau 1}} \right) + \left[(1-p) \cdot \left(\frac{I}{I_{ref}} \right)^2 \cdot T_{ref} \right] \cdot \left(1 - e^{-\frac{\Delta t}{\tau 2}} \right)$$

(Equation 36)

ΔΘ	calculated temperature rise (°C) in transformer
I	measured phase current with the highest TRMS value
I_{ref}	the set value of the *Current reference* setting (rated current of the protected object)
T_{ref}	the set value of the *Temperature rise* setting (temperature rise setting (°C) with the steady-state current I_{ref})
p	the set value of the *Weighting factor p* setting (weighting factor for the short time constant)
Δt	time step between the calculation of the actual temperature
t_1	the set value of the *Short time constant* setting (the short heating / cooling time constant)
t_2	the set value of the *Long time constant* setting (the long heating / cooling time constant)

The warming and cooling following the two time-constant thermal curve is a characteristic of transformers. The thermal time constants of the protected transformer are given in seconds with the *Short time constant* and *Long time constant* settings. The *Short time constant* setting describes the warming of the transformer with respect to windings. The *Long time constant* setting describes the warming of the transformer with respect to the oil. Using the two time-constant model, the protection relay is able to follow both fast and slow changes in the temperature of the protected object.

The *Weighting factor p* setting is the weighting factor between *Short time constant* τ_1 and *Long time constant* τ_2. The higher the value of the *Weighting factor p* setting, the larger is the share of the steep part of the heating curve. When *Weighting factor p* =1, only *Short-time constant* is used. When *Weighting factor p* = 0, only *Long time constant* is used.

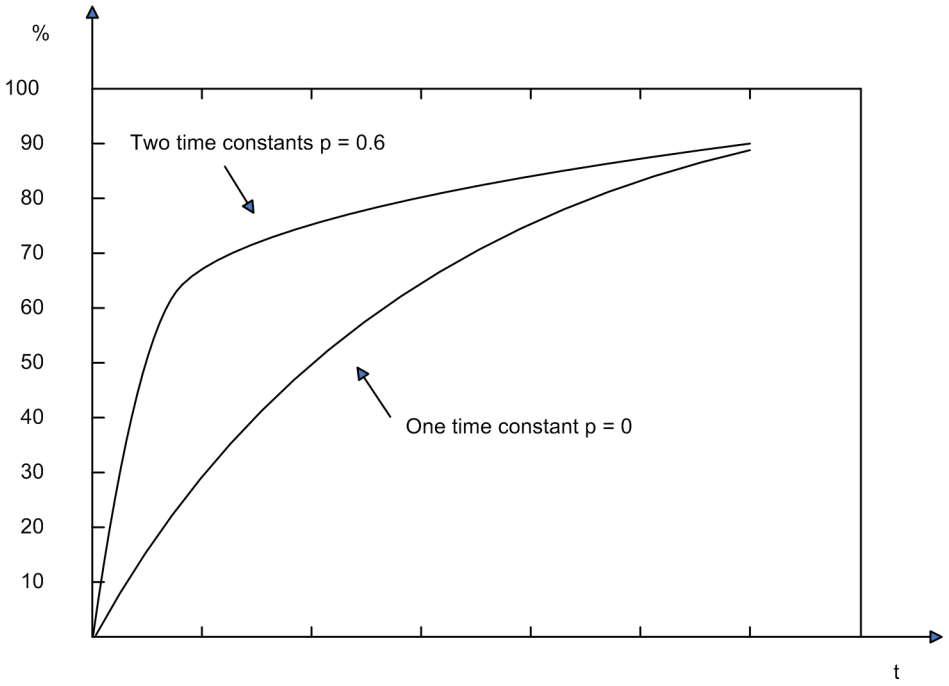

Figure 230: Effect of the Weighting factor p factor and the difference between the two time constants and one time constant models

The actual temperature of the transformer is calculated by adding the ambient temperature to the calculated temperature.

$$\Theta = \Delta\Theta + \Theta_{amb}$$

(Equation 37)

Θ	temperature in transformer (°C)
ΔΘ	calculated temperature rise (°C) in transformer
Θ_{amb}	set value of the *Env temperature Set* setting or measured ambient temperature

The ambient temperature can be measured with RTD measurement. The measured temperature value is connected, for example, from the `AI_VAL3` output of the X130 RTD function to the `AMB_TEMP` input of T2PTTR.

The *Env temperature Set* setting is used to define the ambient temperature if the ambient temperature measurement value is not connected to the `AMB_TEMP` input. The *Env temperature Set* setting is also used when the ambient temperature measurement connected to T2PTTR is set to “Not in use” in the X130 RTD function.

The temperature calculation is initiated from the value defined with the *Initial temperature* and *Max temperature* setting parameters. The initial value is a percentage of *Max temperature* defined by *Initial temperature*. This is done when the protection relay is powered up or the function is turned off and back on or reset through the Clear menu. The temperature is stored in a nonvolatile memory and restored if the protection relay is restarted.

The *Max temperature* setting defines the maximum temperature of the transformer in degrees Celsius (°C). The value of the *Max temperature* setting is usually given by

transformer manufacturers. The actual alarm, operating and lockout temperatures for T2PTTR are given as a percentage value of the *Max temperature* setting.

When the transformer temperature reaches the alarm level defined with the *Alarm temperature* setting, the ALARM output signal is set. When the transformer temperature reaches the trip level value defined with the *Operate temperature* setting, the OPERATE output is activated. The OPERATE output is deactivated when the value of the measured current falls below 10 percent of the *Current Reference* value or the calculated temperature value falls below *Operate temperature*.

There is also a calculation of the present time to operation with the present current. T_OPERATE is only calculated if the final temperature is calculated to be above the operation temperature. The value is available in the monitored data view.

After operating, there can be a lockout to reconnect the tripped circuit due to the thermal overload protection function. The BLK_CLOSE lockout output is activated when the device temperature is above the *Reclose temperature* lockout release temperature setting value. The time to lockout release T_ENA_CLOSE is also calculated. The value is available in the monitored data view.

4.1.6.6 Application

The transformers in a power system are constructed for a certain maximum load current level. If the current exceeds this level, the losses are higher than expected. This results in a rise in transformer temperature. If the temperature rise is too high, the equipment is damaged:

- Insulation within the transformer ages faster, which in turn increases the risk of internal phase-to-phase or phase-to-earth faults.
- Possible hotspots forming within the transformer degrade the quality of the transformer oil.

During stressed situations in power systems, it is required to overload the transformers for a limited time without any risks. The thermal overload protection provides information and makes temporary overloading of transformers possible.

The permissible load level of a power transformer is highly dependent on the transformer cooling system. The two main principles are:

- ONAN: The air is naturally circulated to the coolers without fans, and the oil is naturally circulated without pumps.
- OFAF: The coolers have fans to force air for cooling, and pumps to force the circulation of the transformer oil.

The protection has several parameter sets located in the setting groups, for example one for a non-forced cooling and one for a forced cooling situation. Both the permissive steady-state loading level as well as the thermal time constant are influenced by the transformer cooling system. The active setting group can be changed by a parameter, or through a binary input if the binary input is enabled for it. This feature can be used for transformers where forced cooling is taken out of operation or extra cooling is switched on. The parameters can also be changed when a fan or pump fails to operate.

The thermal overload protection continuously estimates the internal heat content, that is, the temperature of the transformer. This estimation is made by using a thermal model of the transformer which is based on the current measurement.

If the heat content of the protected transformer reaches the set alarm level, a signal is given to the operator. This enables the action that needs to be taken in the

power systems before the temperature reaches a high value. If the temperature continues to rise to the trip value, the protection initiates the trip of the protected transformer.

After the trip, the transformer needs to cool down to a temperature level where the transformer can be taken into service again. T2PTTR continues to estimate the heat content of the transformer during this cooling period using a set cooling time constant. The energizing of the transformer is blocked until the heat content is reduced to the set level.

The thermal curve of two time constants is typical for a transformer. The thermal time constants of the protected transformer are given in seconds with the *Short time constant* and *Long time constant* settings. If the manufacturer does not state any other value, the *Long time constant* can be set to 4920 s (82 minutes) for a distribution transformer and 7260 s (121 minutes) for a supply transformer. The corresponding *Short time constants* are 306 s (5.1 minutes) and 456 s (7.6 minutes).

If the manufacturer of the power transformer has stated only one, that is, a single time constant, it can be converted to two time constants. The single time constant is also used by itself if the p-factor *Weighting factor p* setting is set to zero and the time constant value is set to the value of the *Long time constant* setting. The thermal image corresponds to the one time constant model in that case.

Table 443: Conversion table between one and two time constants

70	7.2	115	0.4
75	7.8	124	0.4

The default *Max temperature* setting is 105°C. This value is chosen since even though the IEC 60076-7 standard recommends 98°C as the maximum allowable temperature in long-time loading, the standard also states that a transformer can withstand the emergency loading for weeks or even months, which may produce the winding temperature of 140°C. Therefore, 105°C is a safe maximum temperature value for a transformer if the *Max temperature* setting value is not given by the transformer manufacturer.

4.1.7 Motor load jam protection JAMPTOC (ANSI 50TDJAM)

4.1.7.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Motor load jam protection	JAMPTOC	Ist>	50TDJAM

4.1.7.2 Function block

Figure 231: Function block

4.1.7.3 Functionality

The motor load jam protection function JAMPTOC is used for protecting the motor in stall or mechanical jam situations during the running state.

When the motor is started, a separate function is used for the startup protection, and JAMPTOC is normally blocked during the startup period. When the motor has passed the starting phase, JAMPTOC monitors the magnitude of phase currents. The function starts when the measured current exceeds the breakdown torque level, that is, above the set limit. The operation characteristic is definite time.

The function contains a blocking functionality. It is possible to block the function outputs.

4.1.7.4 Analog channel configuration

JAMPTOC has one analog group input which must be properly configured.

[1] Overload current > 1.2 x Operate level temperature

Table 452: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.7.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of JAMPTOC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

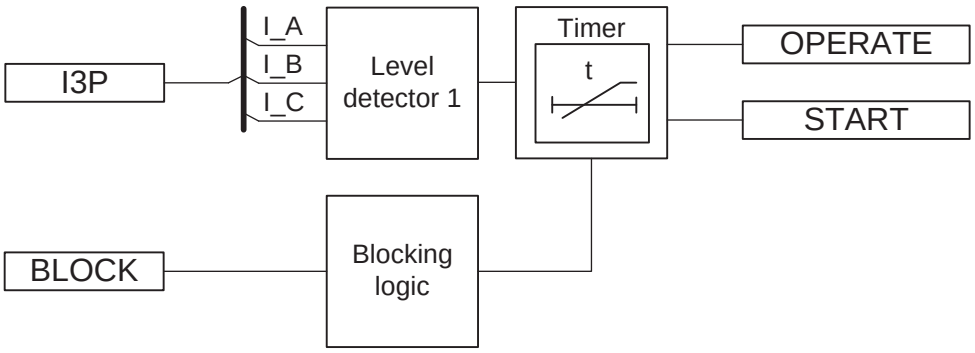

Figure 232: Functional module diagram

Level detector

The measured phase currents are compared to the set *Start value*. The TRMS values of the phase currents are considered for the level detection. The timer module is enabled if at least two of the measured phase currents exceed the set *Start value*.

Timer

Once activated, the internal `START` signal is activated. The value is available only through the Monitored data view. The time characteristic is according to DT. When the operation timer has reached the *Operate delay time* value, the `OPERATE` output is activated.

When the timer has elapsed but the motor stall condition still exists, the `OPERATE` output remains active until the phase currents values drop below the *Start value*, that is, until the stall condition persists. If the drop-off situation occurs while the operating time is still counting, the reset timer is activated. If the drop-off time exceeds the set *Reset delay time*, the operating timer is reset.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.1.7.6 Application

The motor protection during stall is primarily needed to protect the motor from excessive temperature rise, as the motor draws high currents during the stall phase. This condition causes a temperature rise in the stator windings. Due to reduced speed, the temperature also rises in the rotor. The rotor temperature rise is more critical when the motor stops.

The physical and dielectric insulations of the system deteriorate with age and the deterioration is accelerated by the temperature increase. Insulation life is related to the time interval during which the insulation is maintained at a given temperature.

An induction motor stalls when the load torque value exceeds the breakdown torque value, causing the speed to decrease to zero or to some stable operating point well below the rated speed. This occurs, for example, when the applied shaft load is suddenly increased and is greater than the producing motor torque due to the bearing failures. This condition develops a motor current almost equal to the value of the locked-rotor current.

JAMPTOC is designed to protect the motor in stall or mechanical jam situations during the running state. To provide a good and reliable protection for motors in a stall situation, the temperature effects on the motor have to be kept within the allowed limits.

4.1.8 Loss of load supervision LOFLPTUC (ANSI 37)

4.1.8.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Loss of load supervision	LOFLPTUC	3I<	37

4.1.8.2 Function block

Figure 233: Function block

4.1.8.3 Functionality

The loss of load supervision function LOFLPTUC is used to detect a sudden load loss which is considered as a fault condition.

LOFLPTUC starts when the current is less than the set limit. It operates with the definite time (DT) characteristics, which means that the function operates after a predefined operate time and resets when the fault current disappears.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.1.8.4 Analog channel configuration

LOFLPTUC has one analog group input which must be properly configured.

Table 459: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing

blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.8.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of LOFLPTUC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

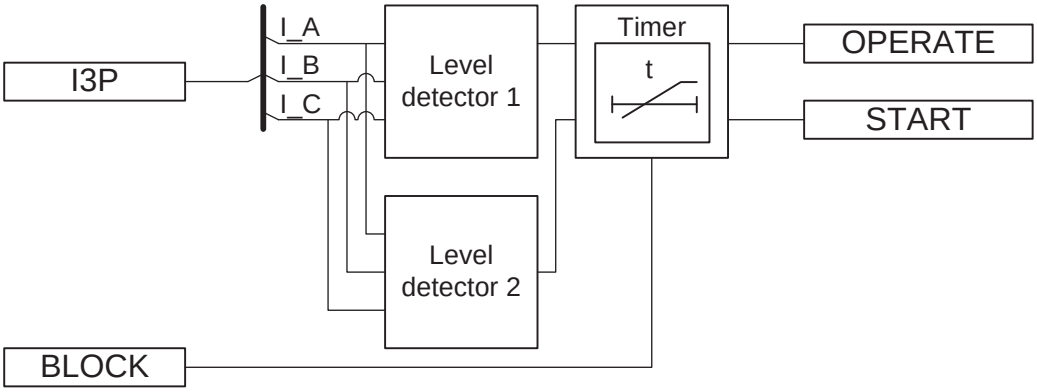

Figure 234: Functional module diagram

Level detector 1

This module compares the phase currents (RMS value) to the set *Start value high* setting. If all the phase current values are less than the set *Start value high* value, the loss of load condition is detected and an enable signal is sent to the timer. This signal is disabled after one or several phase currents have exceeded the set *Start value high* value of the element.

Level detector 2

This is a low-current detection module, which monitors the de-energized condition of the motor. It compares the phase currents (RMS value) to the set *Start value low* setting. If any of the phase current values is less than the set *Start value low*, a signal is sent to block the operation of the timer.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

The BLOCK signal blocks the operation of the function and resets the timer.

4.1.8.6 Application

When a motor runs with a load connected, it draws a current equal to a value between the no-load value and the rated current of the motor. The minimum load current can be determined by studying the characteristics of the connected load. When the current drawn by the motor is less than the minimum load current drawn, it can be inferred that the motor is either disconnected from the load or the coupling mechanism is faulty. If the motor is allowed to run in this condition, it may aggravate the fault in the coupling mechanism or harm the personnel handling the machine. Therefore, the motor has to be disconnected from the power supply as soon as the above condition is detected.

LOFLPTUC detects the condition by monitoring the current values and helps disconnect the motor from the power supply instantaneously or after a delay according to the requirement.

When the motor is at standstill, the current will be zero and it is not recommended to activate the trip during this time. The minimum current drawn by the motor when it is connected to the power supply is the no load current, that is, the higher start value current. If the current drawn is below the lower start value current, the motor is disconnected from the power supply. LOFLPTUC detects this condition and interprets that the motor is de-energized and disables the function to prevent unnecessary trip events.

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Loss of phase, undercurrent	PHPTUC1	3I<	37

4.1.9.2 Function block

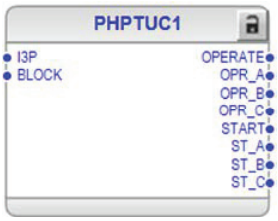

Figure 235: Function block

4.1.9.3 Functionality

The phase undercurrent protection function PHPTUC is used to detect an undercurrent that is considered as a fault condition.

PHPTUC starts when the current is less than the set limit. Operation time characteristics are according to definite time (DT).

The function contains a blocking functionality. It is possible to block function outputs and reset the definite timer.

4.1.9.4 Analog input configuration

PHPTUC has one analog group input which must be properly configured.

Table 467: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.9.5 Operation principle

The function can be enabled and disabled with the *Operation setting*. The corresponding parameter values are "On" and "Off".

The operation of PHPTUC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

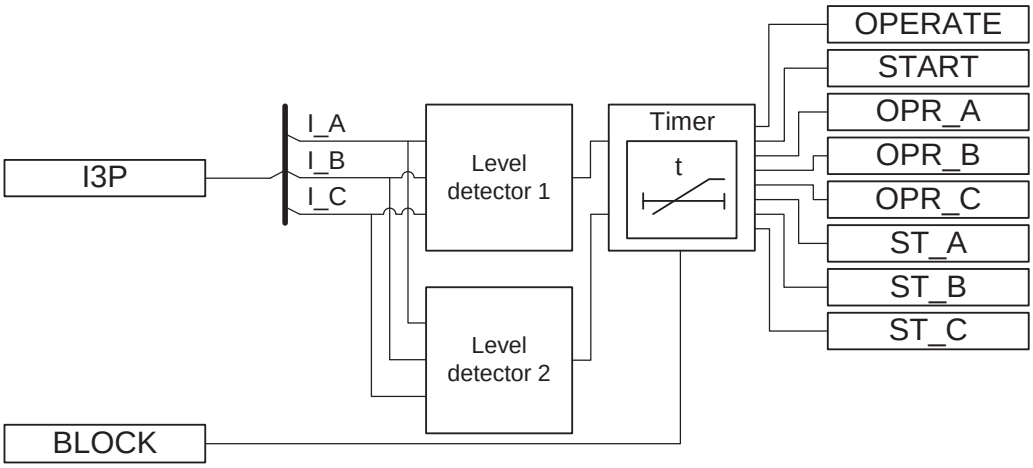

Figure 236: Functional module diagram

Level detector 1

This module compares the phase currents (RMS value) to the *Start value* setting. The *Operation mode* setting can be used to select the "3-phase" or "1-phase" mode.

If in the "3-phase" mode all the phase current values are less than the value of the *Start value* setting, the condition is detected and an enable signal is sent to the timer. This signal is disabled after one or several phase currents have exceeded the set *Start value* value of the element.

If in the "1-phase" mode any of the phase current values are less than the value of the *Start value* setting, the condition is detected and an enable signal is sent to the timer. This signal is disabled after all the phase currents have exceeded the set *Start value* value of the element.

The protection relay does not accept the *Start value* to be smaller than *Current block value*.

Level detector 2

This is a low-current detection module that monitors the de-energized condition of the protected object. The module compares the phase currents (RMS value) to the *Current block value* setting. If all the phase current values are less than the *Current block value* setting, a signal is sent to block the operation of the timer.

Timer

Once activated, the timer activates the `START` output and the phase-specific `ST_X output`. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the `OPERATE` output and the phase specific `OPR_X` output are activated. If the fault disappears before the module

operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available through the monitored data view.

The BLOCK signal blocks the operation of the function and resets the timer.

4.1.9.6 Application

In some cases, smaller distribution power transformers are used where the high-side protection involves only power fuses. When one of the high-side fuses blows in a single-phase condition, knowledge of it on the secondary side is lacking. The resulting negative-sequence current leads to a premature failure due to excessive heating and breakdown of the transformer insulation. Knowledge of this condition when it occurs allows for a quick fuse replacement and saves the asset.

The *Current block value* setting can be set to zero to not block PHPTUC with a low three-phase current. However, this results in an unnecessary event sending when the transformer or protected object is disconnected.

Phase-specific start and operate can give a better picture about the evolving faults when one phase has started first and another follows.

PHPTUC is meant to be a general protection function, so that it could be used in other cases too.

In case of undercurrent-based motor protection, see the Loss of load protection.

4.1.10 Thermal overload protection for motors MPTTR (ANSI 49M)

4.1.10.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Thermal overload protection for motors	MPTTR	3Ith>M	49M

4.1.10.2 Function block

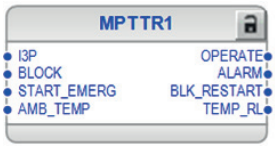

Figure 237: Function block

4.1.10.3 Functionality

The thermal overload protection for motors function MPTTR protects the electric motors from overheating. MPTTR models the thermal behavior of motor on the basis of the measured load current and disconnects the motor when the thermal content reaches 100 percent. The thermal overload conditions are the most often encountered abnormal conditions in industrial motor applications. The thermal overload conditions are typically the result of an abnormal rise in the motor running current, which produces an increase in the thermal dissipation of the motor and temperature or reduces cooling. MPTTR prevents an electric motor from drawing excessive current and overheating, which causes the premature insulation failures of the windings and, in worst cases, burning out of the motors.

4.1.10.4 Analog channel configuration

MPTTR has one analog group input which must be properly configured.

Table 475: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.1.10.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of MPTTR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

The function uses ambient temperature which can be measured locally or remotely. Local measurement is done by the protection relay. Remote measurement uses analog GOOSE to connect `AMB_TEMP` input.

If the quality of remotely measured temperature is invalid or communication channel fails the function uses ambient temperature set in *Env temperature Set*.

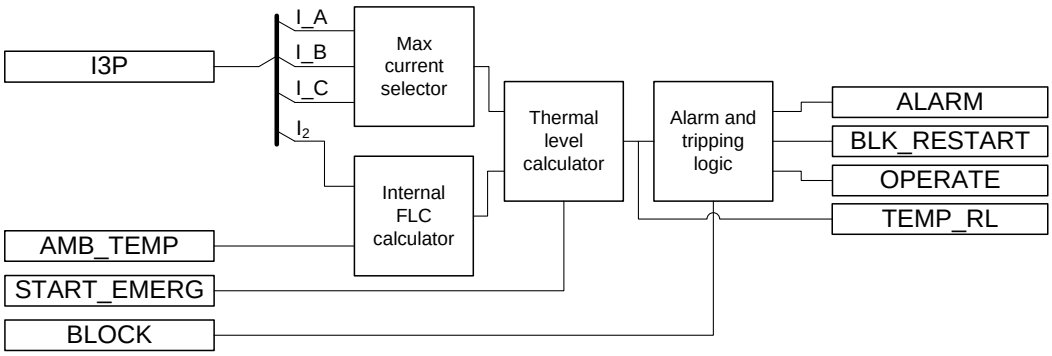

Figure 238: Functional module diagram

Max current selector

Max current selector selects the highest measured TRMS phase current and reports it to Thermal level calculator.

Internal FLC calculator

Full load current (FLC) of the motor is defined by the manufacturer at an ambient temperature of 40°C. Special considerations are required with an application where the ambient temperature of a motor exceeds or remains below 40°C. A motor operating at a higher temperature, even if at or below rated load, can subject the motor windings to excessive temperature similar to that resulting from overload operation at normal ambient temperature. The motor rating has to be appropriately reduced for operation in such high ambient temperatures. Similarly, when the ambient temperature is considerably lower than the nominal 40°C, the motor can be slightly overloaded. For calculating thermal level it is better that the FLC values

are scaled for different temperatures. The scaled currents are known as internal FLC. An internal FLC is calculated based on the ambient temperature shown in the table. The *Env temperature mode* setting defines whether the thermal level calculations are based on FLC or internal FLC.

When the value of the *Env temperature mode* setting is set to the "FLC Only" mode, no internal FLC is calculated. Instead, the FLC given in the data sheet of the manufacturer is used. When the value of the *Env temperature mode* setting is set to "Set Amb Temp" mode, the internal FLC is calculated based on the ambient temperature taken as an input through the *Env temperature Set* setting. When the *Env temperature mode* setting is on "Use input" mode, the internal FLC is calculated from temperature data available through resistance temperature detectors (RTDs) using the AMB_TEMP input.

Table 476: Modification of internal FLC

Ambient Temperature T_{amb}	Internal FLC
<20°C	FLC x 1.09
20 to <40°C	FLC x (1.18 - T_{amb} x 0.09/20)
40°C	FLC
>40 to 65°C	FLC x (1 –[(T_{amb} -40)/100])
>65°C	FLC x 0.75

The ambient temperature is used for calculating thermal level and it is available in the monitored data view from the TEMP_AMB output. The activation of the BLOCK input does not affect the TEMP_AMB output.

The *Env temperature Set* setting is used:

- If the ambient temperature measurement value is not connected to the AMB_TEMP input in ACT.
- When the ambient temperature measurement connected to 49M is set to "Not in use" in the RTD function.
- In case of any errors or malfunctioning in the RTD output.

Thermal level calculator

The module calculates the thermal load considering the TRMS and negative-sequence currents. The heating up of the motor is determined by the square value of the load current.

However, in case of unbalanced phase currents, the negative-sequence current also causes additional heating. By deploying a protection based on both current components, abnormal heating of the motor is avoided.

The thermal load is calculated based on different situations or operations and it also depends on the phase current level. The equations used for the heating calculations are:

$$\theta_B = \left[\left(\frac{I}{k \times I_r} \right)^2 + K_2 \times \left(\frac{I_2}{k \times I_r} \right)^2 \right] \times \left(1 - e^{-t/\tau} \right) \times p\%$$

(Equation 38)

$$\theta_A = \left[\left(\frac{I}{k \times I_r} \right)^2 + K_2 \times \left(\frac{I_2}{k \times I_r} \right)^2 \right] \times \left(1 - e^{-t/\tau} \right) \times 100\%$$

(Equation 39)

I	TRMS value of the measured max of phase currents
I_r	set *Current reference*, FLC or internal FLC
I_2	measured negative sequence current
k	set value of *Overload factor*
K_2	set value of *Negative Seq factor*
p	set value of *Weighting factor*
t	time constant

The equation θ_B is used when the values of all the phase currents are below the overload limit, that is, k x I_r. The equation θ_A is used when the value of any one of the phase currents exceeds the overload limit.

During overload condition, the thermal level calculator calculates the value of θ_B in background, and when the overload ends the thermal level is brought linearly from θ_A to θ_B with a speed of 1.66 percent per second. For the motor at standstill, that is, when the current is below the value of 0.12 x I_r, the cooling is expressed as:

$$\theta = \theta_{02} \times e^{\frac{-t}{\tau}}$$

(Equation 40)

θ_{02}	initial thermal level when cooling begins

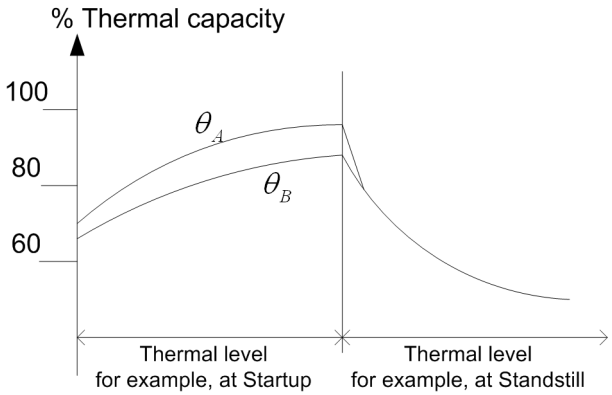

Figure 239: Thermal behavior

The required overload factor and negative sequence current heating effect factor are set by the values of the *Overload factor* and *Negative Seq factor* settings.

In order to accurately calculate the motor thermal condition, different time constants are used in the above equations. These time constants are employed based on different motor running conditions, for example starting, normal or stop, and are set through the *Time constant start*, *Time constant normal* and *Time constant stop* settings. Only one time constant is valid at a time.

Table 477: Time constant and the respective phase current values

Time constant (tau) in use	Phase current
Time constant start	Any current whose value is over 2.5 x I_r
Time constant normal	Any current whose value is over 0.12 x I_r and all currents are below 2.5 x I_r
Time constant stop	All the currents whose values are below 0.12 x I_r

The *Weighting factor p* setting determines the ratio of the thermal increase of the two curves θ_A and θ_B.

The thermal level at the power-up of the protection relay is defined by the *Initial thermal Val* setting.

The temperature calculation is initiated from the value defined in the *Initial thermal Val* setting. This is done if the protection relay is powered up or the function is turned off and back on or reset through the Clear menu.

The calculated temperature of the protected object relative to the operate level, the TEMP_RL output, is available through the monitored data view. The activation of the BLOCK input does not affect the calculated temperature.

The calculated temperature of the protected object relative to the operate level, the TEMP_RL output, is available through the monitored data view or through the output signal TEMP_RL. The activation of the BLOCK input does not affect the calculated temperature.

The thermal level at the beginning of the start-up condition of a motor and at the end of the start-up condition is available in the monitored data view at the THERMLEV_ST and THERMLEV_END outputs respectively. The activation of the BLOCK input does not have any effect on these outputs.

Alarm and tripping logic

The module generates alarm, restart inhibit and tripping signals.

When the thermal level exceeds the set value of the *Alarm thermal value* setting, the ALARM output is activated. Sometimes a condition arises when it becomes necessary to inhibit the restarting of a motor, for example in case of some extreme starting condition like long starting time. If the thermal content exceeds the set value of the *Restart thermal val* setting, the BLK_RESTART output is activated. The time for the next possible motor start-up is available through the monitored data view from the T_ENARESTART output. The T_ENARESTART output estimates the time for the BLK_RESTART deactivation considering as if the motor is stopped.

When the emergency start signal START_EMERG is set high, the thermal level is set to a value below the thermal restart inhibit level. This allows at least one motor start-up, even though the thermal level has exceeded the restart inhibit level.

When the thermal content reaches 100 percent, the OPERATE output is activated. The OPERATE output is deactivated when the value of the measured current falls below 12 percent of *Current reference* or the thermal content drops below 100 percent.

The activation of the BLOCK input blocks the ALARM, BLK_RESTART and OPERATE outputs.

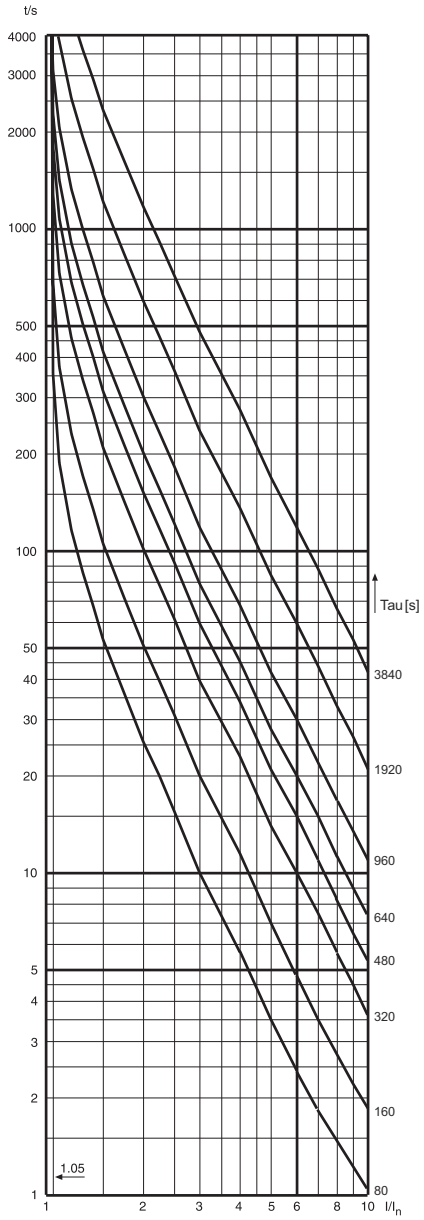

Figure 240: Trip curves when no prior load and p=20...100 %. Overload factor = 1.05.

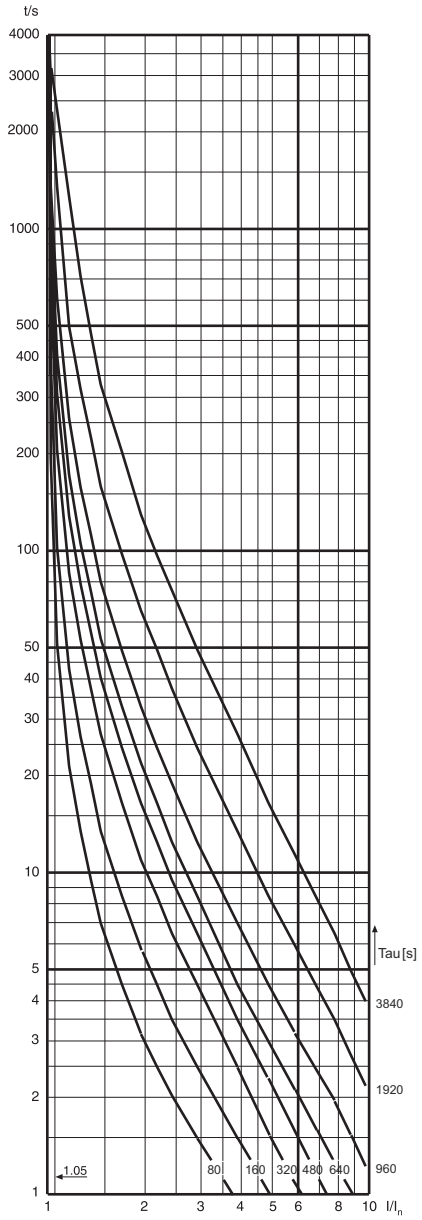

Figure 241: Trip curves at prior load 1 x FLC and p=100 %, Overload factor = 1.05.

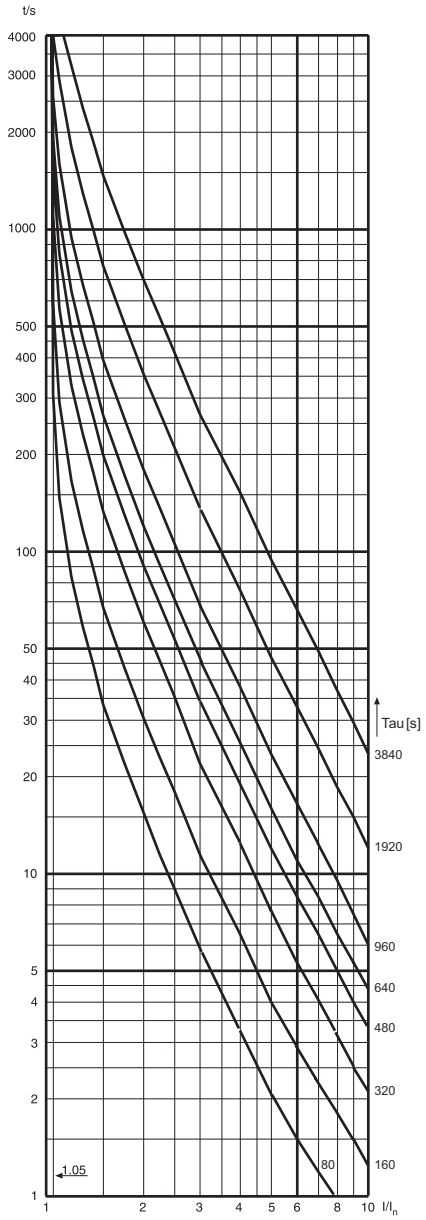

Figure 242: Trip curves at prior load 1 x FLC and p=50 %. Overload factor = 1.05.

4.1.10.6 Application

MPTTR is intended to limit the motor thermal level to predetermined values during the abnormal motor operating conditions. This prevents a premature motor insulation failure.

The abnormal conditions result in overheating and include overload, stalling, failure to start, high ambient temperature, restricted motor ventilation, reduced speed operation, frequent starting or jogging, high or low line voltage or frequency, mechanical failure of the driven load, improper installation and unbalanced line voltage or single phasing. The protection of insulation failure by the implementation of current sensing cannot detect some of these conditions, such as restricted ventilation. Similarly, the protection by sensing temperature alone can be inadequate in cases like frequent starting or jogging. The thermal overload

protection addresses these deficiencies to a larger extent by deploying a motor thermal model based on load current.

The thermal load is calculated using the true RMS phase value and negative sequence value of the current. The heating up of the motor is determined by the square value of the load current. However, while calculating the thermal level, the rated current should be re-rated or de-rated depending on the value of the ambient temperature. Apart from current, the rate at which motor heats up or cools is governed by the time constant of the motor.

Setting the weighting factor

There are two thermal curves: one which characterizes the short-time loads and long-time overloads and which is also used for tripping and another which is used for monitoring the thermal condition of the motor. The value of the *Weighting factor p* setting determines the ratio of the thermal increase of the two curves.

When the *Weighting factor p* setting is 100 percent, a pure single time constant thermal unit is produced which is used for application with the cables. As presented in *Figure 243*, the hot curve with the value of *Weighting factor p* being 100 percent only allows an operate time which is about 10 percent of that with no prior load. For example, when the set time constant is 640 seconds, the operate time with the prior load 1 x FLC (full Load Current) and overload factor 1.05 is only 2 seconds, even if the motor could withstand at least 5 to 6 seconds. To allow the use of the full capacity of the motor, a lower value of *Weighting factor p* should be used.

Normally, an approximate value of half of the thermal capacity is used when the motor is running at full load. Thus by setting *Weighting factor p* to 50 percent, the protection relay notifies a 45 to 50 percent thermal capacity use at full load.

For direct-on-line started motors with hot spot tendencies, the value of *Weighting factor p* is typically set to 50 percent, which will properly distinguish between short-time thermal stress and long-time thermal history. After a short period of thermal stress, for example a motor start-up, the thermal level starts to decrease quite sharply, simulating the leveling out of the hot spots. Consequently, the probability of successive allowed start-ups increases.

When protecting the objects without hot spot tendencies, for example motors started with soft starters, and cables, the value of *Weighting factor p* is set to 100 percent. With the value of *Weighting factor p* set to 100 percent, the thermal level decreases slowly after a heavy load condition. This makes the protection suitable for applications where no hot spots are expected. Only in special cases where the thermal overload protection is required to follow the characteristics of the object to be protected more closely and the thermal capacity of the object is very well known, a value between 50 and 100 percent is required.

For motor applications where, for example, two hot starts are allowed instead of three cold starts, the value of the setting *Weighting factor p* being 40 percent has proven to be useful. Setting the value of *Weighting factor p* significantly below 50 percent should be handled carefully as there is a possibility to overload the protected object as a thermal unit might allow too many hot starts or the thermal history of the motor has not been taken into account sufficiently.

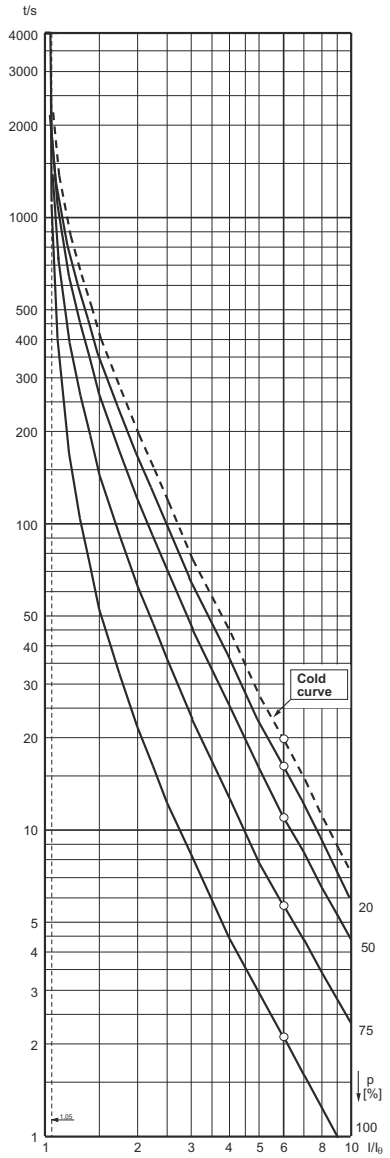

Figure 243: The influence of Weighting factor p at prior load 1xFLC, timeconstant = 640 s, and Overload factor = 1.05

Setting the overload factor

The value of *Overload factor* defines the highest permissible continuous load. The recommended value is 1.05.

Setting the negative sequence factor

During the unbalance condition, the symmetry of the stator currents is disturbed and a counter-rotating negative sequence component current is set up. An increased stator current causes additional heating in the stator and the negative sequence component current excessive heating in the rotor. Also mechanical problems like rotor vibration can occur.

The most common cause of unbalance for three-phase motors is the loss of phase resulting in an open fuse, connector or conductor. Often mechanical problems

can be more severe than the heating effects and therefore a separate unbalance protection is used.

Unbalances in other connected loads in the same busbar can also affect the motor. A voltage unbalance typically produces 5 to 7 times higher current unbalance. Because the thermal overload protection is based on the highest TRMS value of the phase current, the additional heating in stator winding is automatically taken into account. For more accurate thermal modeling, the *Negative Seq factor* setting is used for taking account of the rotor heating effect.

$$Negative\,Seq\ factor = \frac{R_{R2}}{R_{R1}}$$

(Equation 41)

R_{R2} Rotor negative sequence resistance

R_{R1} Rotor positive sequence resistance

A conservative estimate for the setting can be calculated:

$$Negative\,Seq\ factor = \frac{175}{I_{LR}^2}$$

(Equation 42)

I_{LR} Locked rotor current (multiple of set *Rated current*). The same as the start-up current at the beginning of the motor start-up.

For example, if the rated current of a motor is 230 A, start-up current is 5.7 x I_r,

$$Negative\,Seq\ factor = \frac{175}{5.7^2} = 5.4$$

(Equation 43)

Setting the thermal restart level

The restart disable level can be calculated as follows:

$$\theta_i = 100\% - \left(\frac{startup\,time\,of\,the\,motor}{operate\,time\,when\,no\,prior\,load} \times 100\% + margin \right)$$

(Equation 44)

For example, the motor start-up time is 11 seconds, start-up current 6 x rated and *Time constant start* is set for 800 seconds. Using the trip curve with no prior load, the operation time at 6 x rated current is 25 seconds, one motor start-up uses 11/25 ≈ 45 percent of the thermal capacity of the motor. Therefore, the restart disable level must be set to below 100 percent - 45 percent = 55 percent, for example to 50 percent (100 percent - (45 percent + margin), where margin is 5 percent).

Setting the thermal alarm level

Tripping due to high overload is avoided by reducing the load of the motor on a prior alarm.

The value of *Alarm thermal value* is set to a level which allows the use of the full thermal capacity of the motor without causing a trip due to a long overload time. Generally, the prior alarm level is set to a value of 80 to 90 percent of the trip level.

4.1.10.7 Signals

MPTTR Input signals

Table 478: MPTTR Input signals

Name	Type	Default	Description

Thermal overload protection for rotors	RPTTR	3Ith>R	49R

4.1.11.2 Function block

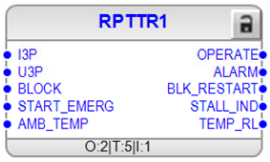

Figure 244: Function block

4.1.11.3 Functionality

The thermal overload protection for rotors RPTTR protects the rotor of the induction motor from overheating. RPTTR models the rotor thermal behavior on the basis of the measured load current and voltage and disconnects the motor when the thermal content reaches 100 percent. The rotor thermal overload conditions are

[1] Overload current > 1.2 × Operate level temperature

often encountered during the motor start-up and with abnormal conditions such as locked rotor or unbalance, which both produce excess heat due to the skin effect. The skin effect causes the current to distribute in a smaller surface in the rotor bars, increasing the resistance, and therefore also the heating effect.

The function also provides locked rotor protection. The locked rotor condition can be identified from the slip estimate that the function calculates.

4.1.11.4 Analog channel configuration

RPTTR has two analog group inputs which must be properly configured.

Table 485: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

4.1.11.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of RPTTR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

The function uses ambient temperature which can be measured locally or remotely. Local measurement is done by the protection relay. Remote measurement uses analog IEC 61850-8-1 GOOSE to connect `AMB_TEMP` input.

If the quality of remotely measured temperature is invalid or communication channel fails the function uses ambient temperature set in *Env temperature Set*.

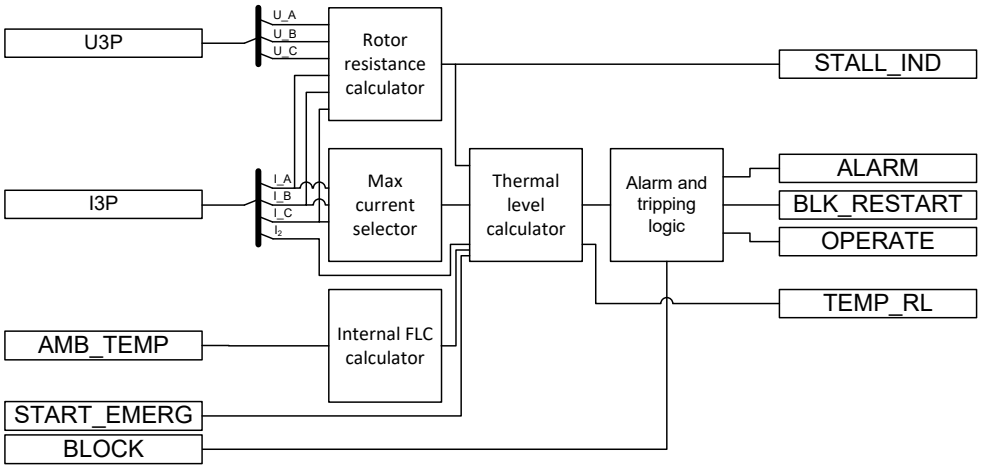

Figure 245: RPTTR module diagram

Alarm and tripping logic

The modules generate alarm, restart inhibit and tripping signal.

When the thermal level exceeds the set value of the *Alarm thermal value* setting, the ALARM output is activated. Sometimes a condition arises when it becomes necessary to inhibit the restarting of a motor, for example in case of some extreme starting condition like long starting time. If the thermal content exceeds the set value of the *Restart thermal Val* setting, the BLK_RESTART output is activated. The time for the next possible motor start-up is available through the monitored data view from T_ENARESTART. The T_ENARESTART estimates the time for the BLK_RESTART deactivation considering as if the motor is stopped.

When the emergency start signal START_EMERG is set high, the thermal level is set to a value below the *Restart thermal Val*. This allows at least one motor start-up, even though the thermal level has exceeded the *Restart thermal Val*.

When the thermal content reaches 100 percent, the OPERATE output is activated. The OPERATE output is deactivated when the value of the measured current falls below 12 percent of *Current reference* or the thermal content drops below 100 percent.

The activation of the BLOCK input blocks the ALARM, BLK_RESTART and OPERATE outputs.

Thermal level calculator

The module calculates the thermal load based on the rotor resistances factors, true RMS and negative sequence current. The rotor heating is determined by the squared value of the load current.

However, in case of unbalanced phase currents, the negative-sequence current also causes additional heating. By deploying a protection based on both current components, abnormal heating of rotor is avoided.

The equations used for the thermal level calculations are:

$$\theta_A = \left(R_{r+} \cdot \left(\frac{I}{k \cdot I_{IFLC}}\right)^2 + R_{r-} \cdot \left(\frac{I_2}{k \cdot I_{IFLC}}\right)^2\right) \cdot \left(1 - e^{-\frac{t}{\tau}}\right) \cdot 100\%$$

(Equation 45)

$$\theta_B = \left(R_{r+} \cdot \left(\frac{I}{k \cdot I_{IFLC}}\right)^2 + R_{r-} \cdot \left(\frac{I_2}{k \cdot I_{IFLC}}\right)^2\right) \cdot \left(1 - e^{-\frac{t}{\tau}}\right) \cdot p\%$$

(Equation 46)

θA	is the thermal level during overload,
θB	is the thermal level during nominal conditions,
R_{r+}	is the rotor positive sequence resistance factor,
R_{r-}	is the rotor negative sequence resistance factor,
I	is the True RMS value of the measured max of phase currents,
I_{IFLC}	is the calculated internal FLC,
I_2	is the measured negative sequence current,

Table continues on the next page

k	is the set value of *Overload factor*,
ρ	is the set value of *Weighting factor* and
t	is the time constant.

The equation θB is used whenever all phase current is below overload limit i.e. 2.5 · I_{IFLC}, whereas equation θA is used when any of the phase current exceeds overload limit.

During overload condition, the function calculated the θB in background, when overload ends the thermal level is brought linearly from θA to θB, with speed of 1.66% per second. For the motor at standstill i.e. when the current is below the value 0.12 · I_{IFLC}, the cooling can be expressed as:

$$\theta = \theta_{02} \cdot e^{-\frac{t}{\tau}}$$

(Equation 47)

θ_{02}	= initial thermal level when cooling begins

The thermal behavior can be understood from *Figure 246*.

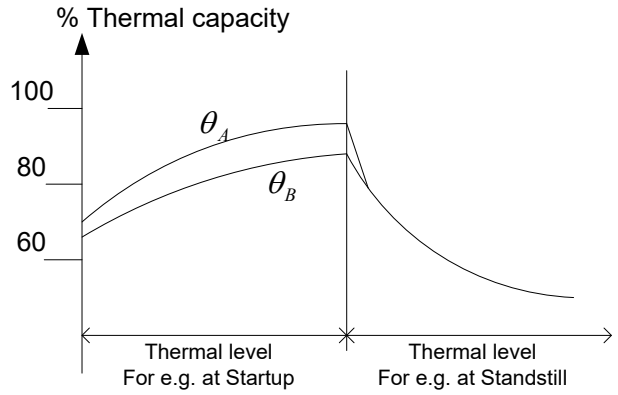

Figure 246: Thermal behavior

The required *Overload factor* is used to define the highest permissible continuous load. The recommended value is at minimum 1.05.

In order to accurately calculate the rotor thermal condition, different time constants are used in the above equations. These time constants are employed based on different motor running conditions, for example starting, normal or stop, and are set through the *Time constant start*, *Time constant normal*, and *Time constant stop* settings. Only one time constant is valid at a time. Different running conditions are defined by the comparison of the I_{IFLC} and the phase currents, which can be seen in *Table 486*.

Table 486: Time constant and the respective phase current values

Time constant in use	Phase current
tStart	Any current is over 2.5 · I_{IFLC}
tNormal	Any current is over 0.12 · I_{IFLC} and all currents are below 2.5 · I_{IFLC}
tStop	All currents are below 0.12 · I_{IFLC}

Setting *Weighting factor p* determines the ratio of the thermal increase of the two curves θA and θB.

The thermal level of the rotor at power up of the protection relay is defined by the setting *Initial thermal Val*.

The temperature calculation is initiated from the value defined in the *Initial thermal Val* setting. This is done if the protection relay is powered up or the function is turned off and back on or reset through the Clear menu.

Calculated thermal level TEMP_RL is available in monitored data view.

Thermal levels at the beginning and the end of the latest startup are available through the monitored data view at THERMLEV_ST and THERMLEV_END respectively.

Internal FLC calculator

Full load current (FLC) of the motor is defined by the manufacturer at an ambient temperature of 40°C. The FLC of the motor is set by *Current reference* setting. Special considerations are required with an application where the ambient temperature of a motor exceeds or remains below 40°C. A motor operating in a higher ambient temperature, even at or below rated load, can subject the motor windings to excessive temperature. The motor rating has to be appropriately reduced for operation in such high ambient temperatures. Similarly, when the ambient temperature is considerably lower than the nominal 40°C, the motor can be slightly overloaded. For calculating thermal level, it is better that the FLC values are scaled for different temperatures. The scaled currents are known as internal FLC (I_{IFLC}). An I_{IFLC} is calculated based on the ambient temperature shown in the table. The *Env temperature mode* setting defines whether the thermal level calculations are based on FLC or I_{IFLC}.

When the value of the *Env temperature mode* setting is set to the "FLC Only" mode, no I_{IFLC} is calculated. Instead, the FLC given in the data sheet of the manufacturer is used. When the value of the *Env temperature mode* setting is set to "Set Amb Temp" mode, the I_{IFLC} is calculated based on the ambient temperature taken as an input through the Env temperature Set setting. When the *Env temperature mode* setting is on "Use input" mode, the I_{IFLC} is calculated from temperature data available through resistance temperature detectors (RTDs) using the `AMB_TEMP` input.

Table 487: Temperature dependency of I_{IFLC}

Ambient Temperature (T_{amb})	I_{IFLC}
<20°C	FLC x 1.09
20 to <40°C	FLC x (1.18 - T_{amb} x 0.09/20)
40°C	FLC
>40 to 65°C	FLC x (1 –[(T_{amb} -40)/100])
>65°C	FLC x 0.75

The ambient temperature TEMP_AMB is available in the monitored data view.

The *Env temperature Set* setting is used:

- If the ambient temperature measurement value is not connected to the AMB_TEMP input in ACT.
- When the ambient temperature measurement connected to RPTTR is set to "Not in use" in the RTD function.
- In case of any errors or malfunctioning in the RTD input.

Max current selector

Max current selector selects the highest measured True RMS phase current and reports it to Thermal level calculator.

Rotor resistance calculator

The module calculates rotor resistances as a function of estimated slip. Slip estimate is based on the measured phase currents and line voltages.

Necessary initial values for slip estimation are rotor resistance at locked rotor and rotor resistance at nominal speed, calculated with following equations. Settings mentioned in equations can be found from the motor datasheet information.

$$R_N = 1 - \frac{RPM_N}{RPM_S}$$

(Equation 48)

R_N	is the rotor resistance at nominal speed,
RPM_N	is the setting *Nominal speed* and
RPM_S	is the setting *Synchronous* speed.

$$R_L = \frac{T_L}{I_L^2}$$

(Equation 49)

R_L	is the rotor resistance at locked rotor,
T_L	is the setting *Relative starting torque* and
I_L	is the setting *Relative starting current* .

In addition to R_N and R_L, the slip estimate calculation uses line voltages and phase currents to calculate the apparent total resistance and the initial stator resistance.

$$S = \frac{R_N}{1.2 \cdot (R - R_{SI}) - (R_L - R_N)}$$

(Equation 50)

S	is the motor slip,
R	is the apparent total resistance calculated from line voltages and phase currents,

Table continues on the next page

R_{SI} is the initial stator resistance calculated from line voltages and phase currents,
R_N is the rotor resistance at nominal speed and
R_L is the rotor resistance at locked rotor.

The rotor positive and negative sequence resistance vary depending on the motor slip. The slip estimate values are used to calculate the rotor positive and negative sequence resistance factors:

$$R_{r+} = \frac{(R_L - R_N)\cdot S + R_N}{R_N}$$

(Equation 51)

$$R_{r-} = \frac{(R_L - R_N)\cdot (2 - S) + R_N}{R_N}$$

(Equation 52)

R_{r+} is the rotor positive sequence resistance factor,
R_{r-} is the rotor negative sequence resistance factor,
R_L is the rotor resistance at locked rotor,
R_N is the rotor resistance at nominal speed and
S is the motor slip.

These resistance factors are then used in the thermal calculations to depict the thermal behavior that the skin effect causes.

The skin effect describes the situation where the rotor bars are induced with high amplitude and high frequency current which make the current flow in the rotor bars to be distributed close to the rotor bar surface, increasing the resistance of the rotor bar.

The rotor resistances depend on the relation of the rotating magnetic fluxes and the rotor speed, i.e. slip. The faster the fluxes cut the rotor bars the higher amplitude and higher frequency currents are induced to the rotor bars.

The rotor positive sequence resistance factor R_{r+} is at its highest at motor standstill (S=1), and smallest when the slip is at nominal value (S≈0). The rotor negative sequence resistance factor R_{r-}, however, grows larger as the rotor starts to revolve in the intended direction since the magnetic flux that the unbalance creates rotates in the opposite direction compared to the rotor, making the skin effect stronger.

STALL_IND output is provided for monitoring purposes or external logic. A TRUE value indicates that the rotor is stalling. The output is functional only when the motor is energized.

The rotational speed of the rotor is provided in monitored data at SPEED_RPM. The monitored data is also only functional when the motor is energized.

4.1.11.6 Application

Rotor thermal overload protection function is intended to prevent the rotor from overheating especially during motor starting and abnormal operating conditions

which cause the heating to be rapid. This prevents premature degeneration of the rotor unit. Additionally, the function provides an estimate of the motor slip, which allows identify locked rotor. This function is applicable for direct-on-line started induction motors with the motor line voltages available.

The rotor thermal overload protection function should be used in parallel with the motor thermal overload protection function MPTTR. This way both, the more rapid heating of the rotor, and the stable heating of the entire motor are taken into account.

Abnormal conditions that can result in overheating the rotor include overload, stalling, failure to start, high ambient temperature, restricted motor ventilation, reduced speed operation, frequent starting or jogging, high or low line voltage or frequency, mechanical failure of the driven load, improper installation, and unbalanced line voltage or single phasing. Protecting from insulation failure by implementation of current sensing alone cannot detect all of these conditions, such as restricted ventilation. Similarly, protection by sensing temperature alone may be inadequate, in cases like frequent starting or jogging. Thermal overload protection addresses these deficiencies to a large extent by deploying a rotor thermal model based on load current and the load voltage.

Rotor thermal level is calculated based on the rotor resistance factors, True RMS phase currents and negative sequence current. The rotor resistance factor is based on the estimated slip, that is calculated based on the measured line voltage and measured load current.

In addition, motor ambient temperature is taken into account in the thermal level calculation. Apart from current and the rotor resistance factor, the rate at which rotor heats up or cools is governed by time constant of the rotor.

Selecting of weighing factor

Motor manufacturers usually define two thermal limit curves one for warm and one for cold starts. The demands that these curves set are answered with the corresponding relay curves *Figure 247*.

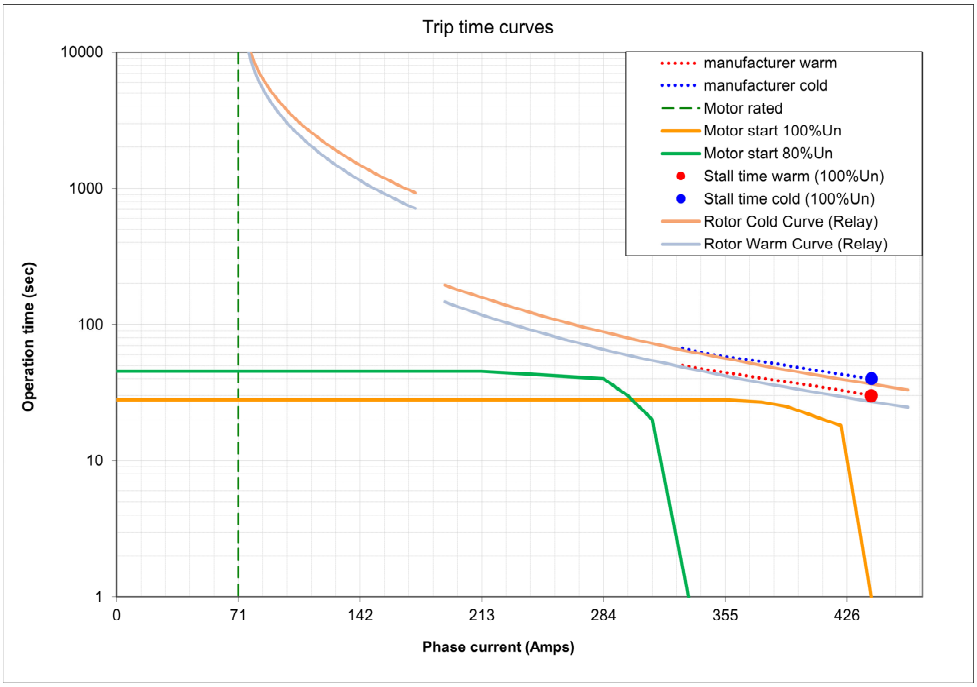

Figure 247: Trip time curves

In order to account for the difference between the warm and cold curves the *Weighting factor p* is used. This defines the difference, which is based on the warm and cold locked rotor times defined by the motor manufacturer. *Weighting factor p* can be calculated by the following equation:

$$Weighting\ factor\ p = k^2 \cdot \left(1 - \frac{LRT_{warm}}{LRT_{cold}}\right) \cdot 100\%$$

(Equation 53)

k	is the *Overload factor*,
LRT_{warm}	is the locked rotor time for warm start and
LRT_{cold}	is the locked rotor time for warm start.

The *Weighting factor p* for the rotor is usually lower than for the stator, since the temperature limit for the rotor is often higher. Therefore, the used thermal capacity, when running at full load, can be quite low. For example, with warm and cold locked rotor times being 5 and 6 seconds and *Overload factor* being 1.05, the *Weighting factor p* could be set to 18.4%.

$$Weighting\ factor\ p = 1.05^2 \cdot \left(1 - \frac{5}{6}\right) \cdot 100\% = 18.4\%$$

(Equation 54)

In addition, the *Weighting factor p* is used in the cumulative thermal level calculation. It is used to properly distinguish between short-time thermal stress

and long-time thermal history, allowing more critical situations like motor start-ups to be taken into consideration more carefully.

Setting of thermal restart level

The *Restart thermal Val* can be calculated as follows:

$$\theta_i = 100\% - \left(\frac{start-up\ time\ of\ the\ motor}{operate\ time\ when\ no\ prior\ load}\right) \cdot 100\% + margin$$

(Equation 55)

For instance, if the start-up time of the motor is 4 seconds, and the calculated operate time of the thermal protection stage for cold motor is 6 seconds, one motor start-up will use 4/6 = 66.6% of the thermal capacity of the motor. Therefore, the *Restart thermal Val* must be set to below 100% - 66.6% = 33.3% say to 28.3% (100% - (66.6% + margin), where margin is 5%).

Setting of thermal alarm level

Tripping due to high overload can be avoided by reducing the load of the motor when the thermal level reaches a set alarm level.

The *Alarm thermal value* can be set to a level, which will allow the use of the motor's full thermal capacity without causing a trip due to long time overload. Generally, the *Alarm thermal value* is set to 80....90% of the trip level.

4.1.11.7 Signals

RPTTR Input signals

Table 488: RPTTR Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
U3P	SIGNAL	-	Three-phase voltages

Generator shaft current leakage protection	GSLPTOC	I>,GS	38, 51

4.1.12.2 Function block

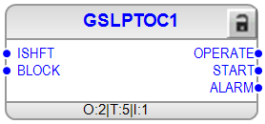

Figure 248: Function block

4.1.12.3 Functionality

Generator shaft current leakage protection function GSLPTOC protects the generator rotor bearings from damage caused by the shaft leakage current.

The function compares measured shaft current to the set alarm and operate levels. Operate time characteristics are according to definite time (DT).

4.1.12.4 Analog channel configuration

GSLPTOC has one analog input which must be properly configured.

Table 495: Analog inputs

Input	Description
ISHFT	Measured shaft current

4.1.12.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of *Generator shaft current leakage protection* can be described by using a module diagram (see figure below). All the modules in the diagram are explained in the next sections.

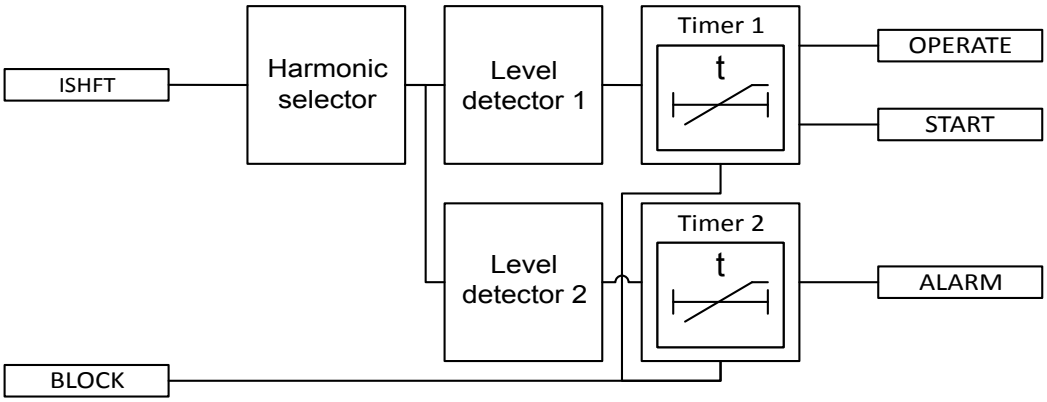

Figure 249: Functional module diagram

Harmonic selector

This module receives the shaft current measurement signal ISHAFT from the measurement arrangement. The recommended measurement arrangements (axial shaft CT with resistor or Rogowski coil with integrator) provide a voltage signal which is amplified for the relay input. The voltage signal is converted to current inside the function. Alternatively shaft current can be directly measured by relay current input when CT is used alone.

The operating harmonic component is selected according to the *Select harmonic* setting which is obtained from the commissioning test.

The selected harmonic component from the shaft current measurement is available in monitored data under `I_SHAFT`. Additionally, each of the available harmonics are available in monitored data under `I_SHAFT_H1`, `I_SHAFT_H3` and `I_SHAFT_H5`.

Level detector 1

The module compares the measured shaft current to the setting *Operate start value*, which is set in primary amps. If the level exceeds the set value, a enable signal is sent to Timer 1 module.

Level detector 2

The module compares the measured shaft current to the setting *Alarm start value*, which is set in primary amps. If the level exceeds the set value, a enable signal is sent to Timer 2 module.

Timer 1

Once activated, the Timer 1 activates the `START` output. The time characteristics are according to DT. When the operate timer reaches the value set by *Operate delay time*, the `OPERATE` output is activated. If the fault disappears before the module generates an `OPERATE` signal, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets.

The activation of the `BLOCK` signal resets the Timer 1 and deactivates the `OPERATE` and `START` outputs.

The module calculates the start duration value *START_DUR*, which indicates the percentage ratio of the start time and the set operating time. The value is available in the monitored data view.

Timer 2

Once activated, the alarm timer is activated. The time characteristics are according to DT. When the alarm timer reaches the value set by *Alarm delay time*, the ALARM output is activated. If the fault disappears before the module generates an ALARM signal, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the alarm timer resets. The activation of the BLOCK signal resets the Timer 2 and deactivates the ALARM output.

4.1.12.6 Application

In order to prevent the generator shaft from getting electrically charged the shaft is grounded. Different types of generators have different ways for shaft grounding. With hydro-generators, the water acts as a grounding point, and with turbogenerators the shaft can be grounded with a slip ring. However, the leakage current can still occur if the bearing pedestal, which is isolated from the ground, becomes grounded. This imposes shaft voltage on the oil-film of the bearing. The current can break the insulation that the oil-film provides and thus it can cause pitting and abrasion on the bearing face.

The measured shaft current is fed to the protection relay. The function compares the current signal to the set alarm and operate levels. Operate time characteristics are according to definite time.

Measurement device options

There are two different applicable shaft current measurement devices, the Rogowski coil and the current transformer (CT). Both devices are installed around the generator shaft. For both devices it is necessary to amplify the voltage signal. The recommended measurement principles are depicted in *Figure 250* and *Figure 251*.

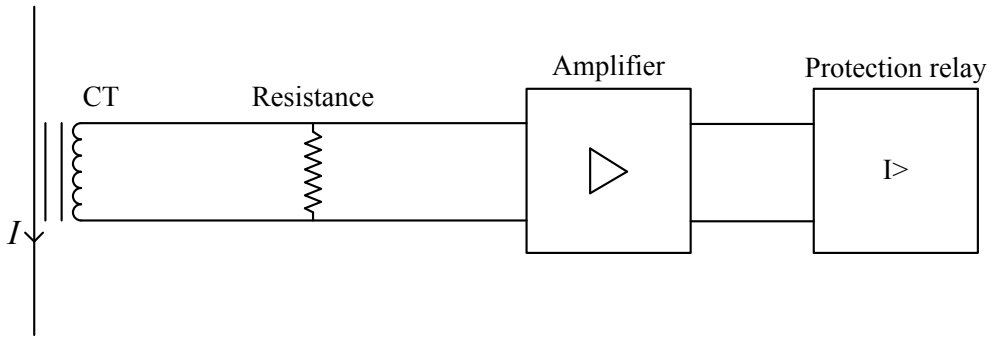

Figure 250: Current transformer measurement arrangement

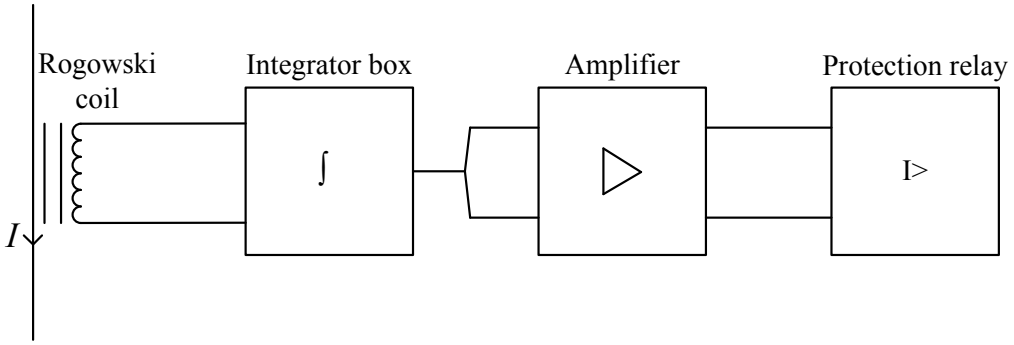

Figure 251: Rogowski coil measurement arrangement

It is also possible to feed shaft current, measured with CT, directly to the relay current input. Proper signal levels need to be ensured for reaching acceptable operation accuracy.

Setting *Alarm start value* and *Operate start value*

The current level that causes damage to bearings depends on the contact surface of the bearings. Current densities over 0.1 A/mm^2 start to damage the bearings. This can be generalized so, that currents over 1 A can be considered harmful. Therefore, the recommended setting for *Operate start value* is 0.5 A and for *Alarm start value* 0.25 A. Both values are set in primary amperes.

Non-directional earth-fault protection, high stage	EFHPTOC	Io>>	51G/51N-2
Non-directional earth-fault protection, instantaneous stage	EFIPTOC	Io>>>	50G/50N

4.2.1.2 Function block

Figure 252: Function block

[1] Current before fault = 0.0 x I_n, f_n = 50 Hz, nominal frequency fault current 1.1 x set *Start value* is injected, results based on statistical distribution of 1000 measurements

[2] Includes the delay (≈0ms) of the static signal output (SSO)

4.2.1.3 Functionality

The non-directional earth-fault protection function EFxPTOC is used as non-directional earth-fault protection for feeders.

The function starts and operates when the residual current exceeds the set limit. The operate time characteristic for low stage EFLPTOC and high stage EFHPTOC can be selected to be either definite time (DT) or inverse definite minimum time (IDMT). The instantaneous stage EFIPTOC always operates with the DT characteristic.

In the DT mode, the function operates after a predefined operate time and resets when the fault current disappears. The IDMT mode provides current-dependent timer characteristics.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.1.4 Analog channel configuration

EFxPTOC has one analog group input which must be properly configured.

Table 502: Analog inputs

Input	Description
IRES	Residual current (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of EFxPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

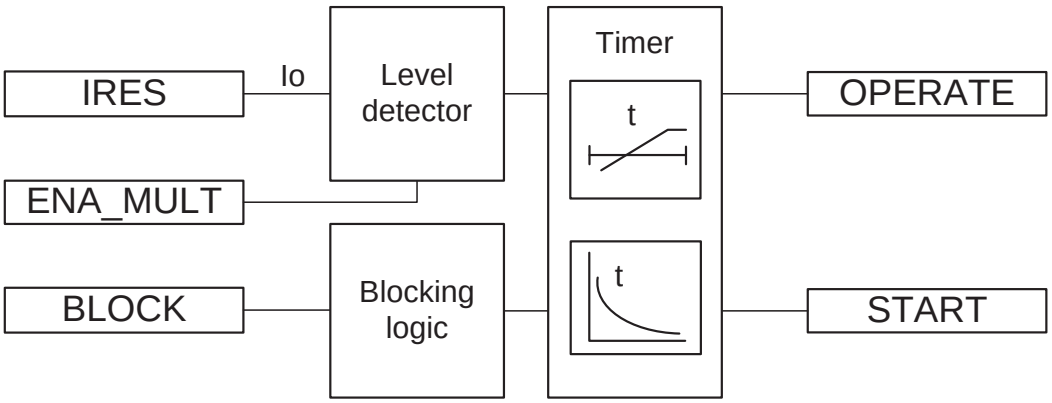

Figure 253: Functional module diagram

Level detector

The measured residual current is compared to the set *Start value*. If the measured value exceeds the set *Start value*, the level detector sends an enable-signal to the timer module. If the ENA_MULT input is active, the *Start value* setting is multiplied by the *Start value Mult* setting.

The protection relay does not accept the *Start value* or *Start value Mult* setting if the product of these settings exceeds the *Start value* setting range.

The start value multiplication is normally done when the inrush detection function (INRPHAR) is connected to the ENA_MULT input.

Timer

Once activated, the timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operate and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.2.1.6 Measurement modes

The function operates on three alternative measurement modes: "RMS", "DFT" and "Peak-to-Peak". The measurement mode is selected with the *Measurement mode* setting.

Table 503: Measurement modes supported by EFxPTOC stages

Measurement mode	EFLPTOC	EFHPTOC	EFIPTOC
RMS	x	x	
DFT	x	x	
Peak-to-Peak	x	x	x

For a detailed description of the measurement modes, see *Chapter 11.6 Measurement modes* in this manual.

4.2.1.7 Timer characteristics

EFxPTOC supports both DT and IDMT characteristics. The user can select the timer characteristics with the *Operating curve type* and *Type of reset curve* settings.

When the DT characteristic is selected, it is only affected by the *Operate delay time* and *Reset delay time* settings.

The protection relay provides 16 IDMT characteristics curves, of which seven comply with the IEEE C37.112 and six with the IEC 60255-3 standard. Two curves follow the special characteristics of ABB praxis and are referred to as RI and RD. In addition to this, a user programmable curve can be used if none of the standard curves are applicable. The user can choose the DT characteristic by selecting the *Operating curve type* values "ANSI Def. Time" or "IEC Def. Time". The functionality is identical in both cases.

The following characteristics, which comply with the list in the IEC 61850-7-4 specification, indicate the characteristics supported by different stages.

Table 504: Timer characteristics supported by different stages

Operating curve type	EFLPTOC	EFHPTOC
(1) ANSI Extremely Inverse	x	x
(2) ANSI Very Inverse	x	
(3) ANSI Normal Inverse	x	x
(4) ANSI Moderately Inverse	x	
(5) ANSI Definite Time	x	x
(6) Long Time Extremely Inverse	x	
(7) Long Time Very Inverse	x	
(8) Long Time Inverse	x	
(9) IEC Normal Inverse	x	x
(10) IEC Very Inverse	x	x
(11) IEC Inverse	x	
(12) IEC Extremely Inverse	x	x
(13) IEC Short Time Inverse	x	
(14) IEC Long Time Inverse	x	
(15) IEC Definite Time	x	x
(17) User programmable curve	x	x
(18) RI type	x	
(19) RD type	x	

EFIPTOC supports only definite time characteristics.

For a detailed description of timers, see *Chapter 11 General function block features* in this manual.

Table 505: Reset time characteristics supported by different stages

Reset curve type	EFLPTOC	EFHPTOC	Note
(1) Immediate	x	x	Available for all operate time curves
(2) Def time reset	x	x	Available for all operate time curves
(3) Inverse reset	x	x	Available only for ANSI and user programmable curves

The *Type of reset curve* setting does not apply to EFIPTOC or when the DT operation is selected. The reset is purely defined by the *Reset delay time* setting.

4.2.1.8 Application

EFxPTOC is designed for protection and clearance of earth faults in distribution and sub-transmission networks where the neutral point is isolated or earthed via a resonance coil or through low resistance. It also applies to solidly earthed networks and earth-fault protection of different equipment connected to the power systems, such as shunt capacitor bank or shunt reactors and for backup earth-fault protection of power transformers.

Many applications require several steps using different current start levels and time delays. EFxPTOC consists of three different protection stages.

- Low EFLPTOC
- High EFHPTOC
- Instantaneous EFIPTOC

EFLPTOC contains several types of time-delay characteristics. EFHPTOC and EFIPTOC are used for fast clearance of serious earth faults.

4.2.2.2 Function block

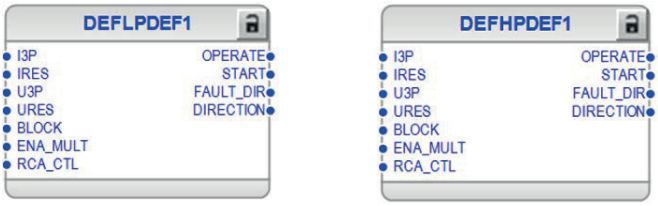

Figure 254: Function block

4.2.2.3 Functionality

The directional earth-fault protection function DEFxPDEF is used as directional earth-fault protection for feeders.

The function starts and operates when the operating quantity (current) and polarizing quantity (voltage) exceed the set limits and the angle between them is inside the set operating sector. The operate time characteristic for low stage (DEFLPDEF) and high stage (DEFHPDEF) can be selected to be either definite time (DT) or inverse definite minimum time (IDMT).

In the DT mode, the function operates after a predefined operate time and resets when the fault current disappears. The IDMT mode provides current-dependent timer characteristics.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.2.4 Analog channel configuration

DEFxPDEF has four analog group inputs which must be properly configured.

Table 528: Analog inputs

Input	Description
I3P [1]	Three-phase currents, necessary when *Pol quantity* is set to "Neg. seq. volt."
IRES	Residual current (measured or calculated)

Table continues on the next page

[1] Can be connected to `GRPOFF` if *Pol quantity* is set to "Zero seq. volt" or *Directional mode* is set to "Nondirectional".

Input	Description
U3P [1]	Three-phase voltages, necessary when *Pol quantity* is set to "Neg. seq. volt."
URES [2]	Residual voltage (measured or calculated), necessary when *Pol quantity* is set to "Zero seq. volt."

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

Table 529: Special conditions

Condition	Description
U3P connected real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.
URES calculated	Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of DEFxPDEF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

[2] Can be connected to GRPOFF if *Pol quantity* is set to "Neg. seq. volt" or *Directional mode* is set to "Nondirectional".

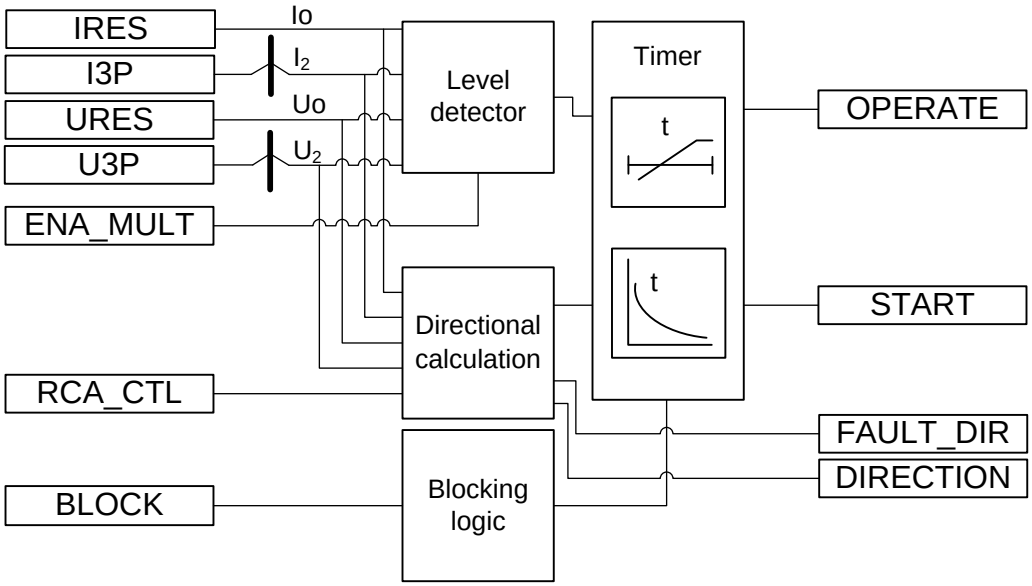

Figure 255: Functional module diagram

Level detector

The magnitude of the operating quantity is compared to the set *Start value* and the magnitude of the polarizing quantity is compared to the set *Voltage start value*. If both the limits are exceeded, the level detector sends an enabling signal to the timer module. When the *Enable voltage limit* setting is set to "False", *Voltage start value* has no effect and the level detection is purely based on the operating quantity. If the ENA_MULT input is active, the *Start value* setting is multiplied by the *Start value Mult* setting.

If the *Enable voltage limit* setting is set to "True", the magnitude of the polarizing quantity is checked even if the *Directional mode* was set to "Non-directional" or *Allow Non Dir* to "True". The protection relay does not accept the *Start value* or *Start value Mult* setting if the product of these settings exceeds the *Start value* setting range.

Typically, the ENA_MULT input is connected to the inrush detection function INRHPAR. In case of inrush, INRPHAR activates the ENA_MULT input, which multiplies *Start value* by the *Start value Mult* setting.

Directional calculation

The directional calculation module monitors the angle between the polarizing quantity and operating quantity. Depending on the *Pol quantity* setting, the polarizing quantity can be the residual voltage (measured or calculated) or the negative sequence voltage. When the angle is in the operation sector, the module sends the enabling signal to the timer module.

The minimum signal level which allows the directional operation can be set with the *Min operate current* and *Min operate voltage* settings.

If *Pol quantity* is set to "Zero. seq. volt", the residual current and residual voltage are used for directional calculation.

If *Pol quantity* is set to "Neg. seq. volt", the negative sequence current and negative sequence voltage are used for directional calculation.

In the phasor diagrams representing the operation of DEFxPDEF, the polarity of the polarizing quantity (Uo or U2) is reversed, that is, the polarizing quantity in the phasor diagrams is either -Uo or -U2. Reversing is done by switching the polarity of the residual current measuring channel (see the connection in the Protection relay's physical connections section). Similarly the polarity of the calculated Io and I_2 is also switched.

For defining the operation sector, there are five modes available through the *Operation mode* setting.

Table 530: Operation modes

Operation mode	Description
Phase angle	The operating sectors for forward and reverse are defined with the settings *Min forward angle*, *Max forward angle*, *Min reverse angle* and *Max reverse angle*.
IoSin	The operating sectors are defined as "forward" when |Io| x sin (ANGLE) has a positive value and "reverse" when the value is negative. ANGLE is the angle difference between -Uo and Io.
IoCos	As "IoSin" mode. Only cosine is used for calculating the operation current.
Phase angle 80	The sector maximum values are frozen to 80 degrees respectively. Only *Min forward angle* and *Min reverse angle* are settable.
Phase angle 88	The sector maximum values are frozen to 88 degrees. Otherwise as "Phase angle 80" mode.

Polarizing quantity selection "Neg. seq. volt." is available only in the "Phase angle" operation mode.

The directional operation can be selected with the *Directional mode* setting. The alternatives are "Non-directional", "Forward" and "Reverse" operation. The operation criterion is selected with the *Operation mode* setting. By setting *Allow Non Dir* to "True", non-directional operation is allowed when the directional information is invalid, that is, when the magnitude of the polarizing quantity is less than the value of the *Min operate voltage* setting.

Typically, the network rotating direction is counter-clockwise and defined as "ABC". If the network rotating direction is reversed, meaning clockwise, that is, "ACB", the equation for calculating the negative sequence voltage component need to be changed. The network rotating direction is defined with a system parameter *Phase rotation*. The calculation of the component is affected but the angle difference calculation remains the same. When the residual voltage is used as the polarizing method, the network rotating direction change has no effect on the direction calculation.

The network rotating direction is set in the protection relay using the parameter in the HMI menu: **Configuration** > **System** > **Phase rotation**.

The default parameter value is "ABC".

If the *Enable voltage limit* setting is set to "True", the magnitude of the polarizing quantity is checked even if *Directional mode* is set to "Non-directional" or *Allow Non Dir* to "True".

The *Characteristic angle* setting is used in the "Phase angle" mode to adjust the operation according to the method of neutral point earthing so that in an isolated network the *Characteristic angle* (ϕ_{RCA}) = -90° and in a compensated network ϕ_{RCA} = 0°. In addition, the characteristic angle can be changed via the control signal RCA_CTL. RCA_CTL affects the *Characteristic angle* setting.

The *Correction angle* setting can be used to improve selectivity due the inaccuracies in the measurement transformers. The setting decreases the operation sector. The correction can only be used with the "IoCos" or "IoSin" modes.

The polarity of the polarizing quantity can be reversed by setting the *Pol reversal* to "True", which turns the polarizing quantity by 180 degrees.

For definitions of different directional earth-fault characteristics, see *Chapter 4.2.2.9 Directional earth-fault characteristics* in this manual.

The DIRECTION output indicates on which operating sector the operating quantity is measured. The FAULT_DIR output indicates in which operation sector the fault current is measured. The output is operational once the function is started.

The directional calculation module calculates several values which are presented in the monitored data.

Table 531: Monitored data values

Monitored data values	Description
ANGLE	Also called operating angle, shows the angle difference between the polarizing quantity (Uo, U_2) and operating quantity (Io, I_2).
ANGLE_RCA	The angle difference between the operating angle and Characteristic angle, that is, ANGLE_RCA = ANGLE – Characteristic angle.
I_OPER	The current that is used for fault detection. If the Operation mode setting is "Phase angle", "Phase angle 80" or "Phase angle 88", I_OPER is the measured or calculated residual current. If the Operation mode setting is "IoSin", I_OPER is calculated as follows I_OPER = Io x sin(ANGLE). If the Operation mode setting is "IoCos", I_OPER is calculated as follows I_OPER = Io x cos(ANGLE).

Timer

Once activated, the timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT

curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operate and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.2.2.6 Directional earth-fault principles

In many cases it is difficult to achieve selective earth-fault protection based on the magnitude of residual current only. To obtain a selective earth-fault protection scheme, it is necessary to take the phase angle of Io into account. This is done by comparing the phase angle of the operating and polarizing quantity.

Relay characteristic angle

The *Characteristic angle* setting, also known as Relay Characteristic Angle (RCA), Relay Base Angle or Maximum Torque Angle (MTA), is used in the "Phase angle" mode to turn the directional characteristic if the expected fault current angle does not coincide with the polarizing quantity to produce the maximum torque. That is, RCA is the angle between the maximum torque line and polarizing quantity. If the polarizing quantity is in phase with the maximum torque line, RCA is 0 degrees. The

angle is positive if the operating current lags the polarizing quantity and negative if it leads the polarizing quantity.

Example 1

The "Phase angle" mode is selected, compensated network (ϕRCA = 0 deg)

=> *Characteristic angle* = 0 deg

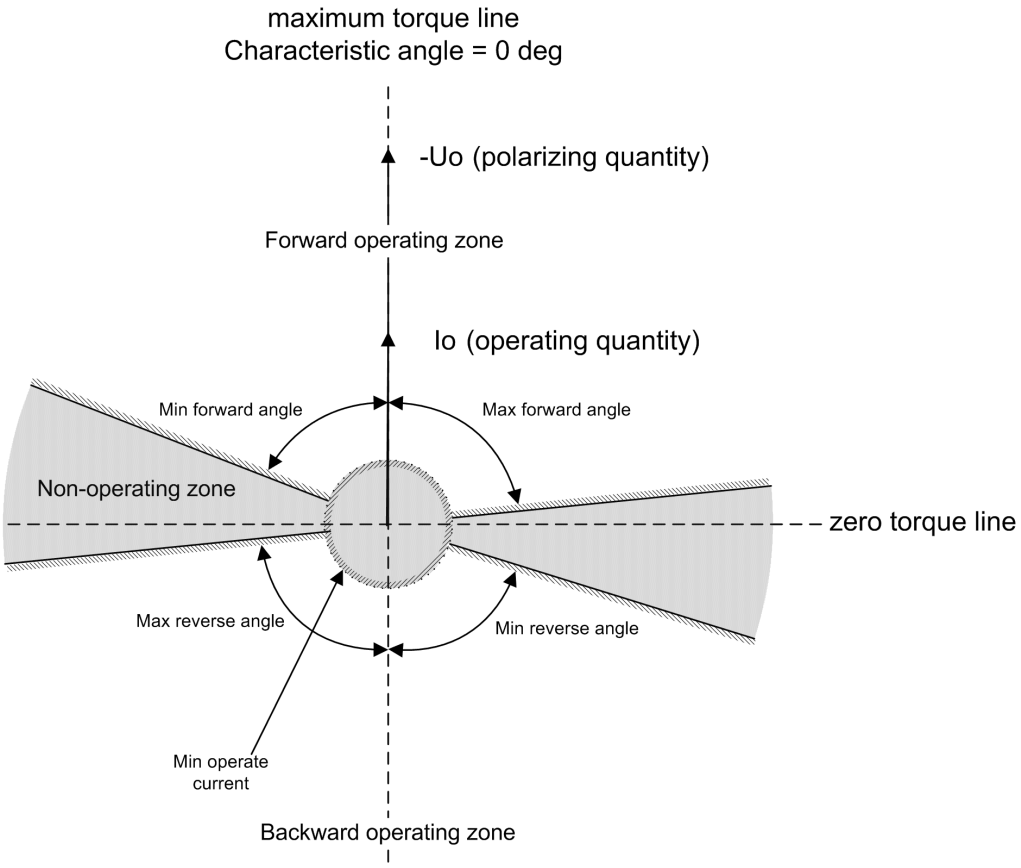

Figure 256: Definition of the relay characteristic angle, RCA=0 degrees in a compensated network

Example 2

The "Phase angle" mode is selected, solidly earthed network (ϕRCA = +60 deg)

=> *Characteristic angle* = +60 deg

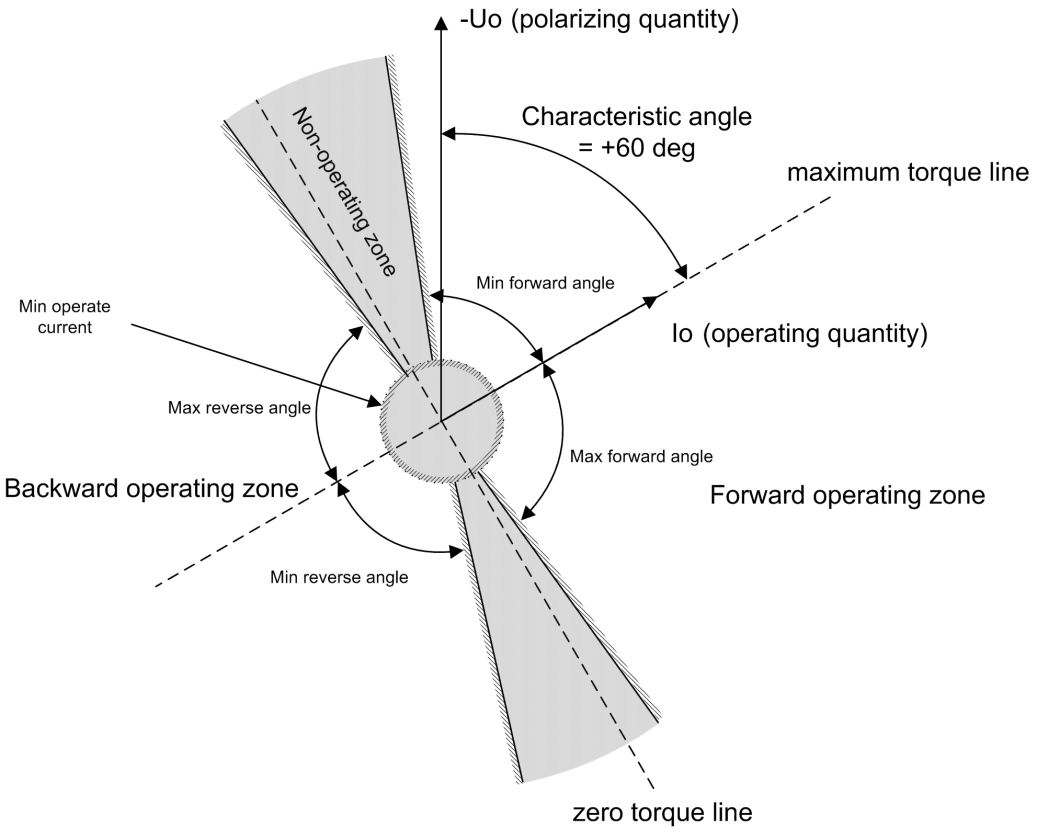

Figure 257: Definition of the relay characteristic angle, RCA=+60 degrees in a solidly earthed network

Example 3

The "Phase angle" mode is selected, isolated network (ϕRCA = -90 deg)

=> *Characteristic angle* = -90 deg

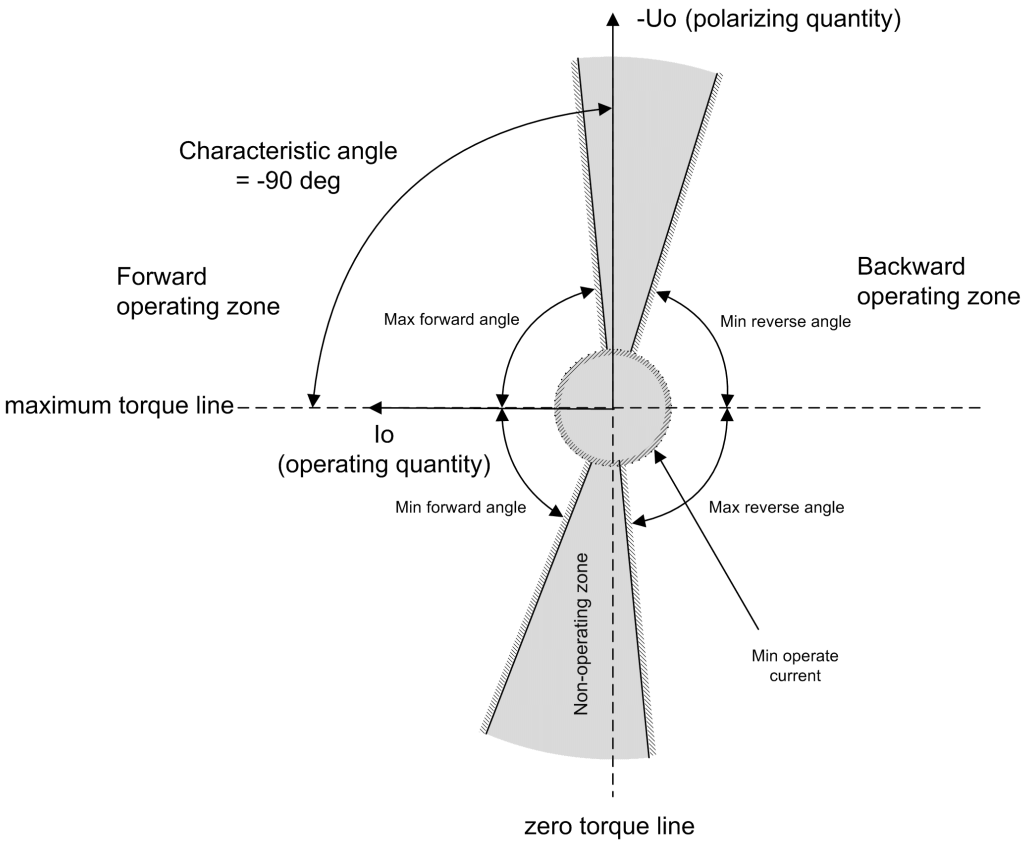

Figure 258: Definition of the relay characteristic angle, RCA=–90 degrees in an isolated network

Directional earth-fault protection in an isolated neutral network

In isolated networks, there is no intentional connection between the system neutral point and earth. The only connection is through the phase-to-earth capacitances (C_0) of phases and leakage resistances (R_0). This means that the residual current is mainly capacitive and has a phase shift of -90 degrees compared to the polarizing voltage. Consequently, the relay characteristic angle (RCA) should be set to -90 degrees and the operation criteria to "IoSin" or "Phase angle". The width of the operating sector in the phase angle criteria can be selected with the settings *Min forward angle*, *Max forward angle*, *Min reverse angle* or *Max reverse angle*. *Figure 259* illustrates a simplified equivalent circuit for an unearthed network with an earth fault in phase C.

For definitions of different directional earth-fault characteristics, see *Chapter 4.2.2.9 Directional earth-fault characteristics* .

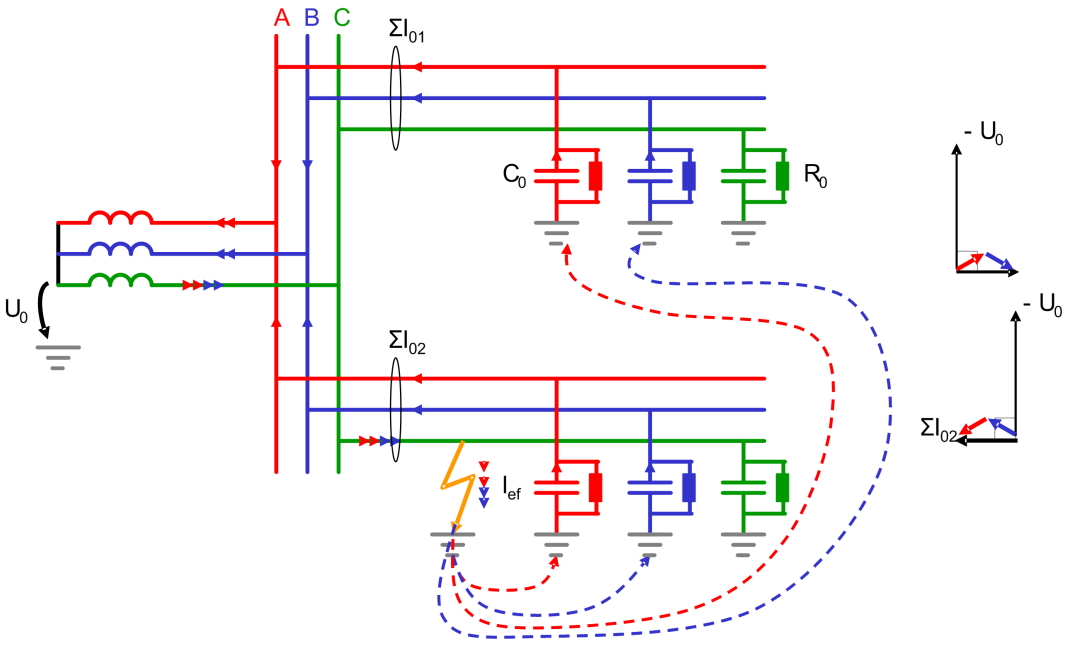

Figure 259: Earth-fault situation in an isolated network

Directional earth-fault protection in a compensated network

In compensated networks, the capacitive fault current and the inductive resonance coil current compensate each other. The protection cannot be based on the reactive current measurement, since the current of the compensation coil would disturb the operation of the protection relays. In this case, the selectivity is based on the measurement of the active current component. The magnitude of this component is often small and must be increased by means of a parallel resistor in the compensation equipment. When measuring the resistive part of the residual current, the *Operation mode* should be set to "Phase angle" and the relay characteristic angle (RCA) should be set to 0 degrees. Alternatively, the *Operation mode* can be set to "IoCos". *Figure 259* illustrates a simplified equivalent circuit for a compensated network with an earth fault in phase C.

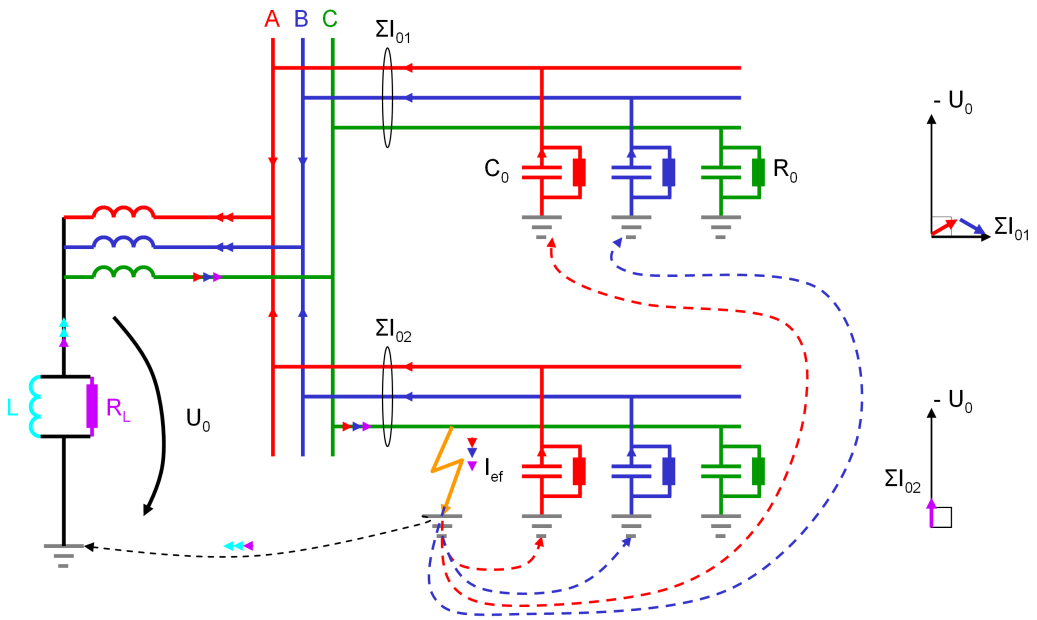

Figure 260: Earth-fault situation in a compensated network

The Petersen coil or the earthing resistor may be temporarily out of operation. To keep the protection scheme selective, it is necessary to update the *Characteristic angle* setting accordingly. This can be done with an auxiliary input in the protection relay which receives a signal from an auxiliary switch of the disconnector of the Petersen coil in compensated networks. As a result the characteristic angle is set automatically to suit the earthing method used. The RCA_CTL input can be used to change the operation criteria as described in *Table 532* and *Table 533*.

Table 532: Relay characteristic angle control in Iosin(ϕ) and Iocos(ϕ) operation criteria

***Operation mode* setting:**	**RCA_CTL = FALSE**	**RCA_CTL = TRUE**
Iosin	Actual operation mode: Iosin	Actual operation mode: Iocos
Iocos	Actual operation mode: Iocos	Actual operation mode: Iosin

Table 533: *Characteristic angle* control in phase angle operation mode

***Characteristic angle* setting**	**RCA_CTL = FALSE**	**RCA_CTL = TRUE**
-90°	ϕ_{RCA} = -90°	ϕ_{RCA} = 0°
0°	ϕ_{RCA} = 0°	ϕ_{RCA} = -90°

Use of the extended phase angle characteristic

The traditional method of adapting the directional earth-fault protection function to the prevailing neutral earthing conditions is done with the *Characteristic angle* setting. In an unearthed network, *Characteristic angle* is set to -90 degrees and in a compensated network *Characteristic angle* is set to 0 degrees. In case the earthing method of the network is temporarily changed from compensated to unearthed due to the disconnection of the arc suppression coil, the *Characteristic angle* setting should be modified correspondingly. This can be done using the setting

groups or the RCA_CTL input. Alternatively, the operating sector of the directional earth-fault protection function can be extended to cover the operating sectors of both neutral earthing principles. Such characteristic is valid for both unearthed and compensated network and does not require any modification in case the neutral earthing changes temporarily from the unearthed to compensated network or vice versa.

The extended phase angle characteristic is created by entering a value of over 90 degrees for the *Min forward angle* setting; a typical value is 170 degrees (*Min reverse angle* in case *Directional mode* is set to "Reverse"). The *Max forward angle* setting should be set to cover the possible measurement inaccuracies of current and voltage transformers; a typical value is 80 degrees (*Max reverse angle* in case *Directional mode* is set to "Reverse").

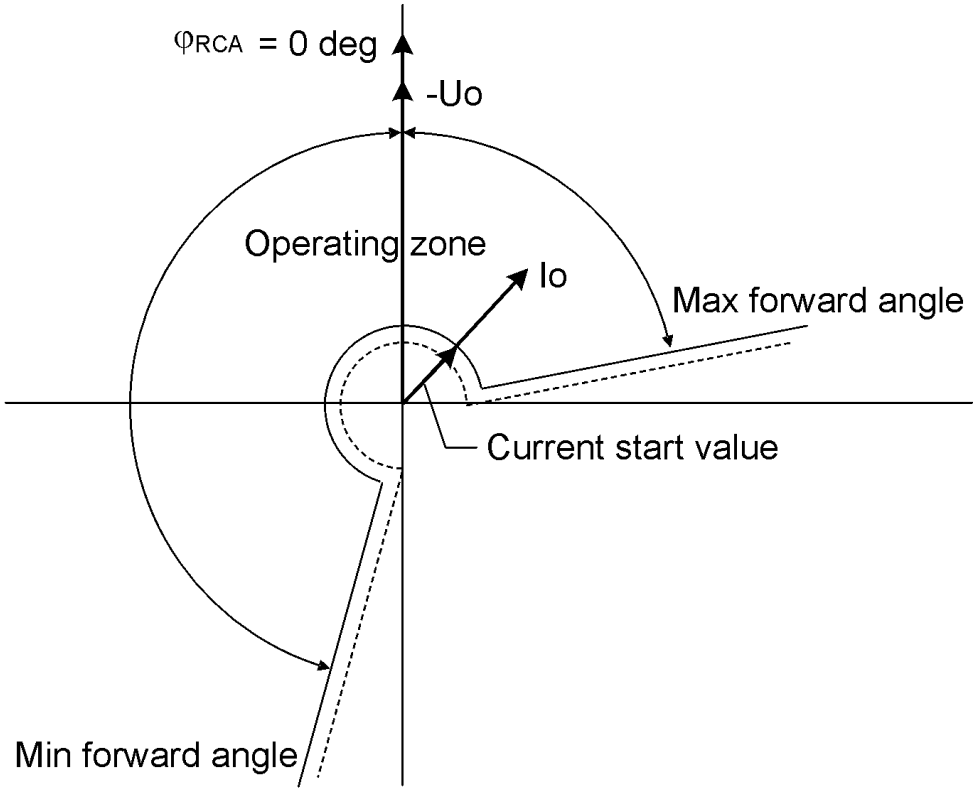

Figure 261: Extended operation area in directional earth-fault protection

4.2.2.7 Measurement modes

The function operates on three alternative measurement modes: "RMS", "DFT" and "Peak-to-Peak". The measurement mode is selected with the *Measurement mode* setting.

Table 534: Measurement modes supported by DEFxPDEF stages

Measurement mode	DEFLPDEF	DEFHPDEF
RMS	x	x
DFT	x	x
Peak-to-Peak	x	x

For a detailed description of the measurement modes, see *Chapter 11.6 Measurement modes* in this manual.

4.2.2.8 Timer characteristics

DEFxPDEF supports both DT and IDMT characteristics. The user can select the timer characteristics with the *Operating curve type* setting.

The protection relay provides 16 IDMT characteristics curves, of which seven comply with the IEEE C37.112 and six with the IEC 60255-3 standard. Two curves follow the special characteristics of ABB praxis and are referred to as RI and RD. In addition to this, a user programmable curve can be used if none of the standard curves are applicable. The user can choose the DT characteristic by selecting the *Operating curve type* values "ANSI Def. Time" or "IEC Def. Time". The functionality is identical in both cases.

The following characteristics, which comply with the list in the IEC 61850-7-4 specification, indicate the characteristics supported by different stages.

Table 535: Timer characteristics supported by different stages

Operating curve type	DEFLPDEF	DEFHPDEF
(1) ANSI Extremely Inverse	x	x
(2) ANSI Very Inverse	x	
(3) ANSI Normal Inverse	x	x
(4) ANSI Moderately Inverse	x	
(5) ANSI Definite Time	x	x
(6) Long Time Extremely Inverse	x	
(7) Long Time Very Inverse	x	
(8) Long Time Inverse	x	
(9) IEC Normal Inverse	x	
(10) IEC Very Inverse	x	
(11) IEC Inverse	x	
(12) IEC Extremely Inverse	x	
(13) IEC Short Time Inverse	x	
(14) IEC Long Time Inverse	x	
(15) IEC Definite Time	x	x
(17) User programmable curve	x	x
(18) RI type	x	
(19) RD type	x	

For a detailed description of the timers, see *Chapter 11 General function block features* in this manual.

Table 536: Reset time characteristics supported by different stages

Reset curve type	DEFLPDEF	DEFHPDEF	Note
(1) Immediate	x	x	Available for all operate time curves
(2) Def time reset	x	x	Available for all operate time curves
(3) Inverse reset	x	x	Available only for ANSI and user programmable curves

4.2.2.9 Directional earth-fault characteristics

Phase angle characteristic

The operation criterion phase angle is selected with the *Operation mode* setting using the value "Phase angle".

When the phase angle criterion is used, the `DIRECTION` output indicates on which operating sector the operating quantity is measured. The `FAULT_DIR` output indicates in which operation sector the fault current is measured. The output is operational once the function is started.

The forward and reverse sectors are defined separately. The forward operation area is limited with the *Min forward angle* and *Max forward angle* settings. The reverse operation area is limited with the *Min reverse angle* and *Max reverse angle* settings.

The sector limits are always given as positive degree values.

In the forward operation area, the *Max forward angle* setting gives the clockwise sector and the *Min forward angle* setting correspondingly the counterclockwise sector, measured from the *Characteristic angle* setting.

In the reverse operation area, the *Max reverse angle* setting gives the clockwise sector and the *Min reverse angle* setting correspondingly the counterclockwise sector, measured from the complement of the *Characteristic angle* setting (180 degrees phase shift) .

The relay characteristic angle (RCA) is set to positive if the operating current lags the polarizing quantity. It is set to negative if it leads the polarizing quantity.

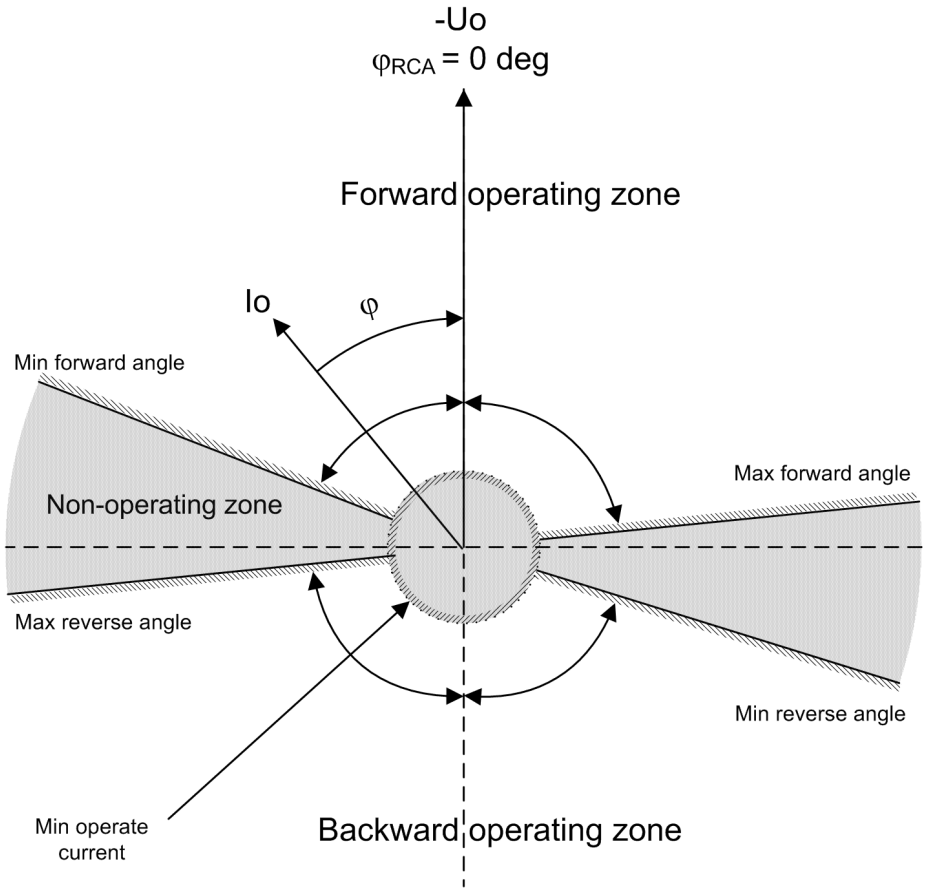

Figure 262: Configurable operating sectors in phase angle characteristic

Table 537: Momentary operating direction

Fault direction	The value for DIRECTION
Angle between the polarizing and operating quantity is not in any of the defined sectors.	0 = unknown
Angle between the polarizing and operating quantity is in the forward sector.	1= forward
Angle between the polarizing and operating quantity is in the reverse sector.	2 = backward
Angle between the polarizing and operating quantity is in both the forward and the reverse sectors, that is, the sectors are overlapping.	3 = both

If the *Allow Non Dir* setting is "False", the directional operation (forward, reverse) is not allowed when the measured polarizing or operating quantities are invalid, that is, their magnitude is below the set minimum values. The minimum values can be defined with the settings *Min operate current* and *Min operate voltage*. In case of low magnitudes, the `FAULT_DIR` and `DIRECTION` outputs are set to 0 = unknown, except when the *Allow non dir* setting is "True". In that case, the function is allowed to operate in the directional mode as non-directional, since the directional information is invalid.

Iosin(ϕ) and Iocos(ϕ) criteria

A more modern approach to directional protection is the active or reactive current measurement. The operating characteristic of the directional operation depends on the earthing principle of the network. The Iosin(ϕ) characteristics is used in an isolated network, measuring the reactive component of the fault current caused by the earth capacitance. The Iocos(ϕ) characteristics is used in a compensated network, measuring the active component of the fault current.

The operation criteria Iosin(ϕ) and Iocos(ϕ) are selected with the *Operation mode* setting using the values "IoSin" or "IoCos" respectively.

The angle correction setting can be used to improve selectivity. The setting decreases the operation sector. The correction can only be used with the Iosin(ϕ) or Iocos(ϕ) criterion. The RCA_CTL input is used to change the Io characteristic:

Table 538: Relay characteristic angle control in the IoSin and IoCos operation criteria

Operation mode:	RCA_CTL = "False"	RCA_CTL = "True"
IoSin	Actual operation criterion: Io-sin(ϕ)	Actual operation criterion: Io-cos(ϕ)
IoCos	Actual operation criterion: Io-cos(ϕ)	Actual operation criterion: Io-sin(ϕ)

When the Iosin(ϕ) or Iocos(ϕ) criterion is used, the component indicates a forward- or reverse-type fault through the FAULT_DIR and DIRECTION outputs, in which 1 equals a forward fault and 2 equals a reverse fault. Directional operation is not allowed (the *Allow non dir* setting is "False") when the measured polarizing or operating quantities are not valid, that is, when their magnitude is below the set minimum values. The minimum values can be defined with the *Min operate current* and *Min operate voltage* settings. In case of low magnitude, the FAULT_DIR and DIRECTION outputs are set to 0 = unknown, except when the *Allow non dir* setting is "True". In that case, the function is allowed to operate in the directional mode as non-directional, since the directional information is invalid.

The calculated Iosin(ϕ) or Iocos(ϕ) current used in direction determination can be read through the I_OPER monitored data. The value can be passed directly to a decisive element, which provides the final start and operate signals.

The I_OPER monitored data gives an absolute value of the calculated current.

The following examples show the characteristics of the different operation criteria:

Example 1.

Iosin(ϕ) criterion selected, forward-type fault

```
=> FAULT_DIR = 1
```

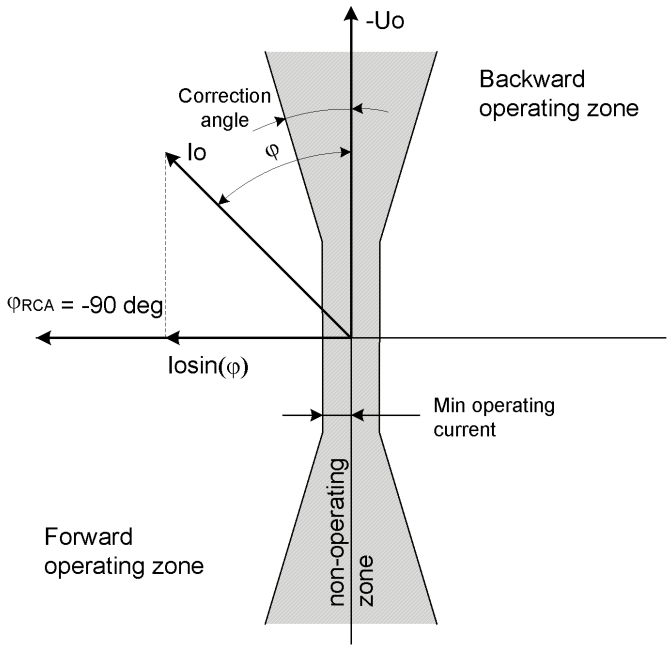

Figure 263: Operating characteristic Iosin(ϕ) in forward fault

The operating sector is limited by angle correction, that is, the operating sector is 180 degrees - 2*(angle correction).

Example 2.

Iosin(ϕ) criterion selected, reverse-type fault

```
=> FAULT_DIR = 2
```

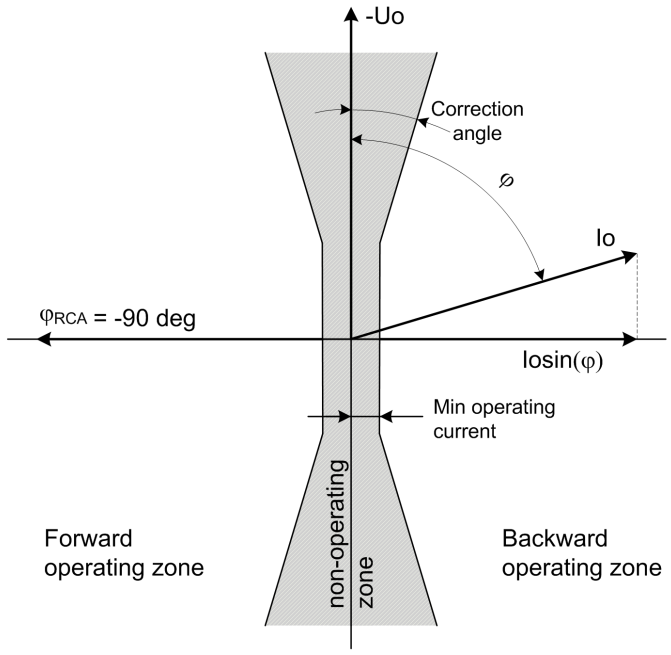

Figure 264: Operating characteristic Iosin(ϕ) in reverse fault

Example 3.

Iocos(ϕ) criterion selected, forward-type fault

```
=> FAULT_DIR = 1
```

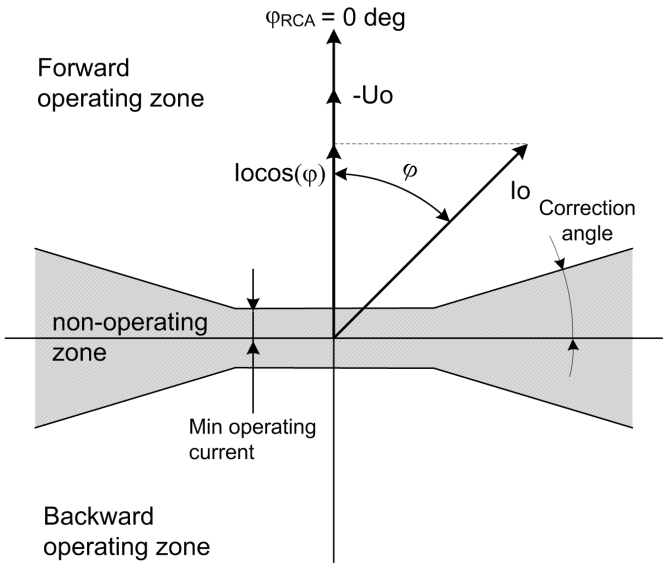

Figure 265: Operating characteristic Iocos(ϕ) in forward fault

Example 4.

Iocos(ϕ) criterion selected, reverse-type fault

```
=> FAULT_DIR = 2
```

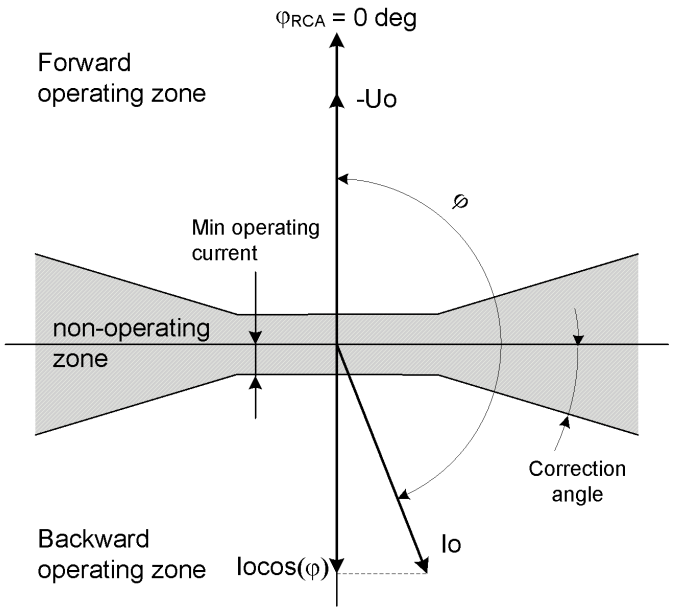

Figure 266: Operating characteristic Iocos(ϕ) in reverse fault

Phase angle 80

The operation criterion phase angle 80 is selected with the *Operation mode* setting by using the value "Phase angle 80".

Phase angle 80 implements the same functionality as the phase angle but with the following differences:

- The *Max forward angle* and *Max reverse angle* settings cannot be set but they have a fixed value of 80 degrees
- The sector limits of the fixed sectors are rounded.

The sector rounding is used for cancelling the CT measurement errors at low current amplitudes. When the current amplitude falls below three percent of the nominal current, the sector is reduced to 70 degrees at the fixed sector side. This makes the protection more selective, which means that the phase angle measurement errors do not cause faulty operation.

There is no sector rounding on the other side of the sector.

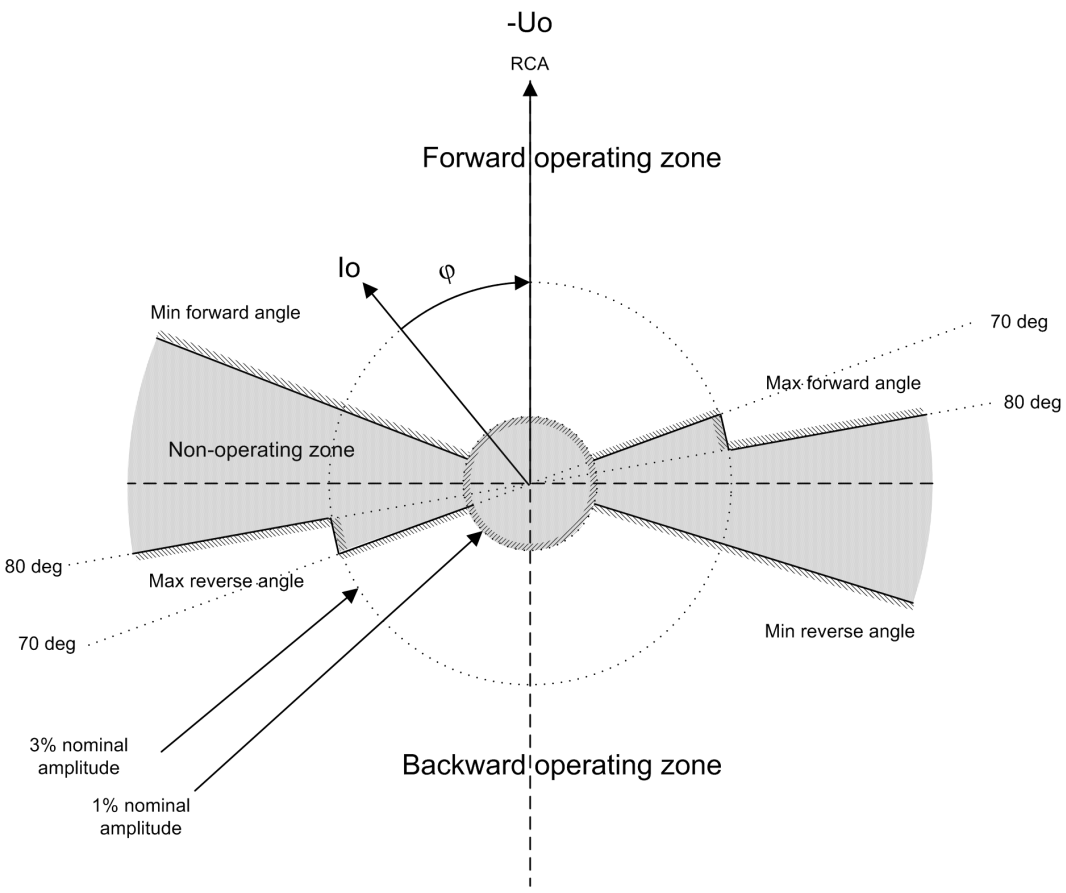

Figure 267: Operating characteristic for phase angle 80

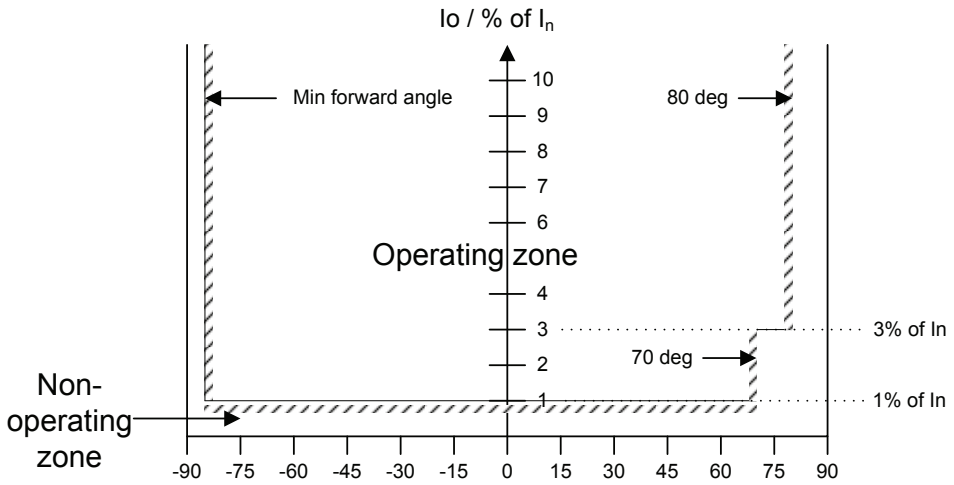

Figure 268: Phase angle 80 amplitude (Directional mode = Forward)

Phase angle 88

The operation criterion phase angle 88 is selected with the *Operation mode* setting using the value "Phase angle 88".

Phase angle 88 implements the same functionality as the phase angle but with the following differences:

- The *Max forward angle* and *Max reverse angle* settings cannot be set but they have a fixed value of 88 degrees
- The sector limits of the fixed sectors are rounded.

Sector rounding in the phase angle 88 consists of three parts.

- If the current amplitude is between 1...20 percent of the nominal current, the sector limit increases linearly from 73 degrees to 85 degrees
- If the current amplitude is between 20...100 percent of the nominal current, the sector limit increases linearly from 85 degrees to 88 degrees
- If the current amplitude is more than 100 percent of the nominal current, the sector limit is 88 degrees.

There is no sector rounding on the other side of the sector.

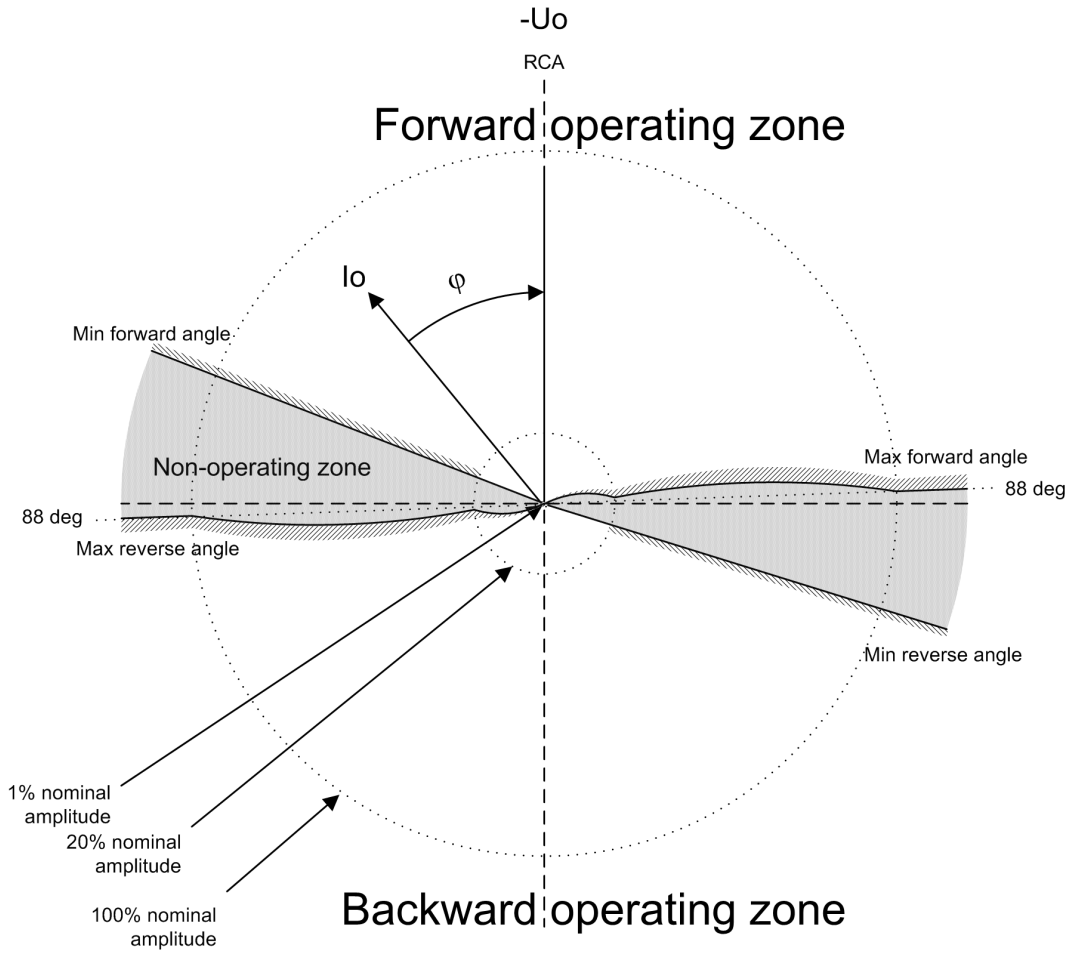

Figure 269: Operating characteristic for phase angle 88

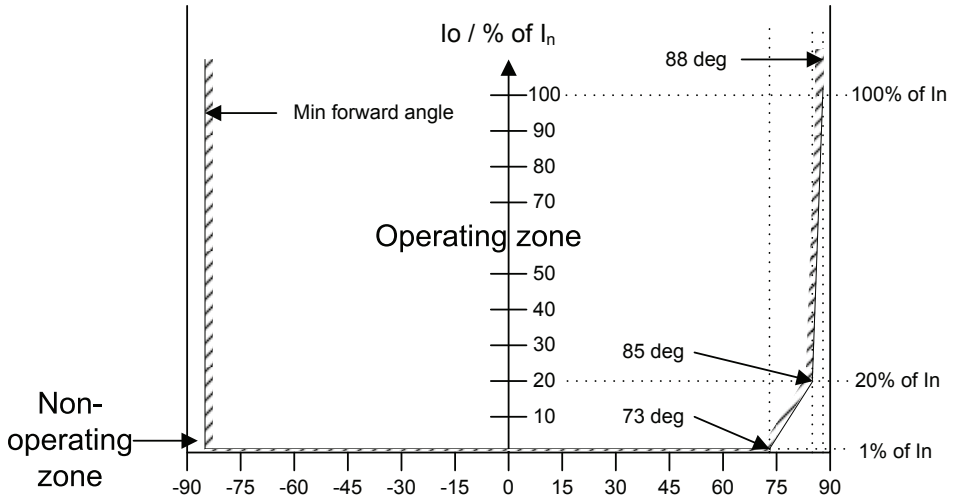

Figure 270: Phase angle 88 amplitude (Directional mode = Forward)

4.2.2.10 Application

The directional earth-fault protection DEFxPDEF is designed for protection and clearance of earth faults and for earth-fault protection of different equipment connected to the power systems, such as shunt capacitor banks or shunt reactors, and for backup earth-fault protection of power transformers.

Many applications require several steps using different current start levels and time delays. DEFxPDEF consists of two different stages.

- Low DEFLPDEF
- High DEFHPDEF

DEFLPDEF contains several types of time delay characteristics. DEFHPDEF is used for fast clearance of serious earth faults.

The protection can be based on the phase angle criterion with extended operating sector. It can also be based on measuring either the reactive part Iosin(ϕ) or the active part Iocos(ϕ) of the residual current. In isolated networks or in networks with high impedance earthing, the phase-to-earth fault current is significantly smaller than the short-circuit currents. In addition, the magnitude of the fault current is almost independent of the fault location in the network.

The function uses the residual current components Iocos(ϕ) or Iosin(ϕ) according to the earthing method, where ϕ is the angle between the residual current and the reference residual voltage (-Uo). In compensated networks, the phase angle criterion with extended operating sector can also be used. When the relay characteristic angle RCA is 0 degrees, the negative quadrant of the operation sector can be extended with the *Min forward angle* setting. The operation sector can be set between 0 and -180 degrees, so that the total operation sector is from +90 to -180 degrees. In other words, the sector can be up to 270 degrees wide. This allows the protection settings to stay the same when the resonance coil is disconnected from between the neutral point and earth.

System neutral earthing is meant to protect personnel and equipment and to reduce interference for example in telecommunication systems. The neutral earthing sets challenges for protection systems, especially for earth-fault protection.

In isolated networks, there is no intentional connection between the system neutral point and earth. The only connection is through the line-to-earth capacitances (C_0) of phases and leakage resistances (R_0). This means that the residual current is mainly capacitive and has -90 degrees phase shift compared to the residual voltage (-Uo). The characteristic angle is -90 degrees.

In resonance-earthed networks, the capacitive fault current and the inductive resonance coil current compensate each other. The protection cannot be based on the reactive current measurement, since the current of the compensation coil would disturb the operation of the relays. In this case, the selectivity is based on the measurement of the active current component. This means that the residual current is mainly resistive and has zero phase shift compared to the residual voltage (-Uo) and the characteristic angle is 0 degrees. Often the magnitude of this component is small, and must be increased by means of a parallel resistor in the compensation equipment.

In networks where the neutral point is earthed through low resistance, the characteristic angle is also 0 degrees (for phase angle). Alternatively, Iocos(ϕ) operation can be used.

In solidly earthed networks, the *Characteristic angle* is typically set to +60 degrees for the phase angle. Alternatively, Iosin(ϕ) operation can be used with a reversal polarizing quantity. The polarizing quantity can be rotated 180 degrees by setting

the *Pol reversal* parameter to "True" or by switching the polarity of the residual voltage measurement wires. Although the Iosin(ϕ) operation can be used in solidly earthed networks, the phase angle is recommended.

Connection of measuring transformers in directional earth fault applications

The residual current Io can be measured with a core balance current transformer or the residual connection of the phase current signals. If the neutral of the network is either isolated or earthed with high impedance, a core balance current transformer is recommended to be used in earth-fault protection. To ensure sufficient accuracy of residual current measurements and consequently the selectivity of the scheme, the core balance current transformers should have a transformation ratio of at least 70:1. Lower transformation ratios such as 50:1 or 50:5 are not recommended.

Attention should be paid to make sure the measuring transformers are connected correctly so that DEFxPDEF is able to detect the fault current direction without failure. As directional earth fault uses residual current and residual voltage (-Uo), the poles of the measuring transformers must match each other and also the fault current direction. Also the earthing of the cable sheath must be taken into notice when using core balance current transformers. The following figure describes how measuring transformers can be connected to the protection relay.

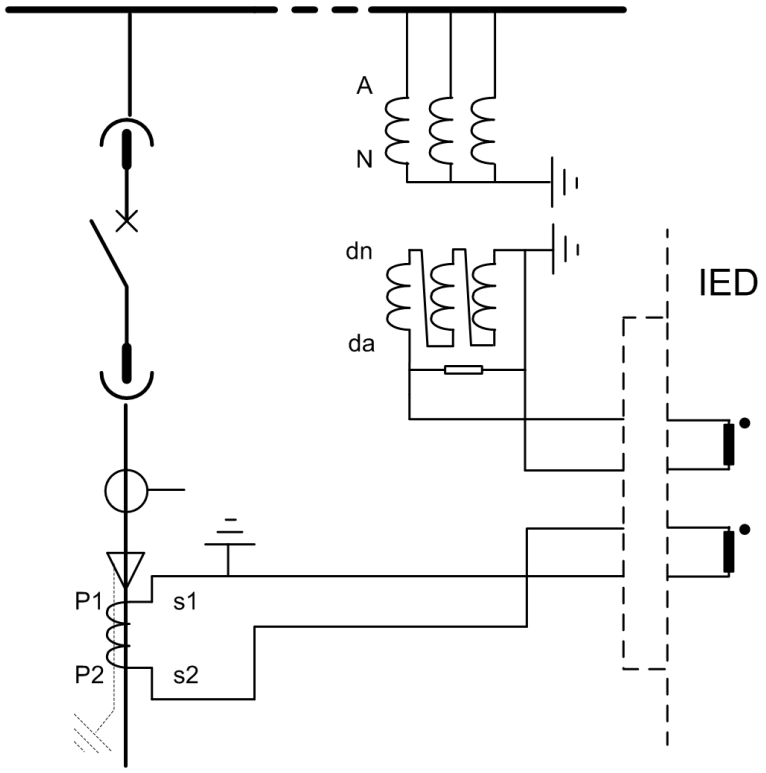

Figure 271: Connection of measuring transformers

Transient/intermittent earth-fault protection	INTRPTEF	Io> -> IEF	67NTEF/NIEF

4.2.3.2 Function block

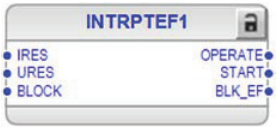

Figure 272: Function block

4.2.3.3 Functionality

The transient/intermittent earth-fault protection function INTRPTEF is a function designed for the protection and clearance of permanent and intermittent earth faults in distribution and sub-transmission networks. Fault detection is done from the residual current and residual voltage signals by monitoring the transients.

The operating time characteristics are according to definite time (DT).

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.3.4 Analog channel configuration

INTRPTEF has two analog group inputs which must be properly configured.

Table 555: Analog inputs

Input	Description
IRES	Residual current (measured or calculated)
URES	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 556: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected for calculating the residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of INTRPTEF can be described with a module diagram. All the modules in the diagram are explained in the next sections.

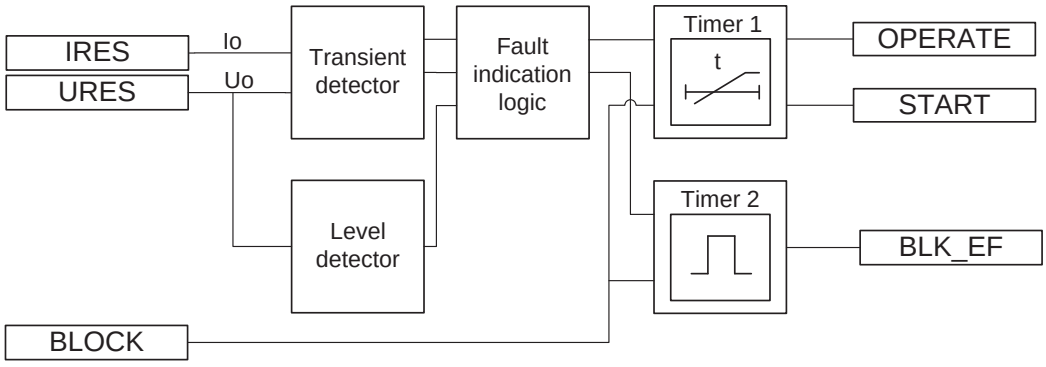

Figure 273: Functional module diagram

Level detector

The Level detector module is used only when selected *Operation mode* is "Transient EF". The module compares the measured residual voltage to the set *Voltage start* value. If the measured value exceeds the set *Voltage start* value, the module reports the exceeding of the value to the Fault indication logic.

Transient detector

The Transient detector module is used for detecting transients in the residual current and residual voltage signals.

The transient detection is supervised with a settable current threshold. With a special filtering technique, the setting *Min operate current* is based on the

fundamental frequency current. This setting should be set based on the value of the parallel resistor of the coil, with security margin. For example, if the resistive current of the parallel resistor is 10 A, then a value of 0.7×10 A = 7 A could be used. The same setting is also applicable in case the coil is disconnected and the network becomes unearthed. Generally, a smaller value should be used and it must never exceed the value of the parallel resistor in order to allow operation of the faulted feeder.

Fault indication logic

Depending on the set *Operation mode*, INTRPTEF has two independent modes for detecting earth faults. The "Transient EF" mode is intended to detect all kinds of earth faults. The "Intermittent EF" mode is dedicated for detecting intermittent earth faults in cable networks.

To satisfy the sensitivity requirements, basic earth-fault protection (based on fundamental frequency phasors) should always be used in parallel with the INTRPTEF function.

The Fault indication logic module determines the direction of the fault. The fault direction determination is secured by multi-frequency neutral admittance measurement and special filtering techniques. This enables fault direction determination which is not sensitive to disturbances in measured Io and Uo signals, for example, switching transients.

When *Directional mode* setting "Forward" is used, the protection operates when the fault is in the protected feeder. When *Directional mode* setting "Reverse" is used, the protection operates when the fault is outside the protected feeder (in the background network). If the direction has no importance, the value "Non-directional" can be selected. The detected fault direction (FAULT_DIR) is available in the monitored data view.

In the "Transient EF" mode, when the start transient of the fault is detected and the Uo level exceeds the set *"Voltage start value"*, Timer 1 is activated. Timer 1 is kept activated until the Uo level exceeds the set value or in case of a drop-off, the drop-off duration is shorter than the set *Reset delay time*.

In the "Intermittent EF" mode, when the start transient of the fault is detected and the Uo level exceeds the set *Voltage start value*, the Timer 1 is activated. When a required number of intermittent earth-fault transients set with the *Peak counter limit* setting are detected without the function being reset (depends on the drop-off time set with the *Reset delay time* setting), the START output is activated. The Timer 1 is kept activated as long as transients are occurring during the drop-off time defined by setting *Reset delay time*.

Timer 1

The time characteristic is according to DT.

In the "Transient EF" mode, the OPERATE output is activated after *Operate delay time* if the residual voltage exceeds the set *"Voltage start value"*. The *Reset delay time* starts to elapse when residual voltage falls below *Voltage start value*. If there is no OPERATE activation, for example, the fault disappears momentarily, START stays activated until the the *Reset delay time* elapses. After OPERATE activation, START and OPERATE signals are reset as soon as Uo falls below *Voltage start value*.

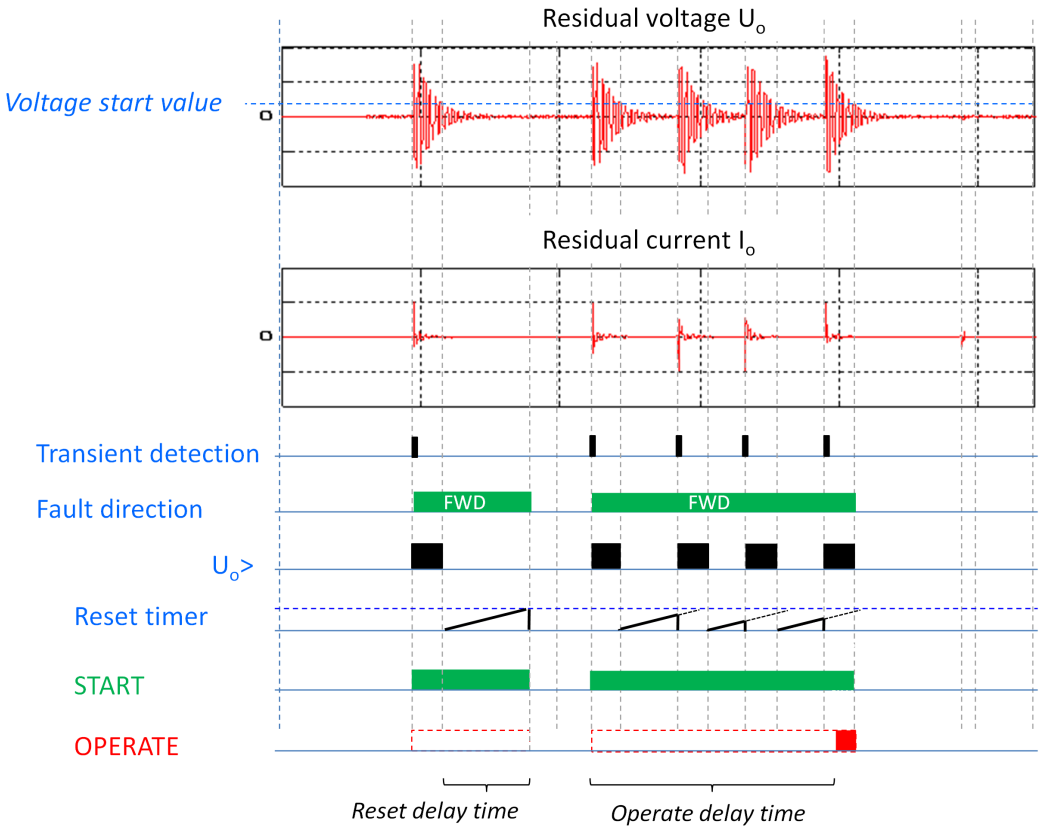

Figure 274: Example of INTRPTEF operation in "Transient EF" mode in the faulty feeder

In the "Intermittent EF" mode the OPERATE output is activated when the following conditions are fulfilled:

- the number of transients that have been detected exceeds the *Peak counter limit* setting
- the timer has reached the time set with the *Operate delay time*
- and one additional transient is detected during the drop-off cycle

The *Reset delay time* starts to elapse from each detected transient (peak). In case there is no OPERATE activation, for example, the fault disappears momentarily START stays activated until the *Reset delay time* elapses, that is, reset takes place if time between transients is more than *Reset delay time*. After OPERATE activation, a fixed pulse length of 100 ms for OPERATE is given, whereas START is reset after *Reset delay time* elapses

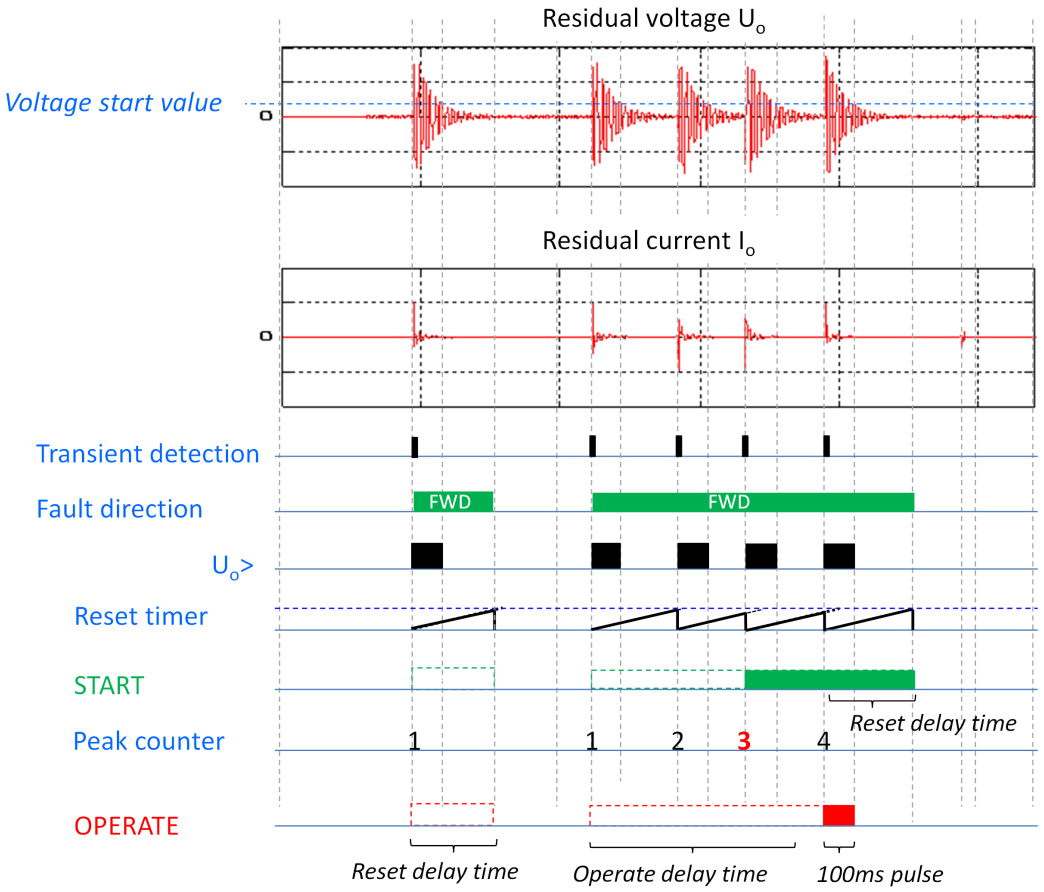

Figure 275: Example of INTRPTEF operation in "Intermittent EF" mode in the faulty feeder, Peak counter limit=3

The timer calculates the start duration value START_DUR which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Timer 2

If the function is used in the directional mode and an opposite direction transient is detected, the BLK_EF output is activated for the fixed delay time of 25 ms. If the START output is activated when the BLK_EF output is active, the BLK_EF output is deactivated.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE

output" mode, the function operates normally but the OPERATE output is not activated.

4.2.3.6 Application

INTRPTEF is an earth-fault function dedicated to operate in intermittent and permanent earth faults occurring in distribution and sub-transmission networks. Fault detection is done from the residual current and residual voltage signals by monitoring the transients with predefined criteria. As the function has a dedicated purpose for the fault types, fast detection and clearance of the faults can be achieved.

Intermittent earth fault

Intermittent earth fault is a special type of fault that is encountered especially in compensated networks with underground cables. A typical reason for this type of fault is the deterioration of cable insulation either due to mechanical stress or due to insulation material aging process where water or moisture gradually penetrates the cable insulation. This eventually reduces the voltage withstand of the insulation, leading to a series of cable insulation breakdowns. The fault is initiated as the phase-to-earth voltage exceeds the reduced insulation level of the fault point and mostly extinguishes itself as the fault current drops to zero for the first time, as shown in *Figure 276*. As a result, very short transients, that is, rapid changes in the form of spikes in residual current (Io) and in residual voltage (Uo), can be repeatedly measured. Typically, the fault resistance in case of an intermittent earth fault is only a few ohms.

Residual current Io and residual voltage Uo

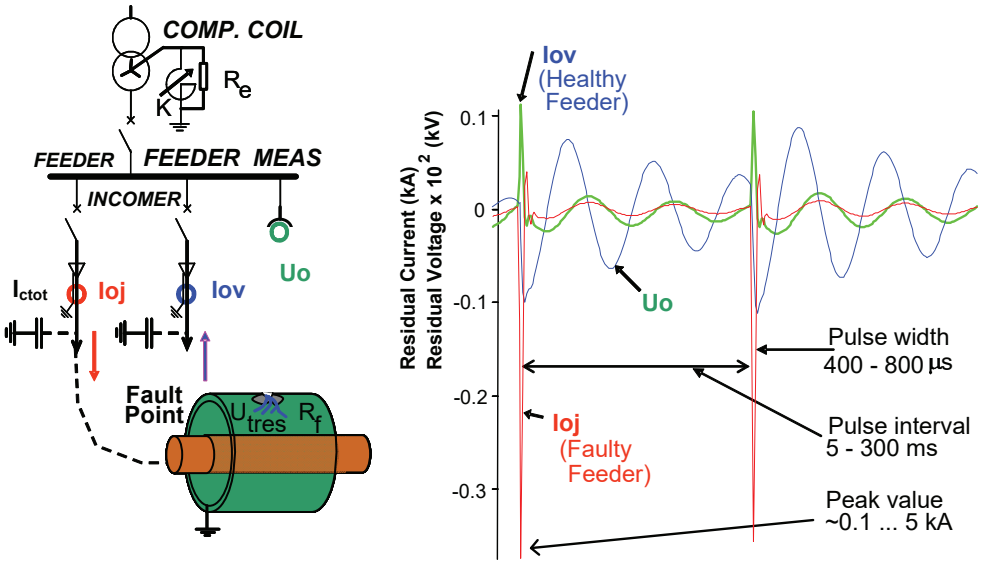

Figure 276: Typical intermittent earth-fault characteristics

Earth-fault transients

In general, earth faults generate transients in currents and voltages. There are several factors that affect the magnitude and frequency of these transients, such as the fault moment on the voltage wave, fault location, fault resistance and the parameters of the feeders and the supplying transformers. In the fault initiation,

the voltage of the faulty phase decreases and the corresponding capacitance is discharged to earth (→ discharge transients). At the same time, the voltages of the healthy phases increase and the related capacitances are charged (→ charge transient).

If the fault is permanent (non-transient) in nature, only the initial fault transient in current and voltage can be measured, whereas the intermittent fault creates repetitive transients.

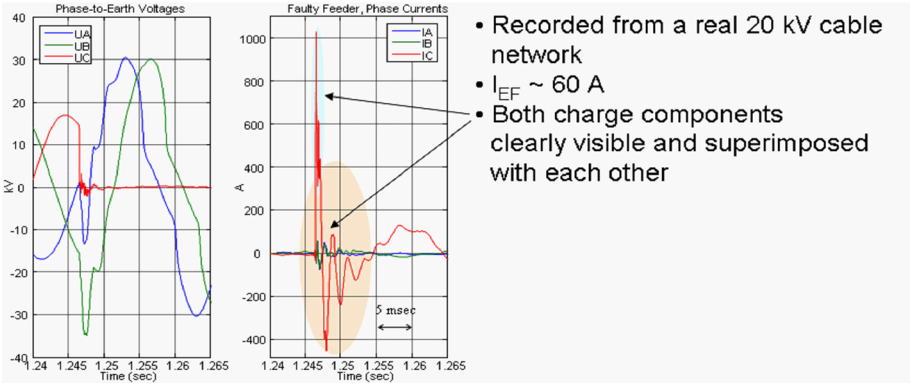

Figure 277: Example of earth-fault transients, including discharge and charge transient components, when a permanent fault occurs in a 20 kV network in phase C

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Admittance-based earth-fault protection	EFPADM	Yo> ->	21NY

4.2.4.2 Function block

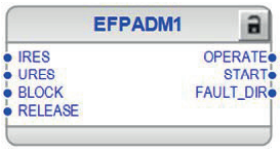

Figure 278: Function block

4.2.4.3 Functionality

The admittance-based earth-fault protection function EFPADM provides a selective earth-fault protection function for high-resistance earthed, unearthed and compensated networks. It can be applied for the protection of overhead lines as well as with underground cables. It can be used as an alternative solution to traditional residual current-based earth-fault protection functions, such as the IoCos mode in DEFxPDEF. Main advantages of EFPADM include a versatile applicability, good sensitivity and easy setting principles.

EFPADM is based on evaluating the neutral admittance of the network, that is, the quotient:

$$\underline{Yo} = \underline{Io} / -\underline{Uo}$$

(Equation 56)

The measured admittance is compared to the admittance characteristic boundaries in the admittance plane. The supported characteristics include overadmittance, oversusceptance, overconductance or any combination of the three. The

directionality of the oversusceptance and overconductance criteria can be defined as forward, reverse or non-directional, and the boundary lines can be tilted if required by the application. This allows the optimization of the shape of the admittance characteristics for any given application.

EFPADM supports two calculation algorithms for admittance. The admittance calculation can be set to include or exclude the prefault zero-sequence values of Io and Uo. Furthermore, the calculated admittance is recorded at the time of the trip and it can be monitored for post-fault analysis purposes.

To ensure the security of the protection, the admittance calculation is supervised by a residual overvoltage condition which releases the admittance protection during a fault condition. Alternatively, the release signal can be provided by an external binary signal.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.4.4 Analog channel configuration

EFPADM has two analog group inputs which must be properly configured.

Table 564: Analog inputs

Input	Description
IRES	Residual current (measured or calculated)
URES	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 565: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected. Setting *VT connection* must be "Wye" in that particular UTVTR..

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of EFPADM can be described using a module diagram. All the modules in the diagram are explained in the next sections.

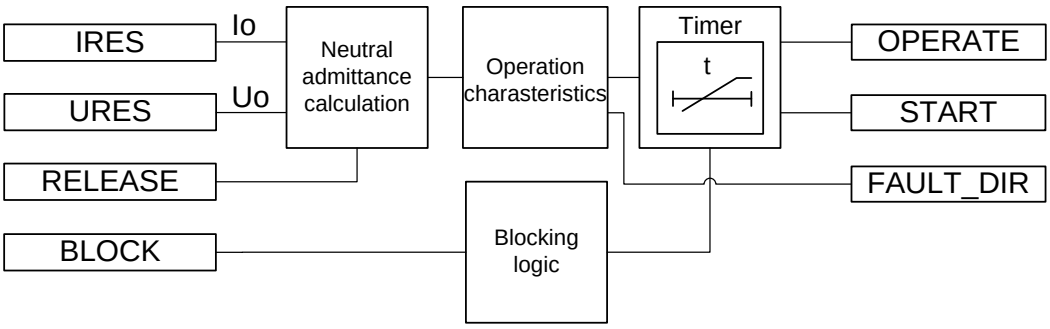

Figure 279: Functional module diagram

Neutral admittance calculation

When the residual voltage exceeds the set threshold *Voltage start value*, an earth fault is detected and the neutral admittance calculation is released.

To ensure a sufficient accuracy for the Io and Uo measurements, it is required that the residual voltage exceeds the value set by *Min operate voltage*. If the admittance calculation mode is "Delta", the minimum change in the residual voltage due to a fault must be 0.01 × Un to enable the operation. Similarly, the residual current must exceed the value set by *Min operate current*.

The polarity of the polarizing quantity Uo can be changed, that is, rotated by 180 degrees, by setting the *Pol reversal* parameter to "True" or by switching the polarity of the residual voltage measurement wires.

As an alternative for the internal residual overvoltage-based start condition, the neutral admittance protection can also be externally released by utilizing the RELEASE input.

When *Admittance Clc mode* is set to "Delta", the external logic used must be able to give RELEASE in less than 0.1 s from fault initiation. Otherwise the collected pre-fault values are overwritten with fault time values. If it is slower, *Admittance Clc mode* must be set to “Normal”.

Neutral admittance is calculated as the quotient between the residual current and residual voltage (polarity reversed) fundamental frequency phasors. The *Admittance Clc mode* setting defines the calculation mode.

Admittance Clc mode = "Normal"

$$\underline{Yo} = \frac{\underline{Io}_{fault}}{-\underline{Uo}_{fault}}$$

(Equation 57)

Admittance Clc mode = "Delta"

$$\underline{Yo} = \frac{\underline{Io}_{fault} - \underline{Io}_{prefault}}{-(\underline{Uo}_{fault} - \underline{Uo}_{prefault})} = \frac{\Delta \underline{Io}}{-\Delta \underline{Uo}}$$

(Equation 58)

$\underline{Yo}$	Calculated neutral admittance [Siemens]
$\underline{Io}_{fault}$	Residual current during the fault [Amperes]
$\underline{Uo}_{fault}$	Residual voltage during the fault [Volts]
$\underline{Io}_{prefault}$	Prefault residual current [Amperes]
$\underline{Uo}_{prefault}$	Prefault residual voltage [Volts]
$\Delta \underline{Io}$	Change in the residual current due to fault [Amperes]
$\Delta \underline{Uo}$	Change in the residual voltage due to fault [Volts]

Traditionally, admittance calculation is done with the calculation mode "Normal", that is, with the current and voltage values directly measured during the fault. As an alternative, by selecting the calculation mode "Delta", the prefault zero-sequence asymmetry of the network can be removed from the admittance calculation. Theoretically, this makes the admittance calculation totally immune to fault resistance, that is, the estimated admittance value is not affected by fault resistance. Utilization of the change in Uo and Io due to a fault in the admittance calculation also mitigates the effects of the VT and CT measurement errors, thus improving the measuring accuracy, the sensitivity and the selectivity of the protection.

Calculation mode "Delta" is recommended in case a high sensitivity of the protection is required, if the network has a high degree of asymmetry during the healthy state or if the residual current measurement is based on sum connection, that is, the Holmgren connection.

Neutral admittance calculation produces certain values during forward and reverse faults.

Fault in reverse direction, that is, outside the protected feeder.

$$\underline{Yo} = -\underline{Y}_{Fdtot}$$

(Equation 59)

$$\approx -j \cdot \frac{I_{eFd}}{U_{ph}}$$

(Equation 60)

$\underline{Y}_{Fdtot}$	Sum of the phase-to-earth admittances ($\underline{Y}_{FdA}$, $\underline{Y}_{FdB}$, $\underline{Y}_{FdC}$) of the protected feeder
I_{eFd}	Magnitude of the earth-fault current of the protected feeder when the fault resistance is zero ohm
U_{ph}	Magnitude of the nominal phase-to-earth voltage of the system

Equation 59 shows that in case of outside faults, the measured admittance equals the admittance of the protected feeder with a negative sign. The measured admittance is dominantly reactive; the small resistive part of the measured admittance is due to the leakage losses of the feeder. Theoretically, the measured admittance is located in the third quadrant in the admittance plane close to the im($\underline{Yo}$) axis, see *Figure 280*.

The result of *Equation 59* is valid regardless of the neutral earthing method. In compensated networks the compensation degree does not affect the result. This enables a straightforward setting principle for the

neutral admittance protection: admittance characteristic is set to cover the value $\underline{Y}o = -\underline{Y}_{Fdtot}$ with a suitable margin.

Due to inaccuracies in voltage and current measurement, the small real part of the calculated neutral admittance may appear as positive, which brings the measured admittance in the fourth quadrant in the admittance plane. This should be considered when setting the admittance characteristic.

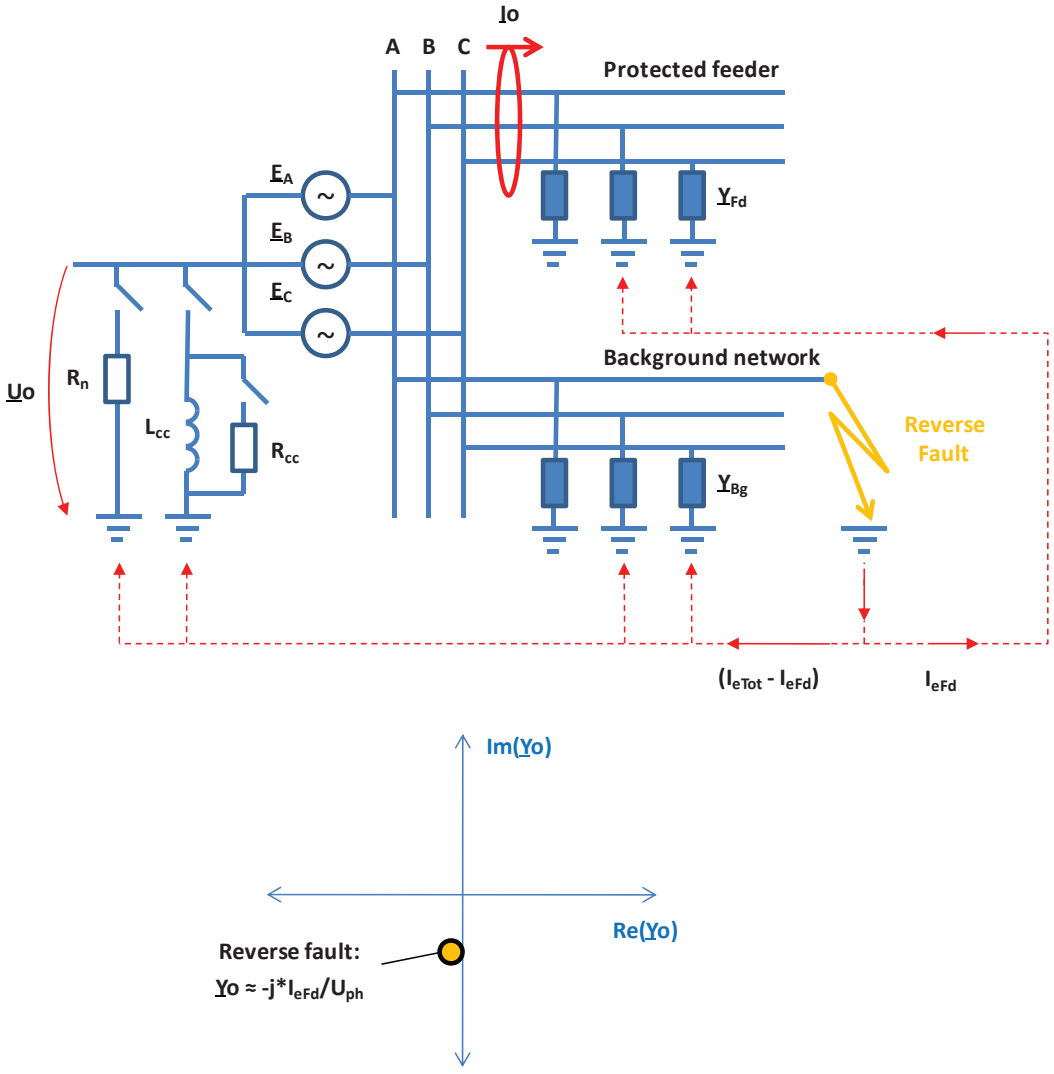

Figure 280: Admittance calculation during a reverse fault

R_{CC}	Resistance of the parallel resistor
L_{CC}	Inductance of the compensation coil
R_n	Resistance of the neutral earthing resistor
$\underline{Y}_{Fd}$	Phase-to-earth admittance of the protected feeder
$\underline{Y}_{Bg}$	Phase-to-earth admittance of the background network

For example, in a 15 kV compensated network with the magnitude of the earth-fault current in the protected feeder being 10 A (Rf = 0 Ω), the theoretical value for the measured admittance during an earth fault in the reverse direction, that is, outside the protected feeder, can be calculated.

$$\underline{Yo} \approx -j \cdot \frac{I_{eFd}}{U_{ph}} = -j \cdot \frac{10A}{15/\sqrt{3}kV} = -j \cdot 1.15 \text{ milliSiemens}$$

(Equation 61)

The result is valid regardless of the neutral earthing method.

In this case, the resistive part of the measured admittance is due to leakage losses of the protected feeder. As they are typically very small, the resistive part is close to zero. Due to inaccuracies in the voltage and current measurement, the small real part of the apparent neutral admittance may appear positive. This should be considered in the setting of the admittance characteristic.

Fault in the forward direction, that is, inside the protected feeder.

Unearthed network:

$$\underline{Yo} = \underline{Y}_{Bgtot}$$

(Equation 62)

$$\approx j \cdot \left(\frac{I_{eTot} - I_{eFd}}{U_{ph}} \right)$$

(Equation 63)

Compensated network:

$$\underline{Yo} = \underline{Y}_{Bgtot} + \underline{Y}_{CC}$$

(Equation 64)

$$\approx \frac{I_{Rcc} + j \cdot \left(I_{eTot} \cdot (1-K) - I_{eFd} \right)}{U_{ph}}$$

(Equation 65)

High-resistance earthed network:

$$\underline{Yo} = \underline{Y}_{Bgtot} + \underline{Y}_{Rn}$$

(Equation 66)

$$\approx \frac{I_{Rn} + j \cdot \left(I_{eTot} - I_{eFd} \right)}{U_{ph}}$$

(Equation 67)

$\underline{Y}_{Bgtot}$	Sum of the phase-to-earth admittances ($\underline{Y}_{BgA}$, $\underline{Y}_{BgB}$, $\underline{Y}_{BgC}$) of the background network
$\underline{Y}_{CC}$	Admittance of the earthing arrangement (compensation coil and parallel resistor)
I_{Rcc}	Rated current of the parallel resistor

Table continues on the next page

I_{eFd}	Magnitude of the earth-fault current of the protected feeder when the fault resistance is zero ohm
I_{eTot}	Magnitude of the uncompensated earth-fault current of the network when Rf is zero ohm
K	Compensation degree, K = 1 full resonance, K<1 undercompensated, K>1 overcompensated
I_{Rn}	Rated current of the neutral earthing resistor

Equation 62 shows that in case of a fault inside the protected feeder in unearthed networks, the measured admittance equals the admittance of the background network. The admittance is dominantly reactive; the small resistive part of the measured admittance is due to the leakage losses of the background network. Theoretically, the measured admittance is located in the first quadrant in the admittance plane, close to the im(Yo) axis, see *Figure 281*.

Equation 64 shows that in case of a fault inside the protected feeder in compensated networks, the measured admittance equals the admittance of the background network and the coil including the parallel resistor. Basically, the compensation degree determines the imaginary part of the measured admittance and the resistive part is due to the parallel resistor of the coil and the leakage losses of the background network and the losses of the coil. Theoretically, the measured admittance is located in the first or fourth quadrant in the admittance plane, depending on the compensation degree, see *Figure 281*.

Before the parallel resistor is connected, the resistive part of the measured admittance is due to the leakage losses of the background network and the losses of the coil. As they are typically small, the resistive part may not be sufficiently large to secure the discrimination of the fault and its direction based on the measured conductance. This and the rating and the operation logic of the parallel resistor should be considered when setting the admittance characteristic in compensated networks.

Equation 66 shows that in case of a fault inside the protected feeder in high-resistance earthed systems, the measured admittance equals the admittance of the background network and the neutral earthing resistor. Basically, the imaginary part of the measured admittance is due to the phase-to-earth capacitances of the background network, and the resistive part is due to the neutral earthing resistor and the leakage losses of the background network. Theoretically, the measured admittance is located in the first quadrant in the admittance plane, see *Figure 281*.

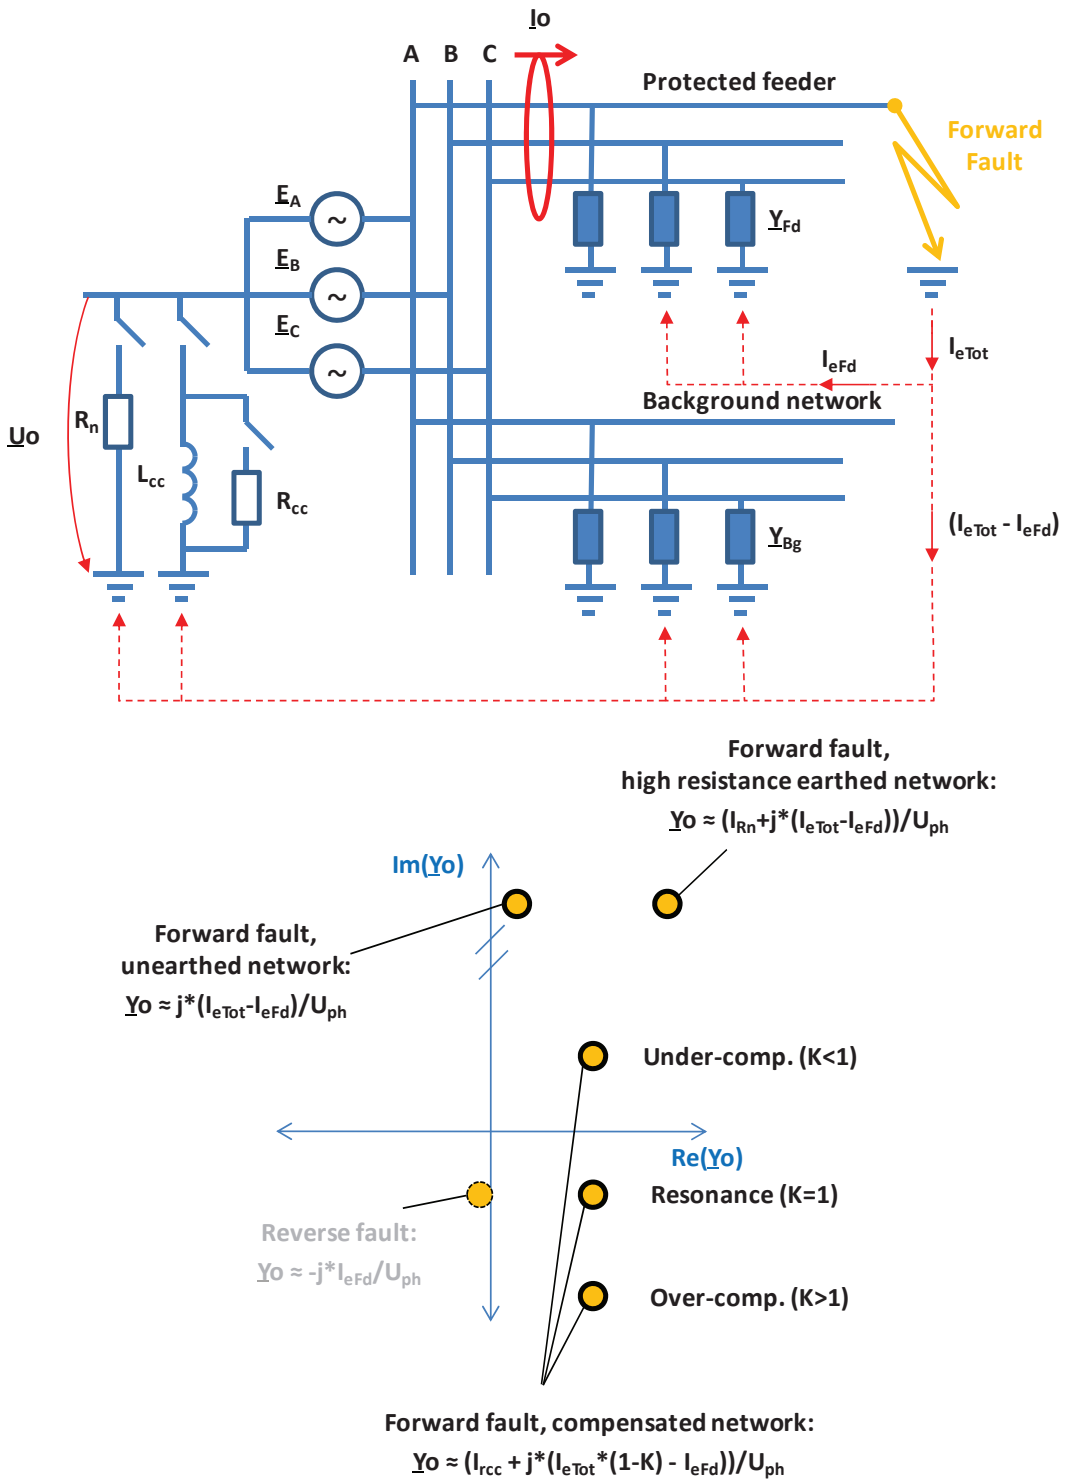

Figure 281: Admittance calculation during a forward fault

When the network is fully compensated in compensated networks, theoretically during a forward fault, the imaginary part of the measured admittance equals the susceptance of the protected feeder with a negative sign. The discrimination between a forward and reverse fault

must therefore be based on the real part of the measured admittance, that is, conductance. Thus, the best selectivity is achieved when the compensated network is operated either in the undercompensated or overcompensated mode.

For example, in a 15 kV compensated network, the magnitude of the earth-fault current of the protected feeder is 10 A (Rf = 0 Ω) and the magnitude of the network is 100 A (Rf = 0 Ω). During an earth fault, a 15 A resistor is connected in parallel to the coil after a 1.0 second delay. Compensation degree is overcompensated, K = 1.1.

During an earth fault in the forward direction, that is, inside the protected feeder, the theoretical value for the measured admittance after the connection of the parallel resistor can be calculated.

$$\underline{Yo} \approx \frac{I_{Rcc} + j \cdot \left(I_{eTot} \cdot (1 - K) - I_{eFd} \right)}{U_{ph}}$$

$$= \frac{15A + j \cdot \left(100A \cdot (1 - 1.1) - 10A \right)}{15kV / \sqrt{3}} \approx (1.73 - j \cdot 2.31) \text{ milliSiemens}$$

(Equation 68)

Before the parallel resistor is connected, the resistive part of the measured admittance is due to the leakage losses of the background network and the losses of the coil. As they are typically small, the resistive part may not be sufficiently large to secure the discrimination of the fault and its direction based on the measured conductance. This and the rating and the operation logic of the parallel resistor should be considered when setting the admittance characteristic.

When a high sensitivity of the protection is required, the residual current should be measured with a cable/ring core CT, that is, the Ferranti CT. Also the use of the sensitive Io input should be considered. The residual voltage measurement should be done with an open delta connection of the three single pole-insulated voltage transformers.

The sign of the admittance characteristic settings should be considered based on the location of characteristic boundary in the admittance plane. All forward-settings are given with positive sign and reverse-settings with negative sign.

Operation characteristic

After the admittance calculation is released, the calculated neutral admittance is compared to the admittance characteristic boundaries in the admittance plane. If the calculated neutral admittance Yo moves outside the characteristic, the enabling signal is sent to the timer.

EFPADM supports a wide range of different characteristics to achieve the maximum flexibility and sensitivity in different applications. The basic characteristic shape is selected with the *Operation mode* and *Directional mode* settings. *Operation mode* defines which operation criterion or criteria are enabled and *Directional mode* defines if the forward, reverse or non-directional boundary lines for that particular operation mode are activated. The FAULT_DIR output indicates which operation sector the fault is measured. The output is operational once the function is started.

Table 566: Operation criteria

Operation mode	Description
Yo	Admittance criterion
Bo	Susceptance criterion
Go	Conductance criterion
Yo, Go	Admittance criterion combined with the conductance criterion
Yo, Bo	Admittance criterion combined with the susceptance criterion
Go, Bo	Conductance criterion combined with the susceptance criterion
Yo, Go, Bo	Admittance criterion combined with the conductance and susceptance criterion

The options for the *Directional mode* setting are "Non-directional", "Forward" and "Reverse".

Figure 282, *Figure 283* and *Figure 284* illustrate the admittance characteristics supported by EFPADM and the settings relevant to that particular characteristic. The most typical characteristics are highlighted and explained in details in *Chapter 4.2.4.6 Neutral admittance characteristics*. Operation is achieved when the calculated neutral admittance Yo moves outside the characteristic (the operation area is marked with gray).

The settings defining the admittance characteristics are given in primary milliSiemens (mS). The conversion equation for the admittance from secondary to primary is:

$$Y_{pri} = Y_{sec} \cdot \frac{ni_{CT}}{nu_{VT}}$$

(Equation 69)

ni $_{CT}$	CT ratio for the residual current Io
nu $_{VT}$	VT ratio for the residual voltage Uo

Example: Admittance setting in the secondary is 5.00 milliSiemens. The CT ratio is 100/1 A and the VT ratio is 11547/100 V. The admittance setting in the primary can be calculated.

$$Y_{pri} = 5.00\ mS \cdot \frac{\frac{100}{1}A}{\frac{11547}{100}V} = 4.33\ mS$$

(Equation 70)

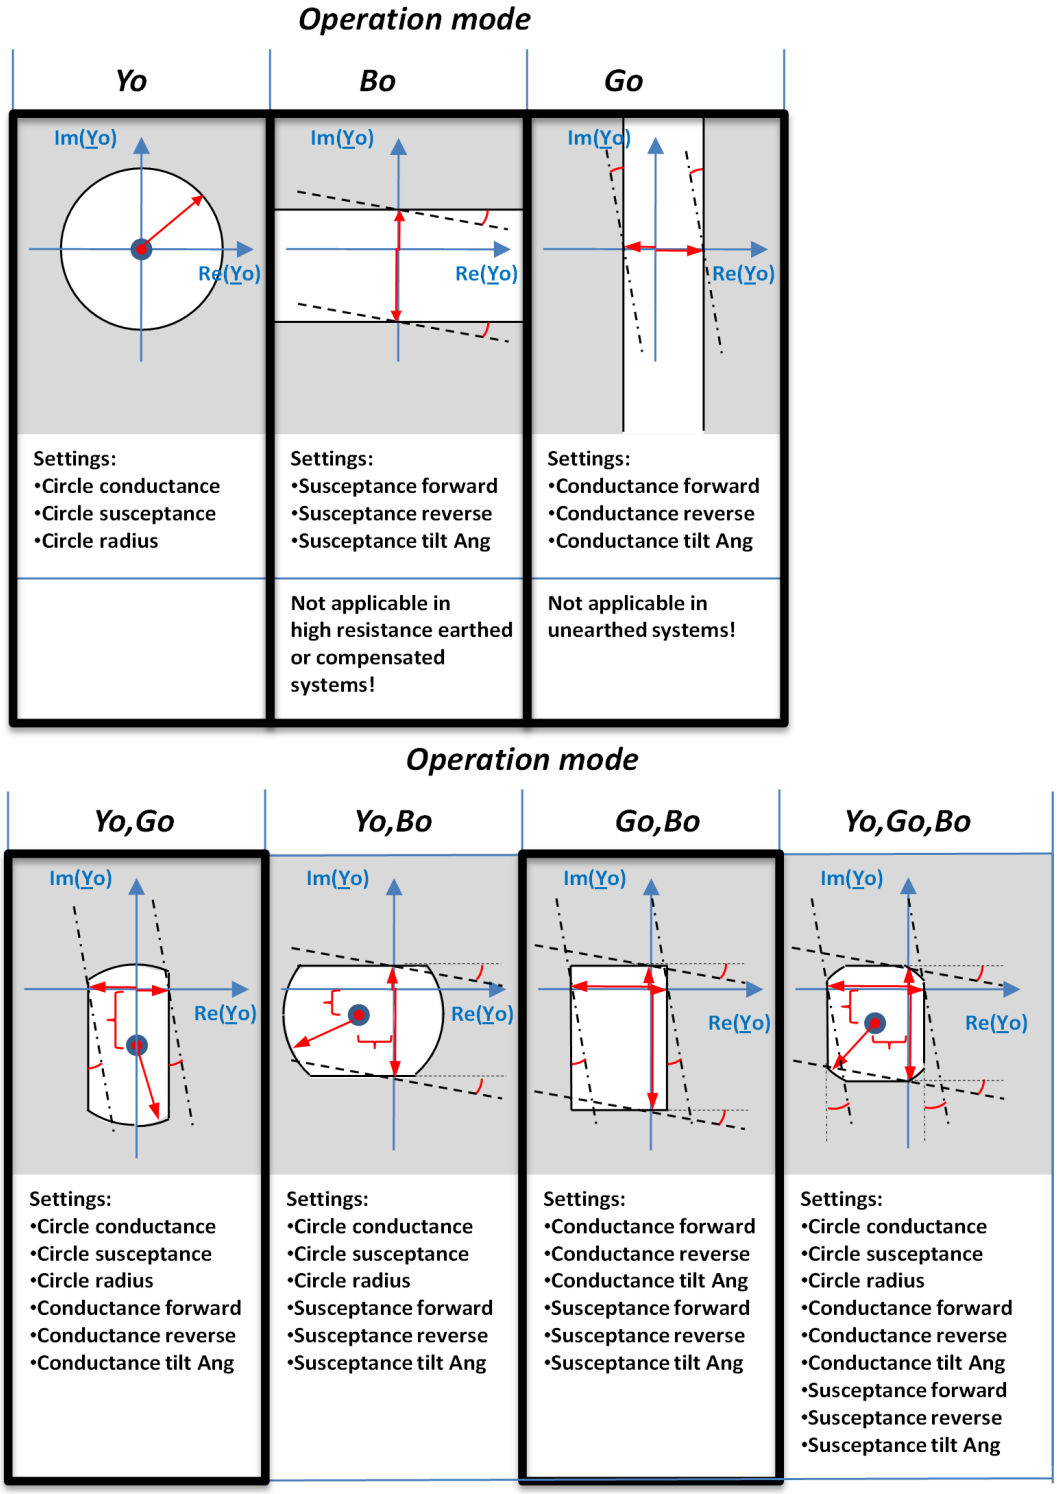

Figure 282: Admittance characteristic with different operation modes when Directional mode = "Non-directional"

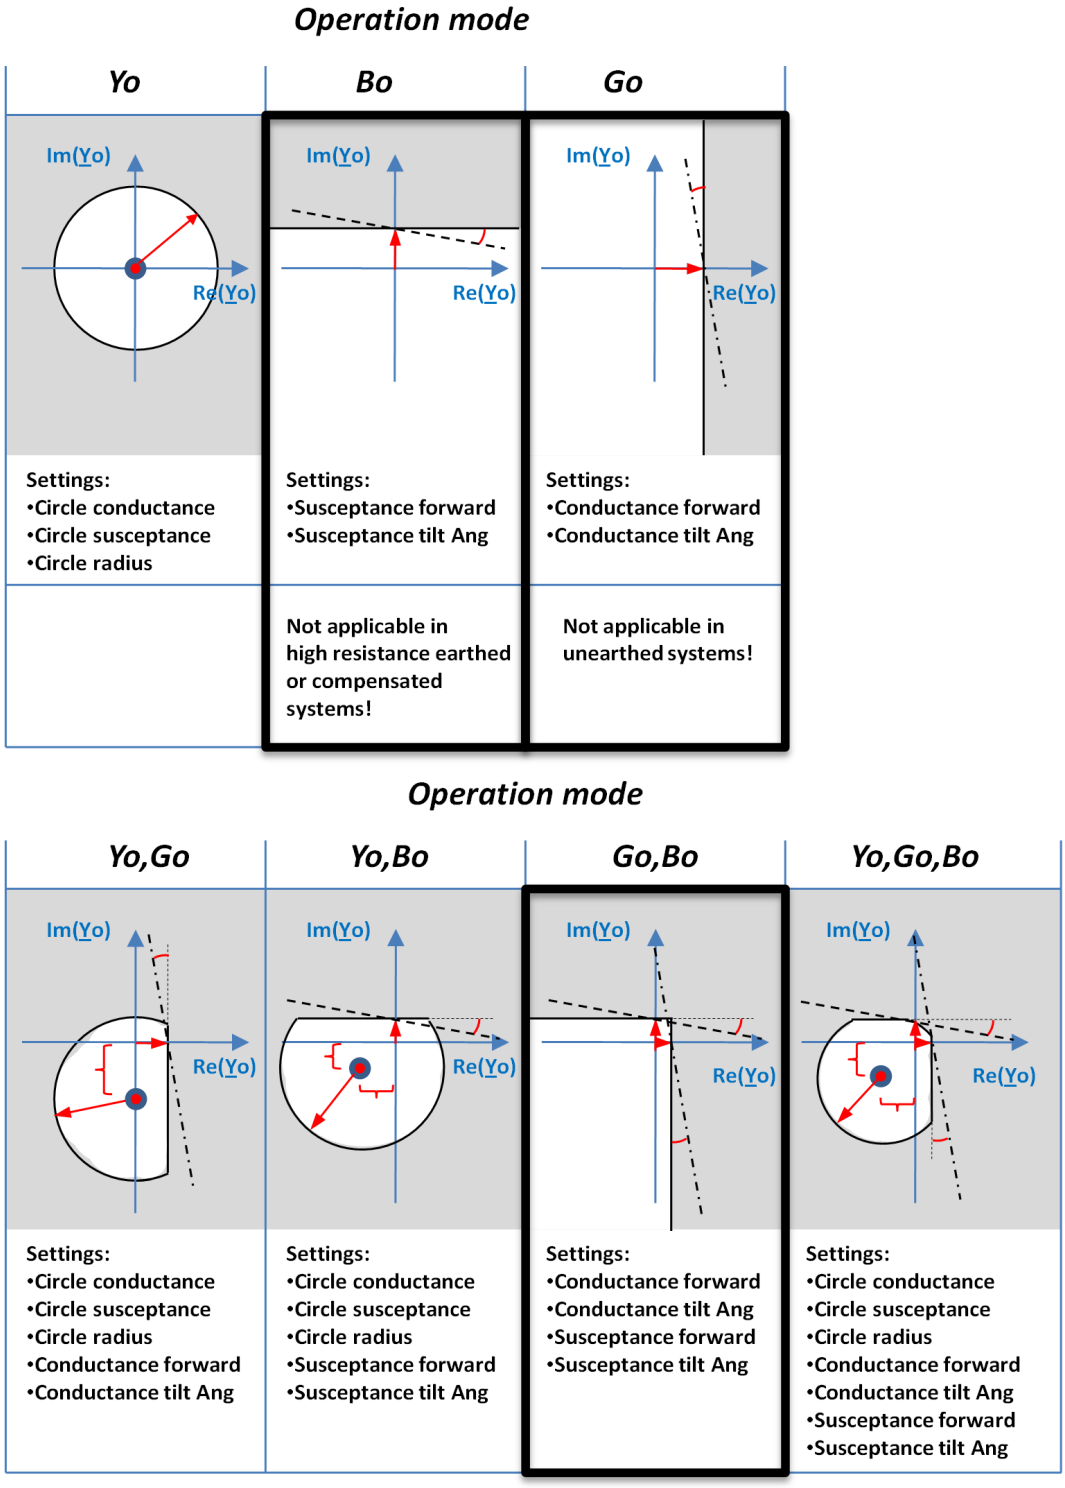

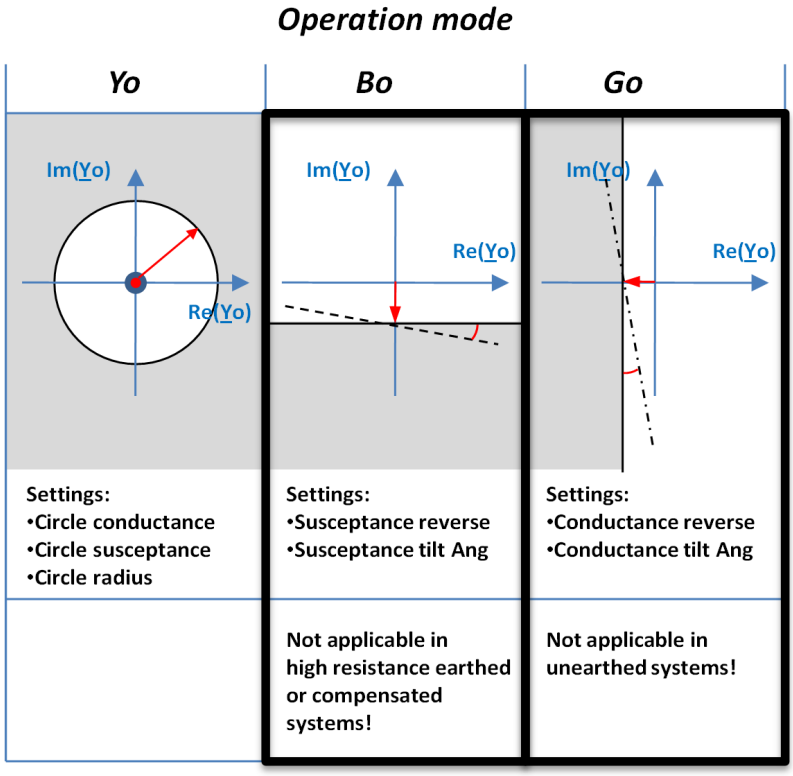

Figure 283: Admittance characteristic with different operation modes when Directional mode = "Forward"

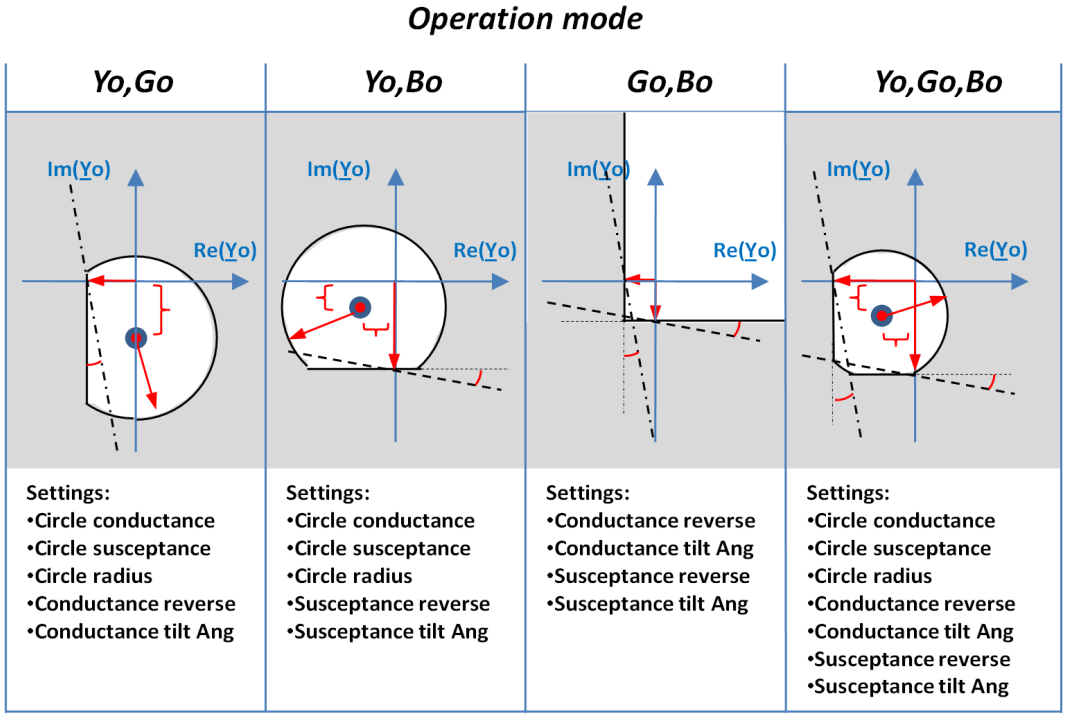

Figure 284: Admittance characteristic with different operation modes when Directional mode = "Reverse"

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set with the *Operate delay time* setting, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set with the *Reset delay time* setting, the operation timer resets and the START output is deactivated. The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.2.4.6 Neutral admittance characteristics

The applied characteristic should always be set to cover the total admittance of the protected feeder with a suitable margin. However, more detailed setting value selection principles depend on the characteristic in question.

The settings defining the admittance characteristics are given in primary milliSiemens.

The forward and reverse boundary settings should be set so that the forward setting is always higher than the reverse setting and that there is space between them.

Overadmittance characteristic

The overadmittance criterion is enabled with the setting *Operation mode* set to "Yo". The characteristic is a circle with the radius defined with the *Circle radius* setting. For the sake of application flexibility, the midpoint of the circle can be moved away from the origin with the *Circle conductance* and *Circle susceptance* settings. Default values for *Circle conductance* and *Circle susceptance* are 0.0 mS, that is, the characteristic is an origin-centered circle.

Operation is achieved when the measured admittance moves outside the circle.

The overadmittance criterion is typically applied in unearthed networks, but it can also be used in compensated networks, especially if the circle is set off from the origin.

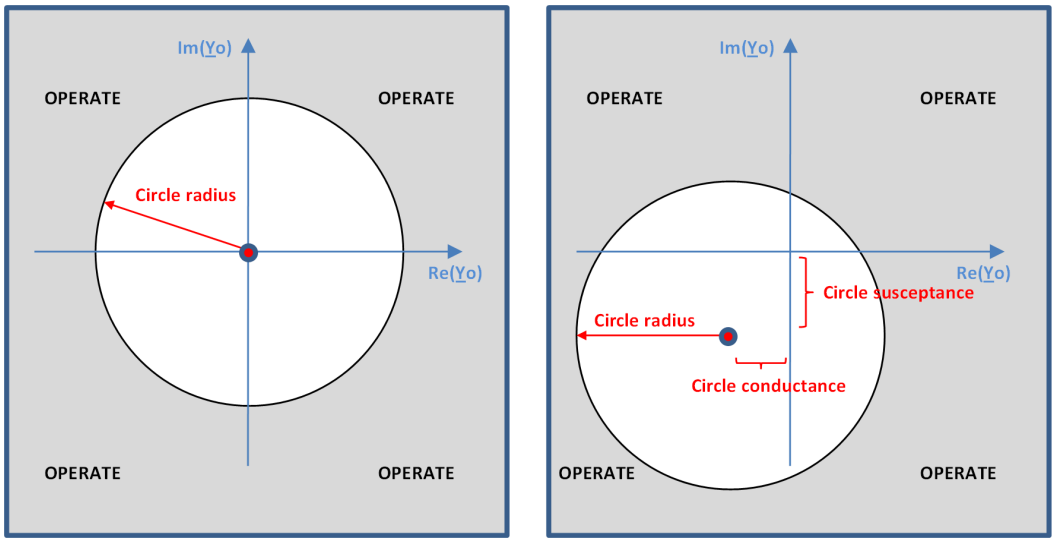

Figure 285: Overadmittance characteristic. Left figure: classical origin-centered admittance circle. Right figure: admittance circle is set off from the origin.

Non-directional overconductance characteristic

The non-directional overconductance criterion is enabled with the *Operation mode* setting set to "Go" and *Directional mode* to "Non-directional". The characteristic is defined with two overconductance boundary lines with the *Conductance forward* and *Conductance reverse* settings. For the sake of application flexibility, the boundary lines can be tilted by the angle defined with the *Conductance tilt Ang* setting. By default, the tilt angle is zero degrees, that is, the boundary line is a vertical line in the admittance plane. A positive tilt value rotates the boundary line counterclockwise from the vertical axis.

In case of non-directional conductance criterion, the *Conductance reverse* setting must be set to a smaller value than *Conductance forward*.

Operation is achieved when the measured admittance moves over either of the boundary lines.

The non-directional overconductance criterion is applicable in high-resistance earthed and compensated networks. It must not be applied in unearthed networks.

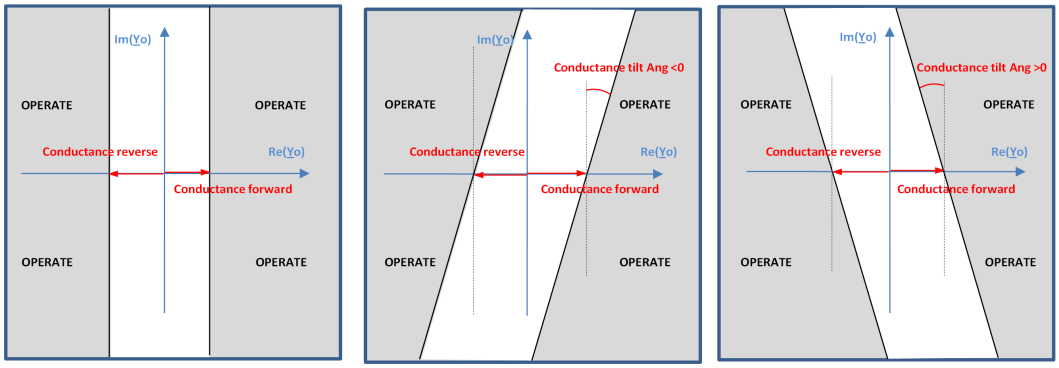

Figure 286: Non-directional overconductance characteristic. Left figure: classical non-directional overconductance criterion. Middle figure: characteristic is tilted with negative tilt angle. Right figure: characteristic is tilted with positive tilt angle.

Forward directional overconductance characteristic

The forward directional overconductance criterion is enabled with the *Operation mode* setting set to "Go" and *Directional mode* set to "Forward". The characteristic is defined by one overconductance boundary line with the *Conductance forward* setting. For the sake of application flexibility, the boundary line can be tilted with the angle defined with the *Conductance tilt Ang* setting. By default, the tilt angle is zero degrees, that is, the boundary line is a vertical line in the admittance plane. A positive tilt value rotates the boundary line counterclockwise from the vertical axis.

Operation is achieved when the measured admittance moves over the boundary line.

The forward directional overconductance criterion is applicable in high-resistance earthed and compensated networks. It must not be applied in unearthed networks.

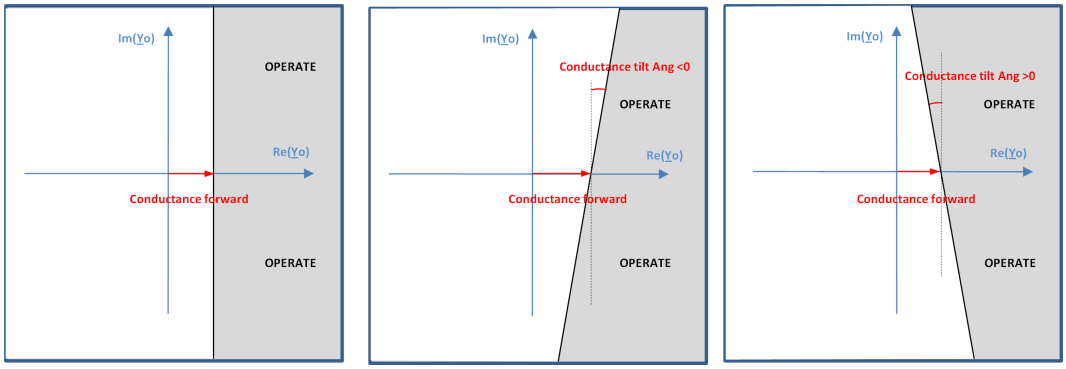

Figure 287: Forward directional overconductance characteristic. Left figure: classical forward directional overconductance criterion. Middle figure: characteristic is tilted with negative tilt angle. Right figure: characteristic is tilted with positive tilt angle.

Forward directional oversusceptance characteristic

The forward directional oversusceptance criterion is enabled with the *Operation mode* setting set to "Bo" and *Directional mode* to "Forward". The characteristic is defined by one oversusceptance boundary line with the *Susceptance forward* setting. For the sake of application flexibility, the boundary line can be tilted by the angle defined with the *Susceptance tilt Ang* setting. By default, the tilt angle is zero degrees, that is, the boundary line is a horizontal line in the admittance plane. A positive tilt value rotates the boundary line counterclockwise from the horizontal axis.

Operation is achieved when the measured admittance moves over the boundary line.

The forward directional oversusceptance criterion is applicable in unearthed networks. It must not be applied to compensated networks.

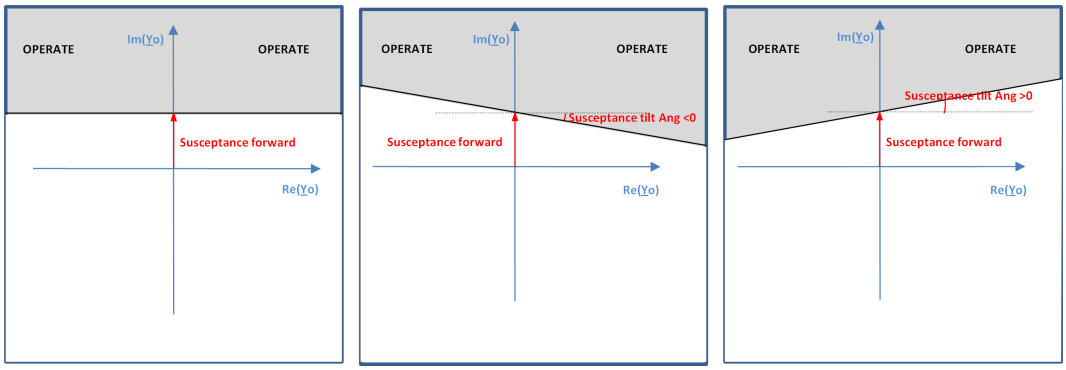

Figure 288: Forward directional oversusceptance characteristic. Left figure: classical forward directional oversusceptance criterion. Middle figure: characteristic is tilted with negative tilt angle. Right figure: characteristic is tilted with positive tilt angle.

Combined overadmittance and overconductance characteristic

The combined overadmittance and overconductance criterion is enabled with the *Operation mode* setting set to "Yo, Go" and *Directional mode* to "Non-directional". The characteristic is a combination of a circle with the radius defined with the *Circle radius* setting and two overconductance boundary lines with the settings *Conductance forward* and *Conductance reverse*. For the sake of application flexibility, the midpoint of the circle can be moved from the origin with the *Circle conductance* and *Circle susceptance* settings. Also the boundary lines can be tilted by the angle defined with the *Conductance tilt Ang* setting. By default, the *Circle conductance* and *Circle susceptance* are 0.0 mS and *Conductance tilt Ang* equals zero degrees, that is, the characteristic is a combination of an origin-centered circle with two vertical overconductance boundary lines. A positive tilt value for the *Conductance tilt Ang* setting rotates boundary lines counterclockwise from the vertical axis.

In case of the non-directional conductance criterion, the *Conductance reverse* setting must be set to a smaller value than *Conductance forward*.

Operation is achieved when the measured admittance moves outside the characteristic.

The combined overadmittance and overconductance criterion is applicable in unearthed, high-resistance earthed and compensated networks or in systems where the system earthing may temporarily change during normal operation from compensated network to unearthed system.

Compared to the overadmittance criterion, the combined characteristic improves sensitivity in high-resistance earthed and compensated networks. Compared to the non-directional overconductance criterion, the combined characteristic enables the protection to be applied also in unearthed systems.

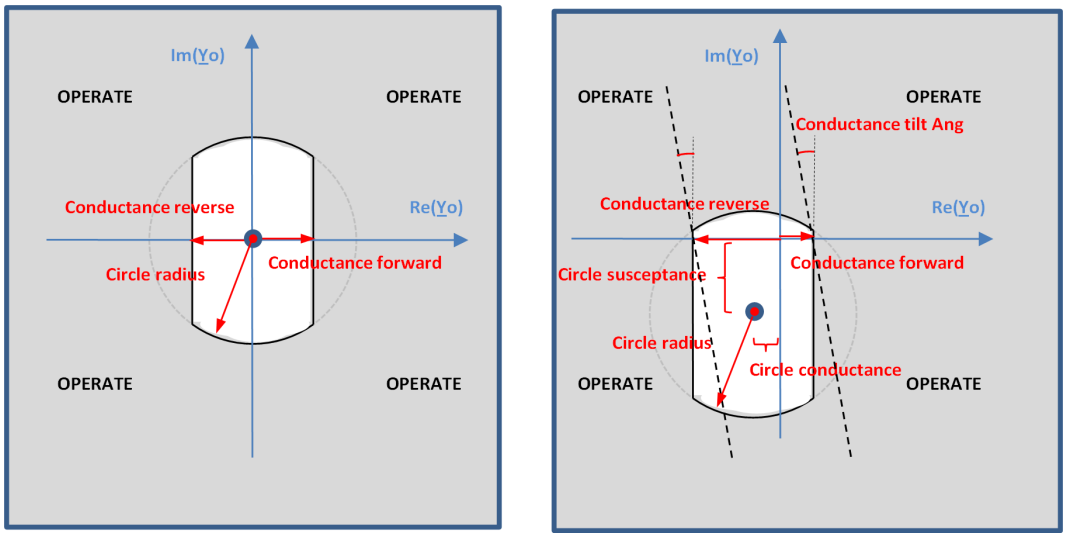

Figure 289: Combined overadmittance and overconductance characteristic. Left figure: classical origin-centered admittance circle combined with two overconductance boundary lines. Right figure: admittance circle is set off from the origin.

Combined overconductance and oversusceptance characteristic

The combined overconductance and oversusceptance criterion is enabled with the *Operation mode* setting set to "Go, Bo".

By setting *Directional mode* to "Forward", the characteristic is a combination of two boundary lines with the settings *Conductance forward* and *Susceptance forward*. See *Figure 290*.

By setting *Directional mode* to "Non-directional", the characteristic is a combination of four boundary lines with the settings *Conductance forward*, *Conductance reverse*, *Susceptance forward* and *Susceptance reverse*. See *Figure 291*.

For the sake of application flexibility, the boundary lines can be tilted by the angle defined with the *Conductance tilt Ang* and *Susceptance tilt Ang* settings. By default, the tilt angles are zero degrees, that is, the boundary lines are straight lines in the admittance plane. A positive *Conductance tilt Ang* value rotates the overconductance boundary line counterclockwise from the vertical axis. A positive *Susceptance tilt Ang* value rotates the oversusceptance boundary line counterclockwise from the horizontal axis.

In case of the non-directional conductance and susceptance criteria, the *Conductance reverse* setting must be set to a smaller value than *Conductance forward* and the *Susceptance reverse* setting must be set to a smaller value than *Susceptance forward*.

Operation is achieved when the measured admittance moves outside the characteristic.

The combined overconductance and oversusceptance criterion is applicable in high-resistance earthed, unearthed and compensated networks or in the systems where the system earthing may temporarily change during normal operation from compensated to unearthed system.

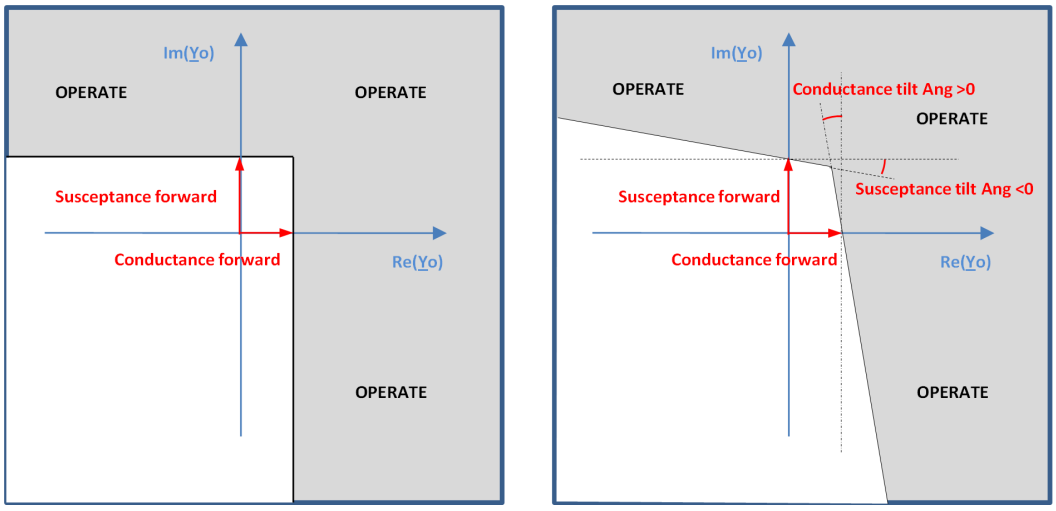

Figure 290: Combined forward directional overconductance and forward directional oversusceptance characteristic. Left figure: the Conductance tilt Ang and Susceptance tilt Ang settings equal zero degrees. Right figure: the setting Conductance tilt Ang > 0 degrees and the setting Susceptance tilt Ang < 0 degrees.

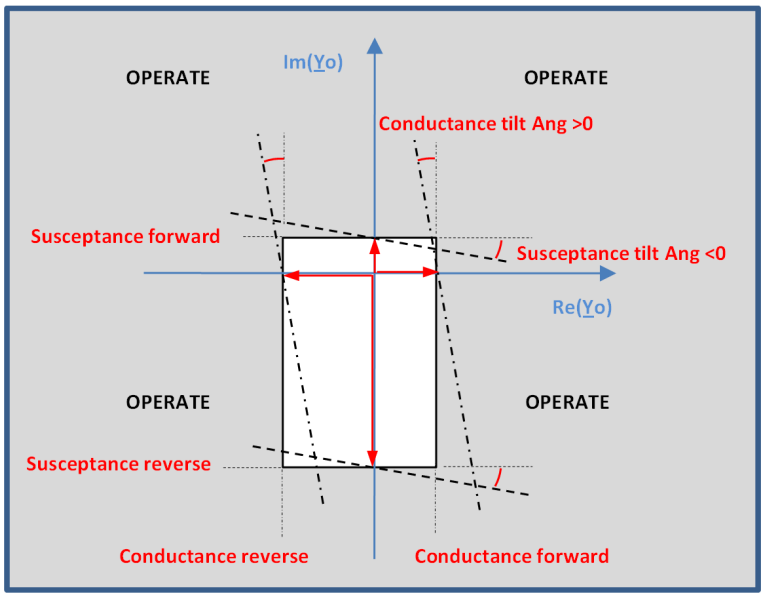

Figure 291: Combined non-directional overconductance and non-directional oversusceptance characteristic

The non-directional overconductance and non-directional oversusceptance characteristic provides a good sensitivity and selectivity when the characteristic is set to cover the total admittance of the protected feeder with a proper margin.

The sign of the admittance characteristic settings should be considered based on the location of characteristic boundary in the admittance plane. All forward-settings are given with positive sign and reverse-settings with negative sign.

4.2.4.7 Application

Admittance-based earth-fault protection provides a selective earth-fault protection for high-resistance earthed, unearthed and compensated networks. It can be applied for the protection of overhead lines as well as with underground cables. It can be used as an alternative solution to traditional residual current-based earth-fault protection functions, for example the IoCos mode in DEFxPDEF. Main advantages of EFPADM include versatile applicability, good sensitivity and easy setting principles.

Residual overvoltage condition is used as a start condition for the admittance-based earth-fault protection. When the residual voltage exceeds the set threshold *Voltage start value*, an earth fault is detected and the neutral admittance calculation is released. In order to guarantee a high security of protection, that is, avoid false starts, the *Voltage start value* setting must be set above the highest possible value of Uo during normal operation with a proper margin. It should consider all possible operation conditions and configuration changes in the network. In unearthed systems, the healthy-state Uo is typically less than 1%×Uph (Uph = nominal phase-to-earth voltage). In compensated networks, the healthy-state Uo may reach values even up to 30%×Uph if the network includes large parts of overheadlines without a phase transposition. Generally, the highest Uo is achieved when the compensation coil is tuned to the full resonance and when the parallel resistor of the coil is not connected.

The residual overvoltage-based start condition for the admittance protection enables a multistage protection principle. For example, one instance of EFPADM could be used for alarming to detect faults with a high fault resistance using a relatively low value for the *Voltage start value* setting. Another instance of EFPADM could then be set to trip with a lower sensitivity by selecting a higher value of the *Voltage start value* setting than in the alarming instance (stage).

To apply the admittance-based earth-fault protection, at least the following network data are required:

- System earthing method
- Maximum value for Uo during the healthy state
- Maximum earth-fault current of the protected feeder when the fault resistance Rf is zero ohm
- Maximum uncompensated earth-fault current of the system (Rf = 0 Ω)
- Rated current of the parallel resistor of the coil (active current forcing scheme) in the case of a compensated neutral network
- Rated current of the neutral earthing resistor in the case of a high-resistance earthed system
- Knowledge of the magnitude of Uo as a function of the fault resistance to verify the sensitivity of the protection in terms of fault resistance

Figure 292 shows the influence of fault resistance on the residual voltage magnitude in unearthed and compensated networks. Such information should be available to verify the correct *Voltage start value* setting, which helps fulfill the requirements for the sensitivity of the protection in terms of fault resistance.

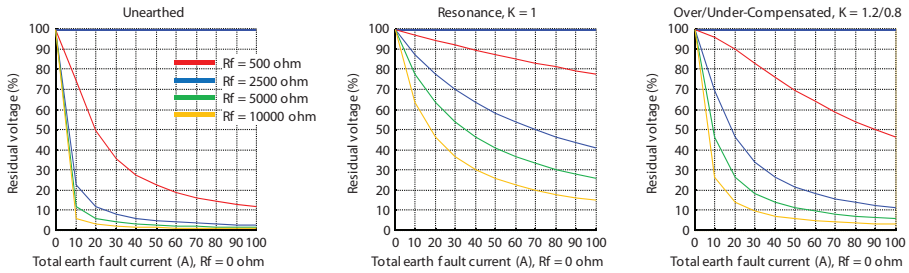

Figure 292: Influence of fault resistance on the residual voltage magnitude in 10 kV unearthed and compensated networks. The leakage resistance is assumed to be 30 times higher than the absolute value of the capacitive reactance of the network. Parallel resistor of the compensation coil is assumed to be disconnected.

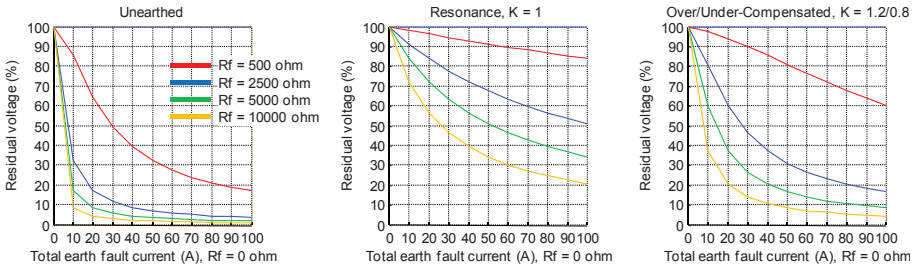

Figure 293: Influence of fault resistance on the residual voltage magnitude in 15 kV unearthed and compensated networks. The leakage resistance is assumed to be 30 times higher than the absolute value of the capacitive reactance of the network. Parallel resistor of the compensation coil is assumed to be disconnected.

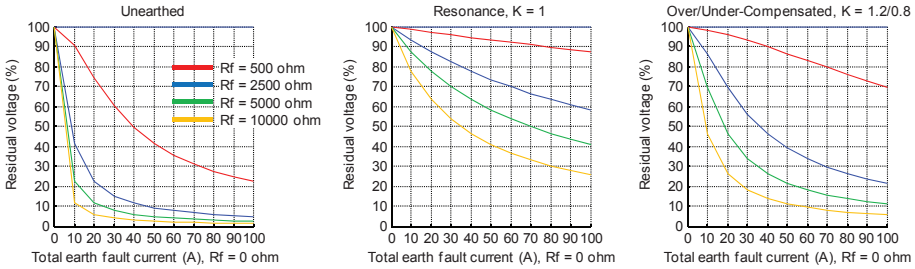

Figure 294: Influence of fault resistance on the residual voltage magnitude in 20 kV unearthed and compensated networks. The leakage resistance is assumed to be 30 times higher than the absolute value of the capacitive reactance of the network. Parallel resistor of the compensation coil is assumed to be disconnected.

Example

In a 15 kV, 50 Hz compensated network, the maximum value for Uo during the healthy state is 10%×Uph. Maximum earth-fault current of the system is 100 A. The maximum earth-fault current of the protected feeder is 10 A (Rf = 0 Ω). The applied active current forcing scheme uses a 15 A resistor (at 15 kV), which is connected in parallel to the coil during the fault after a 1.0 second delay.

Solution: As a start condition for the admittance-based earth-fault protection, the internal residual overvoltage condition of EFPADM is used. The *Voltage start value* setting must be set above the maximum healthy-state Uo of 10%×Uph with a suitable margin.

Voltage start value = 0.15 × Un

According to *Figure 293*, this selection ensures at least a sensitivity corresponding to a 2000 ohm fault resistance when the compensation degree varies between 80% and 120%. The greatest sensitivity is achieved when the compensation degree is close to full resonance.

An earth-fault current of 10 A can be converted into admittance.

$$\underline{Y}_{Fdtot} = \frac{10A}{15kV/\sqrt{3}} \approx j \cdot 1.15 \text{ mS}$$

(Equation 71)

A parallel resistor current of 15 A can be converted into admittance.

$$G_{cc} = \frac{15A}{15kV/\sqrt{3}} \approx 1.73 \text{ mS}$$

(Equation 72)

According to *Equation 59*, during an outside fault EFPADM measures the following admittance:

$$\underline{Yo} = -\underline{Y}_{Fdtot} \approx -j \cdot 1.15 \text{ mS}$$

(Equation 73)

According to *Equation 62*, during an inside fault EFPADM measures the admittance after the connection of the parallel resistor:

$$\underline{Yo} = \underline{Y}_{Bgtot} + \underline{Y}_{CC} \approx \left(1.73 + j \cdot B\right) \text{ mS}$$

(Equation 74)

Where the imaginary part of the admittance, B, depends on the tuning of the coil (compensation degree).

The admittance characteristic is selected to be the combined overconductance and oversusceptance characteristic ("Box"-characteristics) with four boundary lines:

Operation mode = "Go, Bo"

Directional mode = "Non-directional"

The admittance characteristic is set to cover the total admittance of the protected feeder with a proper margin, see *Figure 295*. Different setting groups can be used to allow adaptation of protection settings to different feeder and network configurations.

Conductance forward

This setting should be set based on the parallel resistor value of the coil. It must be set to a lower value than the conductance of the parallel resistor, in order to enable dependable operation. The selected value should move the boundary line

from origin to include some margin for the admittance operation point due to CT/VT-errors, when fault is located outside the feeder.

Conductance forward: 15 A/(15 kV/sqrt(3)) * 0.2 = +0.35 mS corresponding to 3.0 A (at 15 kV). The selected value provides margin considering also the effect of CT/VT-errors in case of outside faults.

In case of a lower rated value of the parallel resistor, for example, 5 A (at 15 kV), the recommended security margin should be higher, for example 0.7, so that sufficient margin for CT/VT-errors can be achieved.

Susceptance forward

By default, this setting should be based on the minimum operate current of 1 A.

Susceptance forward: 1 A/(15 kV/sqrt(3)) = +0.1 mS

Susceptance reverse

This setting should be set based on the value of the maximum earth-fault current produced by the feeder (considering possible feeder topology changes) with a security margin. This ensures that the admittance operating point stays inside the "Box"-characteristics during outside fault. The recommended security margin should not be lower than 1.5.

Susceptance reverse: - (10 A * 1.5)/ (15 kV/sqrt(3)) = -1.73 mS

Conductance reverse

This setting is used to complete the non-directional characteristics by closing the "Box"-characteristic. In order to keep the shape of the characteristic reasonable and to allow sufficient margin for the admittance operating point during outside fault, it is recommended to use the same value as for setting Susceptance reverse.

Conductance reverse = -1.73 mS

Rotor earth-fault protection, injection method	MREFPTOC	Io>R	64R

4.2.5.2 Function block

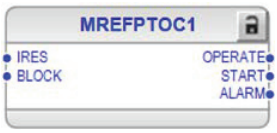

Figure 296: Function block

4.2.5.3 Functionality

The rotor earth-fault protection, injection method, function MREFPTOC is used to detect an earth fault in the rotor circuit of synchronous machines. MREFPTOC is used with the injection device REK510, which requires a secured 58, 100 or 230 V AC

[1] $U_o = 1.0 \times U_n$.
[2] Includes the delay of the signal output contact, results based on statistical distribution of 1000 measurements.

50/60 Hz input source and injects a 100 V AC voltage via its coupling capacitors to the rotor circuit towards earth.

MREFPTOC consists of independent alarm and operating stages. The operating time characteristic is according to definite time (DT) for both stages.

MREFPTOC contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.5.4 Analog channel configuration

MREFPTOC has one analog group input which must be properly configured.

Table 575: Analog signals

Input	Description
IRES	Residual current (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of MREFPTOC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

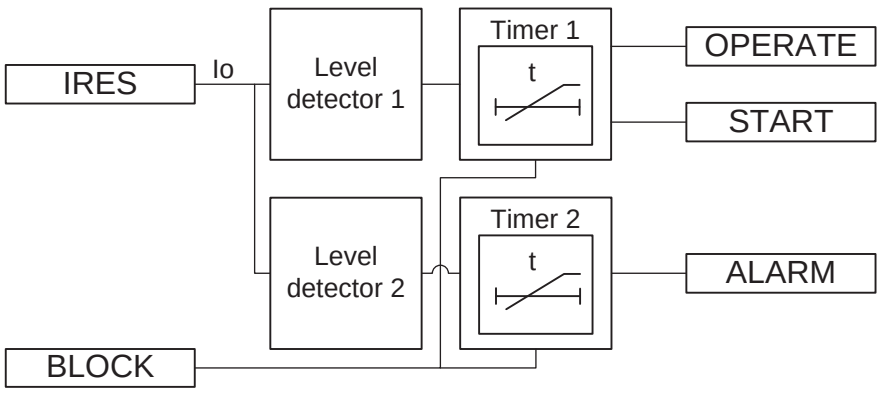

Figure 297: Functional module diagram

Level detector 1

The measured rotor earth-fault current (DFT value) is compared to the *Operate start value* setting. If the measured value exceeds that of the *Operate start value* setting, Level detector 1 sends a signal to start the Timer 1 module.

Level detector 2

The measured rotor earth-fault current (DFT value) is compared to the set *Alarm start value*. If the measured value exceeds that of the *Alarm start value* setting, Level detector 2 sends a signal to start the Timer 2 module.

For MREFPTOC, the earth-fault current is the current that flows due to the voltage injected by the injection device in the rotor circuit when an earth fault arises.

A considerable amount of harmonics, mainly 3rd and 6th, can occur in the excitation current under normal no-fault conditions, especially with the thyristor excitation and rotating diode rectifier systems. MREFPTOC uses DFT value calculation to filter DC and harmonic components which could otherwise give out false alarms or trips.

Timer 1

Once activated, the Timer activates the START output. The timer characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time* in the DT mode, the OPERATE output is activated. If a drop-off situation occurs, that is, a fault suddenly disappears before the operating delay is exceeded, the timer reset state is activated. The reset time depends on the *Reset delay time* setting.

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates all outputs and resets the internal timers.

Timer 2

Once activated, the Timer activates the alarm timer. The timer characteristic is according to DT. When the alarm timer has reached the value set by *Alarm delay time* in the DT mode, the ALARM output is activated. If a drop-off situation occurs, that is, a fault suddenly disappears before the alarm delay is exceeded, the timer reset state is activated. The reset time depends on the *Alm reset delay time* setting.

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates all outputs and resets the internal timers.

4.2.5.6 Application

The rotor circuit of synchronous machines is normally isolated from the earth. The rotor circuit can be exposed to an abnormal mechanical or thermal stress due to, for example, vibrations, overcurrent and choked cooling medium flow. This can result in the breakdown of the insulation between the field winding and the rotor iron at the point exposed to excessive stress. If the isolation resistance is decreased significantly, this can be seen as an earth fault. For generators with slip rings, the rotor insulation resistance is sometimes reduced due to the accumulated carbon dust layer produced by the carbon brushes. As the circuit has a high impedance to earth, a single earth fault does not lead to any immediate damage because the fault current is small due to a low voltage. There is, however, a risk that a second earth

fault appears, creating a rotor winding interturn fault and causing severe magnetic imbalance and heavy rotor vibrations that soon lead to a severe damage.

Therefore, it is essential that any occurrence of an insulation failure is detected and that the machine is disconnected as soon as possible. Normally, the device is tripped after a short time delay.

A 50/60 Hz voltage is injected via the injection device REK 510 to the rotor field winding circuit of the synchronous machine as shown in *Figure 298*. The injected voltage is 100 V AC via the coupling capacitors. A coupling capacitor prevents a DC current leakage through the injection device.

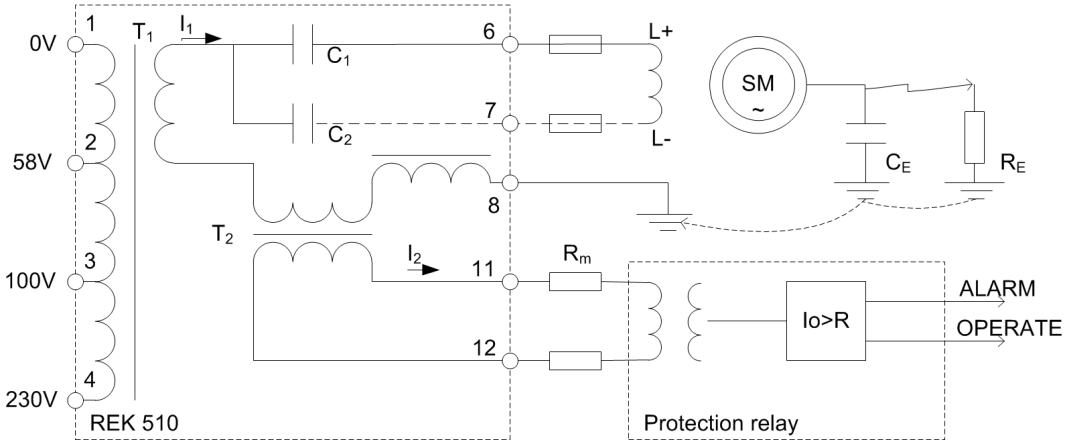

Figure 298: Principle of the rotor earth-fault protection with the current injection device

The auxiliary AC voltage forms a small charging current I_1 to flow via the coupling capacitors, resistances of the brushes and the leakage capacitance between the field circuit and earth. The field-to-earth capacitance C_E affects the level of the resulting current to an extent which is a few milliamperes during normal no-fault operating conditions.

If an earth fault arises in the rotor field circuit, this current increases and can reach a level of 130 mA at a fully developed earth fault (fault resistance R_E = 0, one coupling capacitor C_1 = 2µF is used). The integrated current transformer of the injection device REK 510 then amplifies this current with the ratio of 1:10 to a measurable level. MREFPTOC is used to measure this current.

An example of the measured curves with various field-to-earth leakage capacitance values is given in *Figure 299*.

It is recommended that the alarm and operation stages of MREFPTOC are both used. The alarm stage for giving an indication for weakly developed earth faults with a start value setting corresponds to a 10 kΩ fault resistance with a 10-second delay. The operation stage for a protection against fully developed earth faults with a start value setting corresponds to a 1...2 kΩ fault resistance with a 0.5-second delay.

The current setting values corresponding to the required operating fault resistances can be tested by connecting an adjustable fault simulating resistor between the excitation winding poles and the earth. Whether only one of the coupling capacitors or both should be used in a parallel connection should be determined on a case-by-case basis, taking into consideration the consequences of a possibly excessive current at a direct earth fault.

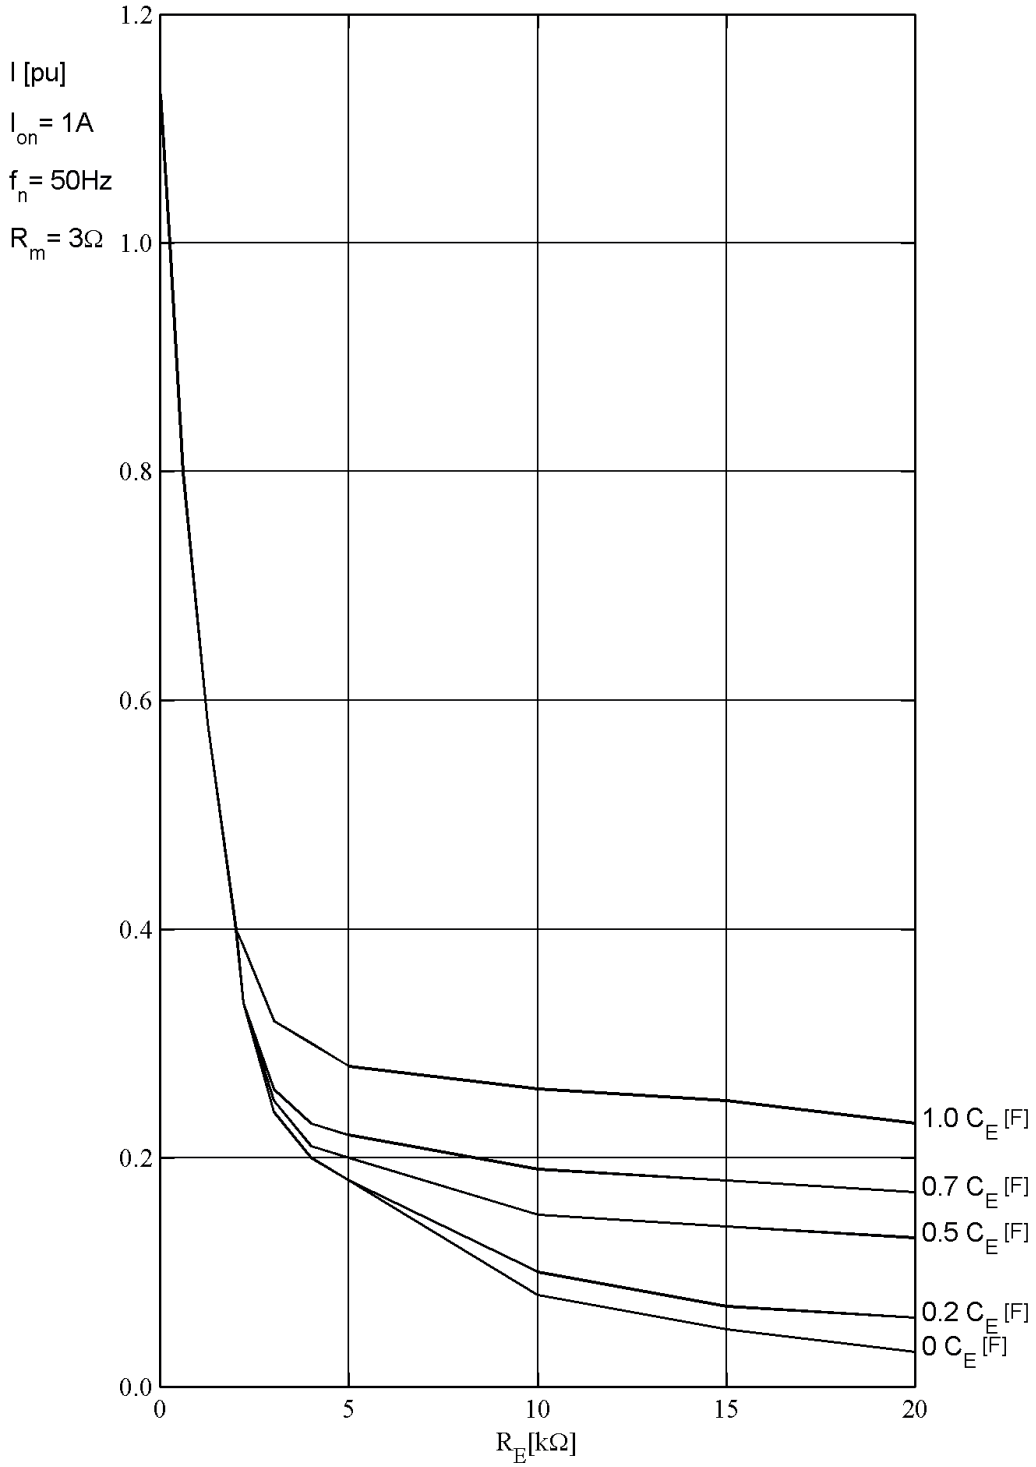

Figure 299: Measured current as a function of the rotor earth-fault resistance with various field-to-earth capacitance values with the measuring circuit resistance Rm = 3.0 Ω, fn = 50 Hz. Only one coupling capacitor is used.

Description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Harmonics-based earth-fault protection	HAEFPTOC	Io>HA	51NH

4.2.6.2 Function block

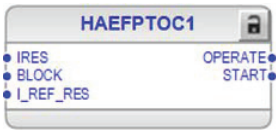

Figure 300: Function block

4.2.6.3 Functionality

The harmonics-based earth-fault protection function HAEFPTOC is used instead of a traditional earth-fault protection in networks where a fundamental frequency component of the earth-fault current is low due to compensation.

[1] Current before fault = 0.0 × I_n, f_n = 50 Hz, earth-fault current with nominal frequency injected from random phase angle, results based on statistical distribution of 1000 measurements.
[2] Includes the delay of the signal output contact.

By default, HAEFPTOC is used as a standalone mode. Substation-wide application can be achieved using horizontal communication where the detection of a faulty feeder is done by comparing the harmonics earth-fault current measurements.

The function starts when the harmonics content of the earth-fault current exceeds the set limit. The operation time characteristic is either definite time (DT) or inverse definite minimum time (IDMT). If the horizontal communication is used for the exchange of current values between the protection relays, the function operates according to the DT characteristic.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.2.6.4 Analog channel configuration

HAEFPTOC has one analog group input which must be properly configured.

Table 583: Analog signals

Input	Description
IRES	Residual current (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.6.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of HAEFPTOC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

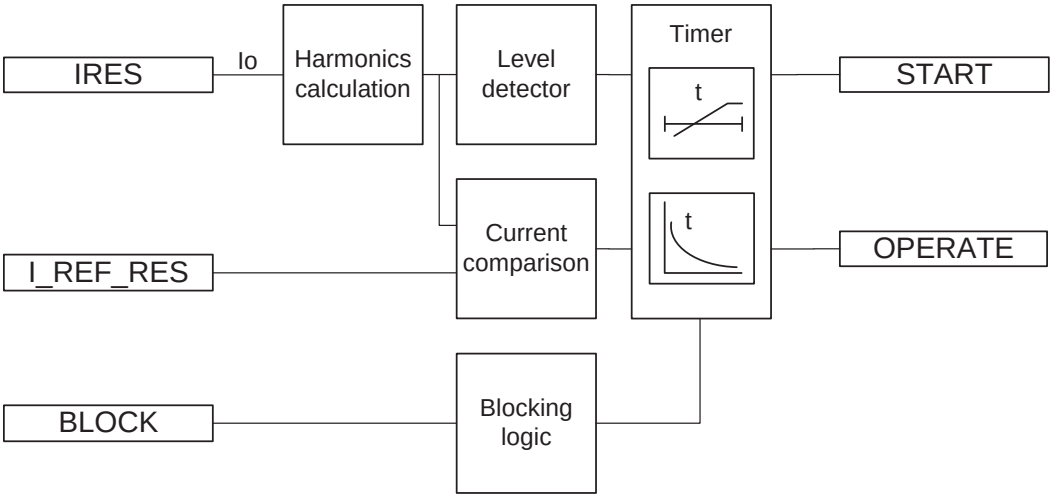

Figure 301: Functional module diagram

Harmonics calculation

This module feeds the measured residual current to the high-pass filter, where the frequency range is limited to start from two times the fundamental frequency of the network (for example, in a 50 Hz network the cutoff frequency is 100 Hz), that is, summing the harmonic components of the network from the second harmonic. The output of the filter, later referred to as the harmonics current, is fed to the Level detector and Current comparison modules.

The harmonics current I_HARM_RES is available in the monitored data view. The value is also sent over horizontal communication to the other protection relays on the parallel feeders configured in the protection scheme.

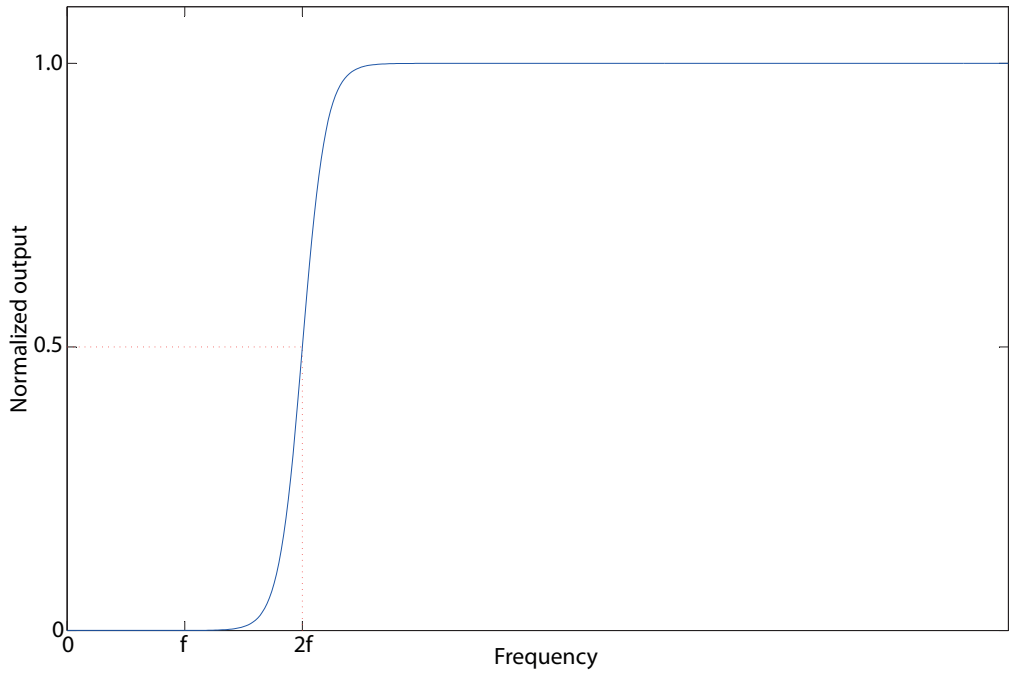

Figure 302: High-pass filter

Level detector

The harmonics current is compared to the *Start value* setting. If the value exceeds the value of the *Start value* setting, Level detector sends an enabling signal to the Timer module.

Current comparison

The maximum of the harmonics currents reported by other parallel feeders in the substation, that is, in the same busbar, is fed to the function through the I_REF_RES input. If the locally measured harmonics current is higher than I_REF_RES, the enabling signal is sent to Timer.

If the locally measured harmonics current is lower than I_REF_RES, the fault is not in that feeder. The detected situation blocks Timer internally, and simultaneously also the BLKD_I_REF output is activated.

The module also supervises the communication channel validity which is reported to the Timer.

Timer

The START output is activated when Level detector sends the enabling signal. Functionality and the time characteristics depend on the selected value of the *Enable reference use* setting.

Table 584: Values of the Enable reference use setting

Enable reference use		Functionality
Standalone		In the standalone mode, depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of the *Operate delay time* setting in the DT mode or the value defined by the inverse time curve, the OPERATE output is activated.
Reference use	Communication valid	When using the horizontal communication, the function is forced to use the DT characteristics. When the operation timer has reached the value of the *Minimum operate time* setting and simultaneously the enabling signal from the Current comparison module is active, the OPERATE signal is activated.
	Communication invalid	Function operates as in the standalone mode.

The *Enable reference use* setting forces the function to use the DT characteristics where the operating time is set with the *Minimum operate time* setting.

If the communication for some reason fails, the function switches to use the *Operation curve type* setting, and if DT is selected, *Operate delay time* is used. If the IDMT curve is selected, the time characteristics are according to the selected curve and the *Minimum operate time* setting is used for restricting too fast an operation time.

In case of a communication failure, the start duration may change substantially depending on the user settings.

When the programmable IDMT curve is selected, the operation time characteristics are defined with the *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E* parameters.

If a drop-off situation happens, that is, a fault suddenly disappears before the operation delay is exceeded, the Timer reset state is activated. The functionality of Timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the value of the *Reset delay time* setting is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. If the drop-off situation continues, the reset timer is reset and the START output is deactivated.

The "Inverse reset" selection is only supported with ANSI or the programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operation and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operation time for IDMT. The setting is applicable only when the IDMT curves are used

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve but always at least the value of the *Minimum operate time* setting. More information can be found in *Chapter 11.2.1 IDMT curves for overcurrent protection*.

Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation, and the set operating time, which can be either according to DT or IDMT. The value is available in the monitored data view.

More information can be found in *Chapter 11 General function block features*.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the *Block OPERATE output* mode, the function operates normally but the OPERATE output is not activated.

4.2.6.6 Application

During an earth fault, HAEFPTOC calculates the maximum current for the current feeder. The value is sent over an analog GOOSE to other protection relays of the busbar in the substation. At the configuration level, all the values received over the analog GOOSE are compared through the MAX function to find the maximum value. The maximum value is sent back to HAEFPTOC as the I_REF_RES input. The operation of HAEFPTOC is allowed in case I_REF_RES is lower than the locally measured harmonics current. If I_REF_RES exceeds the locally measured harmonics current, the operation of HAEFPTOC is blocked.

	-3 dB at f = 13 × f_n

4.2.7 Wattmetric-based earth-fault protection WPWDE (ANSI 32N)

4.2.7.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Wattmetric-based earth-fault protection	WPWDE	Po> ->	32N

4.2.7.2 Function block

Figure 304: Function block

4.2.7.3 Functionality

The wattmetric-based earth-fault protection function WPWDE can be used to detect earth faults in unearthed networks, compensated networks (Petersen coil-earthed networks) or networks with a high-impedance earthing. It can be used as an alternative solution to the traditional residual current-based earth-fault protection functions, for example, the IoCos mode in the directional earth-fault protection function DEFxPDEF.

[1] Fundamental frequency current = 1.0 × I_n, harmonics current before fault = 0.0 × I_n, harmonics fault current 2.0 × *Start value*, results based on statistical distribution of 1000 measurements.
[2] Includes the delay of the signal output contact.
[3] Start time of the function also included.
[4] Maximum *Start value* = 2.5 × I_n, *Start value* multiples in range of 2...20.

WPWDE measures the earth-fault power 3UoIoCosϕ and gives an operating signal when the residual current Io, residual voltage Uo and the earth-fault power exceed the set limits and the angle (ϕ) between the residual current and the residual voltage is inside the set operating sector, that is, forward or backward sector. The operating time characteristic can be selected to be either definite time (DT) or a special wattmetric-type inverse definite minimum type (wattmetric type IDMT).

The wattmetric-based earth-fault protection is very sensitive to current transformer errors and it is recommended that a core balance CT is used for measuring the residual current.

WPWDE contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.2.7.4 Analog channel configuration

WPWDE has two analog group inputs which must be properly configured.

Table 593: Analog inputs

Input	Description
IRES	Residual current (measured or calculated)
URES	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 594: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected for calculating the residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.7.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

For WPWDE, certain notations and definitions are used.

Residual voltage Uo = (UA+UB+UC)/3 = U_0, where U_0 = zero-sequence voltage

Residual current Io = -(IA+IB+IC) = 3×- I_0, where I_0 = zero-sequence current

The minus sign (-) is needed to match the polarity of calculated and measured residual currents.

The operation of WPWDE can be described with a module diagram. All the modules in the diagram are explained in the next sections.

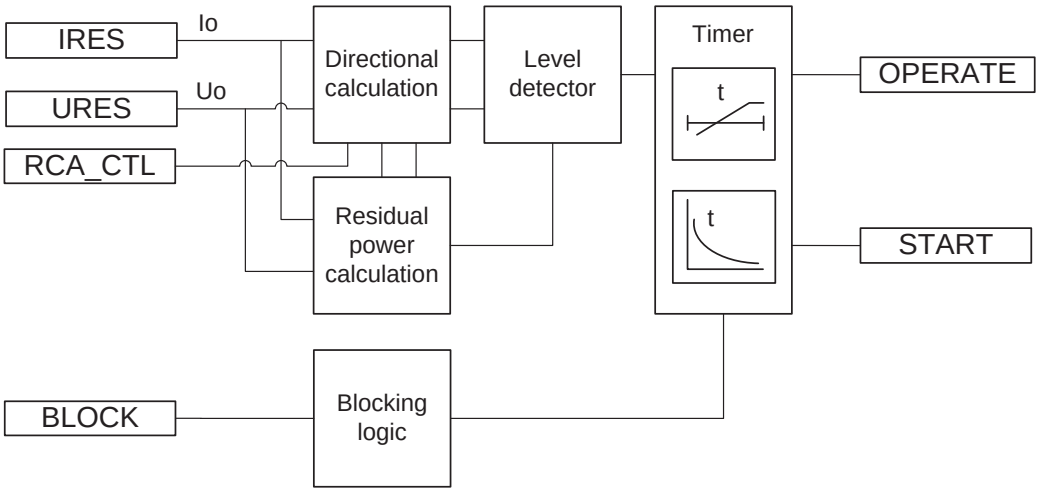

Figure 305: Function module diagram

Directional calculation

The Directional calculation module monitors the angle between the operating quantity (residual current Io) and polarizing quantity (residual voltage Uo). The operating quantity can be selected with the setting *Io signal Sel*. The selectable options are “Measured Io” and “Calculated Io”. The polarizing quantity can be selected with the setting *Pol signal Sel*. The selectable options are “Measured Uo” and “Calculated Uo”. When the angle between operating quantity and polarizing quantity after considering the *Characteristic angle* setting is in the operation sector, the module sends an enabling signal to Level detector. The directional operation is selected with the *Directional mode* setting. Either the “Forward” or “Reverse” operation mode can be selected. The direction of fault is calculated based on the phase angle difference between the operating quantity Io and polarizing quantity Uo, and the value (ANGLE) is available in the monitored data view.

In the phasor diagrams representing the operation of WPWDE, the polarity of the polarizing quantity (residual voltage Uo) is reversed. Reversing is done by switching the polarity of the residual current measuring channel (see the connection in the Protection relay's physical connections section).

If the angle difference lies between -90° to 0° or 0° to +90°, a forward-direction fault is considered. If the phase angle difference lies within -90° to -180° or +90° to +180°, a reverse-direction fault is detected. Thus, the normal width of a sector is 180°.

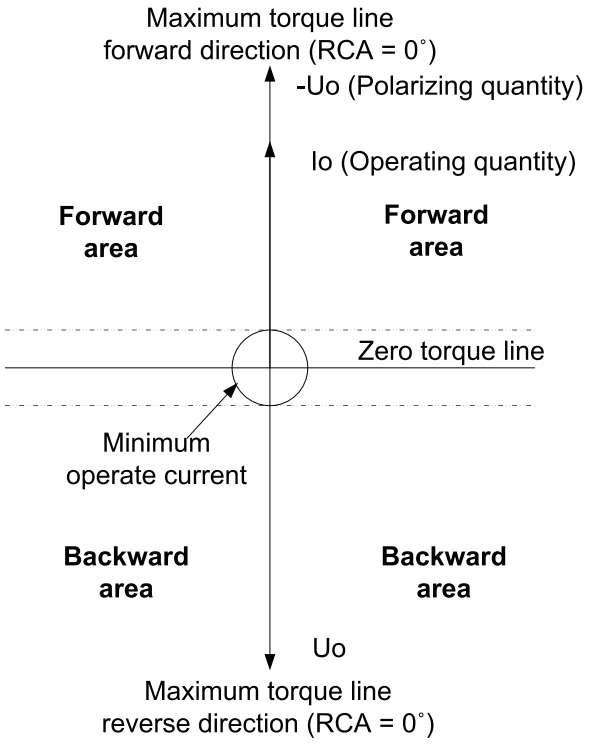

Figure 306: Definition of the relay characteristic angle

The phase angle difference is calculated based on the *Characteristic angle* setting (also known as Relay Characteristic Angle (RCA) or Relay Base Angle or Maximum Torque Angle (MTA)). The *Characteristic angle* setting is done based on the method of earthing employed in the network. For example, in case of an unearthed network, the *Characteristic angle* setting is set to -90°, and in case of a compensated network, the *Characteristic angle* setting is set to 0°. In general, *Characteristic angle* is selected so that it is close to the expected fault angle value, which results in maximum sensitivity. *Characteristic angle* can be set anywhere between -179° to +180°. Thus, the effective phase angle (ϕ) for calculating the residual power considering characteristic angle is according to the equation.

$$\phi = \left(\angle(-Uo) - \angle Io - Characteristic\ angle \right)$$

(Equation 75)

In addition, the characteristic angle can be changed via the control signal RCA_CTL. The RCA_CTL input is used in the compensated networks where the compensation coil sometimes is temporarily disconnected. When the coil is disconnected, the compensated network becomes isolated and the *Characteristic angle* setting must be changed. This can be done automatically with the RCA_CTL input, which results in the addition of -90° in the *Characteristic angle* setting.

The value (ANGLE_RCA) is available in the monitored data view.

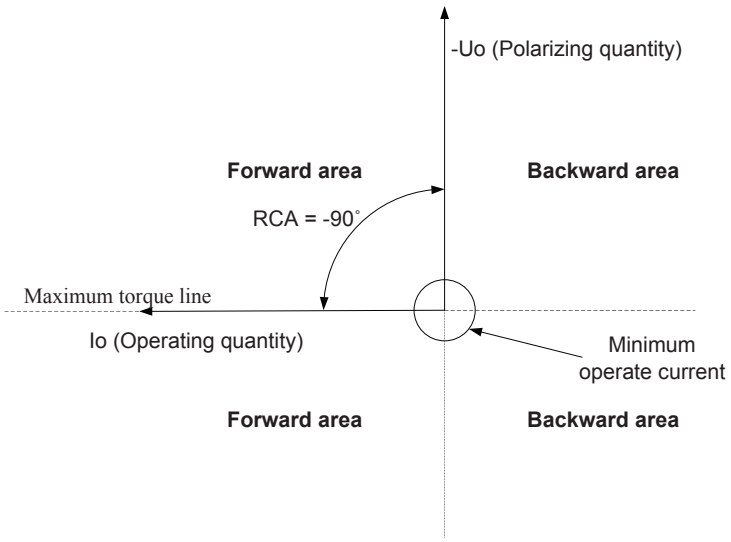

Figure 307: Definition of relay characteristic angle, RCA = -90° in an isolated network

Characteristic angle should be set to a positive value if the operating signal lags the polarizing signal and to a negative value if the operating signal leads the polarizing signal.

Type of network	Recommended characteristic angle
Compensated network	0°
Unearthed network	-90°

In unearthed networks, when the characteristic angle is -90°, the measured residual power is reactive (varmetric power).

The fault direction is also indicated `FAULT_DIR` (available in the monitored data view), which indicates 0 if a fault is not detected, 1 for faults in the forward direction and 2 for faults in the backward direction.

The direction of the fault is detected only when the correct angle calculation can be made. If the magnitude of the operating quantity or polarizing quantity is not high enough, the direction calculation is not reliable. Hence, the magnitude of the operating quantity is compared to the *Min operate current* setting and the magnitude of the polarizing quantity is compared to *Min operate voltage*, and if both the operating quantity and polarizing quantity are higher than their respective limit, a valid angle is calculated and the residual power calculation module is enabled.

The *Correction angle* setting can be used to improve the selectivity when there are inaccuracies due to the measurement transformer. The setting decreases the operation sector. The *Correction angle* setting should be done carefully as the phase angle error of the measurement transformer varies with the connected burden as well as with the magnitude of the actual primary current that is being measured. An example of how *Correction angle* alters the operating region is as shown:

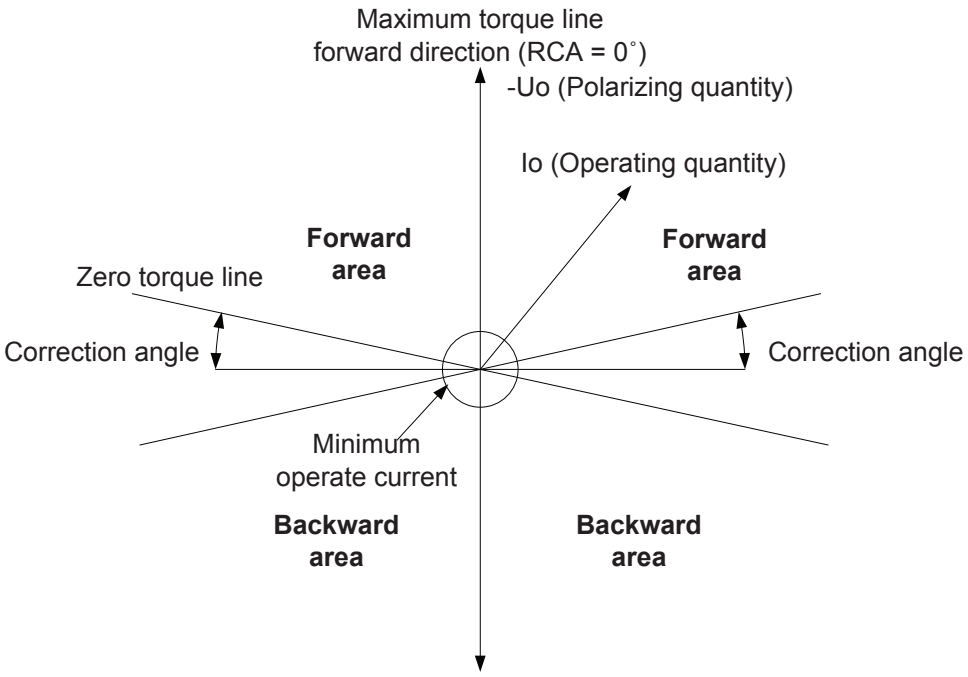

Figure 308: Definition of correction angle

The polarity of the polarizing quantity can be changed (rotated by 180°) by setting *Pol reversal* to "True" or by switching the polarity of the residual voltage measurement wires.

Residual power calculation

The Residual power calculation module calculates the magnitude of residual power 3UoIoCosϕ. Angle ϕ is the angle between the operating quantity and polarizing quantity, compensated with a characteristic angle. The angle value is received from the Directional calculation module. The Directional calculation module enables the residual power calculation only if the minimum signal levels for both operating quantity and polarizing quantity are exceeded. However, if the angle calculation is not valid, the calculated residual power is zero. Residual power (RES_POWER) is calculated continuously and it is available in the monitored data view. The power is given in relation to nominal power calculated as Pn = Un × In, where Un and In are obtained from the entered voltage transformer and current transformer ratios entered.

Level detector

Level detector compares the magnitudes of the measured operating quantity (residual current Io), polarizing quantity (residual voltage Uo) and calculated residual power to the set *Current start value* (×In), *Voltage start value* (×Un) and *Power start value* (×Pn) respectively. When all three quantities exceed the limits, Level detector enables the Timer module.

As nominal power is the result of the multiplication of the nominal current and the nominal voltage Pn = Un × In, the calculation of the setting value for *Power start value* (×Pn) depends on whether Io and Uo are measured or calculated from the phase quantities.

Timer

Once activated, Timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or wattmetric IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated. If a drop-off situation happens, that is, a fault suddenly disappears before the operating delay is exceeded, the timer reset state is activated. The reset time is identical for both DT or wattmeter IDMT. The reset time depends on the *Reset delay time* setting.

Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the *Block OPERATE output* mode, the function operates normally but the OPERATE output is not activated.

4.2.7.6 Timer characteristics

In the wattmetric IDMT mode, the OPERATE output is activated based on the timer characteristics:

$$t[s] = \frac{k * P_{ref}}{P_{cal}}$$

(Equation 76)

t[s]	operation time in seconds
k	set value of *Time multiplier*
P_{ref}	set value of *Reference power*
P_{cal}	calculated residual power

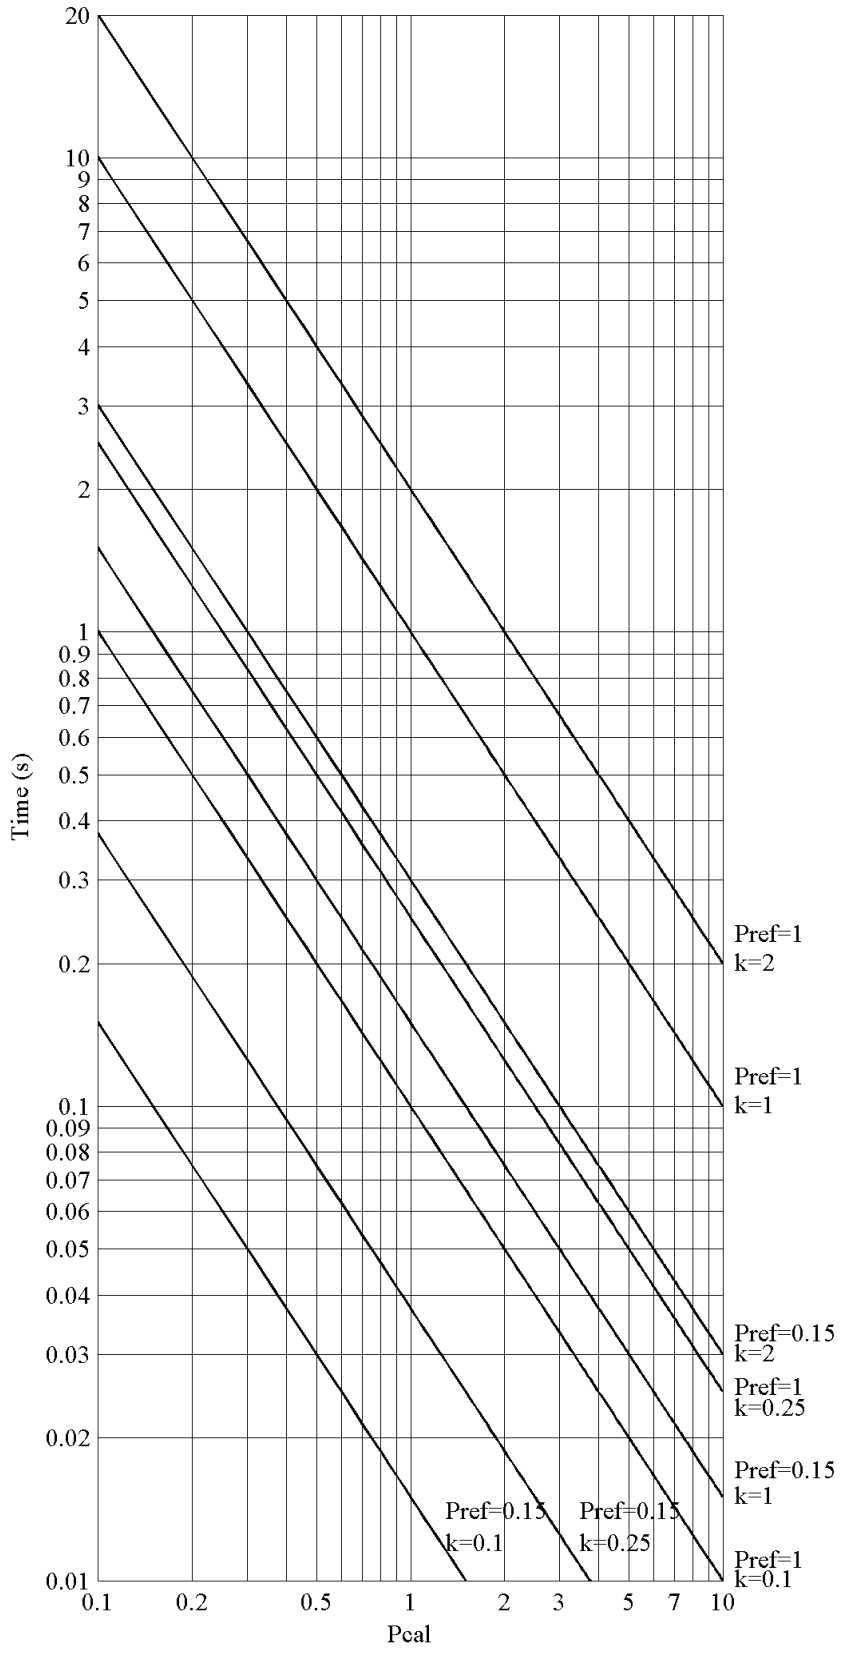

Figure 309: Operation time curves for wattmetric IDMT for S ref set at 0.15 xPn

4.2.7.7 Measurement modes

The function operates on three alternative measurement modes: "RMS", "DFT" and "Peak-to-Peak". The measurement mode is selected with the *Measurement mode* setting.

4.2.7.8 Application

The wattmetric method is one of the commonly used directional methods for detecting the earth faults especially in compensated networks. The protection uses the residual power component 3UoIoCosϕ (ϕ is the angle between the polarizing quantity and operating quantity compensated with a relay characteristic angle).

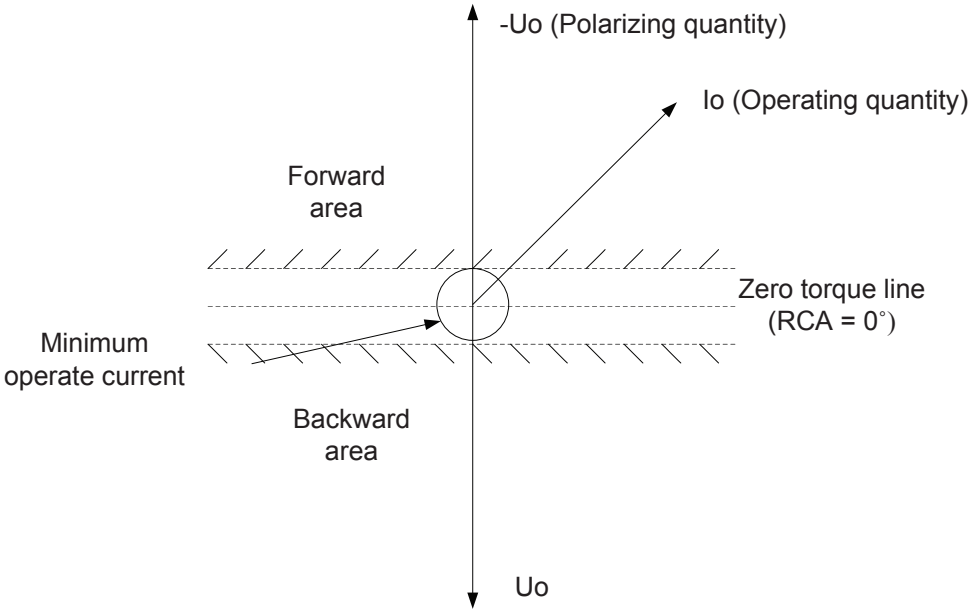

Figure 310: Characteristics of wattmetric protection

In a fully compensated radial network with two outgoing feeders, the earth-fault currents depend mostly on the system earth capacitances (C_0) of the lines and the compensation coil (L). If the coil is tuned exactly to the system capacitance, the fault current has only a resistive component. This is due to the resistances of the coil and distribution lines together with the system leakage resistances (R_0). Often a resistor (R_L) in parallel with the coil is used for increasing the fault current.

When a single phase-to-earth fault occurs, the capacitance of the faulty phase is bypassed and the system becomes unsymmetrical. The fault current is composed of the currents flowing through the earth capacitances of two healthy phases. The protection relay in the healthy feeder tracks only the capacitive current flowing through its earth capacitances. The capacitive current of the complete network (sum of all feeders) is compensated with the coil.

A typical network with the wattmetric protection is an undercompensated network where the coil current $I_L = I_{Ctot} - I_{Cfd}$ (I_{Ctot} is the total earth-fault current of the network and I_{Cfd} is the earth-fault current of the healthy feeder).

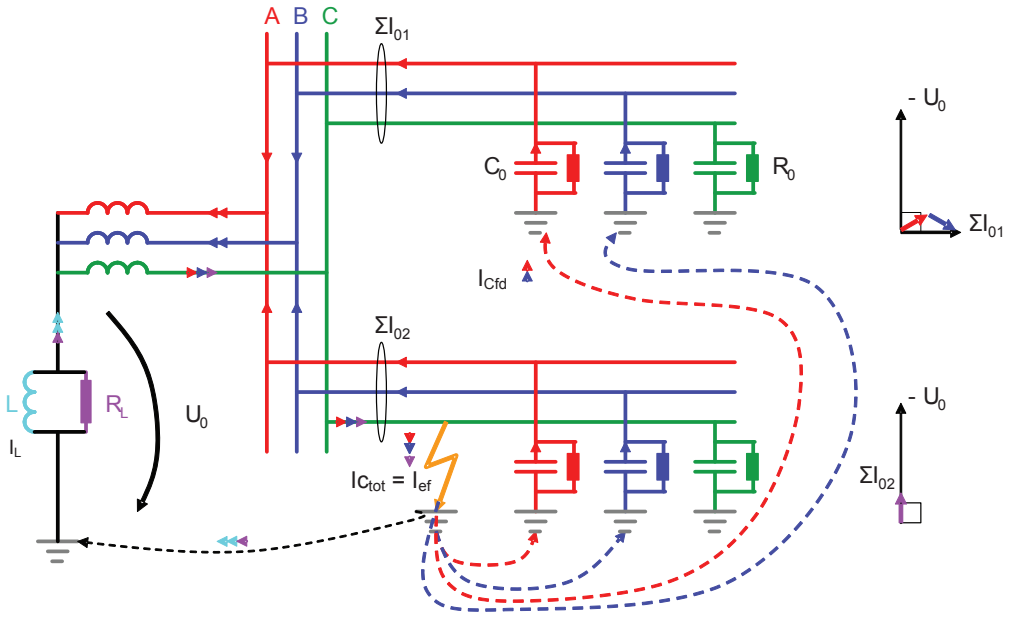

Figure 311: Typical radial compensated network employed with wattmetric protection

The wattmetric function is activated when the residual active power component exceeds the set limit. However, to ensure a selective operation, it is also required that the residual current and residual voltage also exceed the set limit.

It is highly recommended that core balance current transformers are used for measuring Io when using the wattmetric method. When a low transformation ratio is used, the current transformer can suffer accuracy problems and even a distorted secondary current waveform with some core balance current transformers. Therefore, to ensure a sufficient accuracy of the residual current measurement and consequently a better selectivity of the scheme, the core balance current transformer should preferably have a transformation ratio of at least 70:1. Lower transformation ratios such as 50:1 or 50:5 are not recommended, unless the phase displacement errors and current transformer amplitude are checked first.

It is not recommended to use the directional wattmetric protection in case of a ring or meshed system as the wattmetric requires a radial power flow to operate.

The relay characteristic angle needs to be set based on the system earthing. In an unearthed network, that is, when the network is only coupled to earth via the capacitances between the phase conductors and earth, the characteristic angle is chosen as -90°.

In compensated networks, the capacitive fault current and inductive resonance coil current compensate each other, meaning that the fault current is mainly resistive and has zero phase shift compared to the residual voltage. In such networks, the characteristic angle is chosen as 0°. Often the magnitude of an active component is small and must be increased by means of a parallel resistor in a compensation coil. In networks where the neutral point is earthed through a low resistance, the characteristic angle is always 0°.

As the amplitude of the residual current is independent of the fault location, the selectivity of the earth-fault protection is achieved with time coordination.

The use of wattmetric protection gives a possibility to use the dedicated inverse definite minimum time characteristics. This is applicable in large high-impedance earthed networks with a large capacitive earth-fault current.

In a network employing a low-impedance earthed system, a medium-size neutral point resistor is used. Such a resistor gives a resistive earth-fault current component of about 200...400 A for an excessive earth fault. In such a system, the directional residual power protection gives better possibilities for selectivity enabled by the inverse time power characteristics.

4.2.7.9 Signals

WPWDE Input signals

Table 595: WPWDE Input signals

Name	Type	Default	Description
IRES	SIGNAL	-	Residual current
URES	SIGNAL	-	Residual voltage
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode
RCA_CTL	BOOLEAN	0=False	Relay characteristic angle control

4.2.7.12 Technical data

Table 601: WPWDE Technical data

Characteristic	Value
Operation accuracy	Depending on the frequency of the measured current: f_n ±2 Hz
	Current and voltage: ±1.5% of the set value or ±0.002 × I_n Power: ±3% of the set value or ±0.002 × P_n
Start time [1, 2]	Typically 63 ms
Reset time	Typically 40 ms
Reset ratio	Typically 0.96
Operate time accuracy in definite time mode [3]	±1.0% of the set value or ±20 ms
Operate time accuracy in IDMT mode	±5.0% of the set value or ±20 ms
Suppression of harmonics	-50 dB at f = n × f_n, where n = 2,3,4,5,…

4.2.8 Third harmonic based stator earth-fault protection H3EFPSEF (ANSI 64TN)

4.2.8.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Third harmonic-based stator earth-fault protection	H3EFPSEF	dUo>/Uo3H	64TN

[1] Io varied during the test, U_o = 1.0 × U_n = phase-to-earth voltage during earth fault in compensated or unearthed network, the residual power value before fault = 0.0 pu, f_n = 50 Hz, results based on statistical distribution of 1000 measurements.
[2] Includes the delay of the signal output contact.
[3] Start time of the function also included.

4.2.8.2 Function block

Figure 312: Function block

4.2.8.3 Functionality

The third harmonic-based stator earth-fault protection H3EFPSEF is used to detect stator earth fault at the neutral point and at least up to 15...20% from the neutral point along the stator winding. H3EFPSEF compares the third harmonic voltages produced by the generator itself at both neutral and terminal side of the generator for detecting earth fault.

H3EFPSEF provides two alternative protection methods:

- Differential of the third harmonic component measured both at generator neutral and terminal side
- Neutral side third harmonic undervoltage

H3EFPSEF operates with the definite time DT characteristics.

H3EFPSEF contains a blocking functionality. Blocking deactivates all outputs and reset timers.

4.2.8.4 Analog channel configuration

H3EFPSEF has three analog group inputs which must be properly configured.

Table 602: Analog inputs

Input	Description
U3P [1]	Three-phase voltages Necessary when *Voltage selection* is set to "Uo", "Phase A", "Phase B" or "Phase C"
URES [2]	Residual voltage (measured or calculated) Necessary when *Voltage selection* is set to "Uo"
UNEUT	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

[1] Can be connected to GRPOFF if *Voltage selection* is set to "No voltage" or "Uo".
[2] Can be connected to GRPOFF if *Voltage selection* is other than "Uo".

Table 603: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with at least one voltage channel connected.
URES calculated	The function requires that all three voltage channels from the terminal side are connected to calculate residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.
UNEUT calculated	The function requires that all three voltage channels from the neutral side are connected to calculate residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.8.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”.

The operation of the third harmonic-based stator earth-fault protection function can be described using a module diagram. All the modules in the diagram are explained in the next sections.

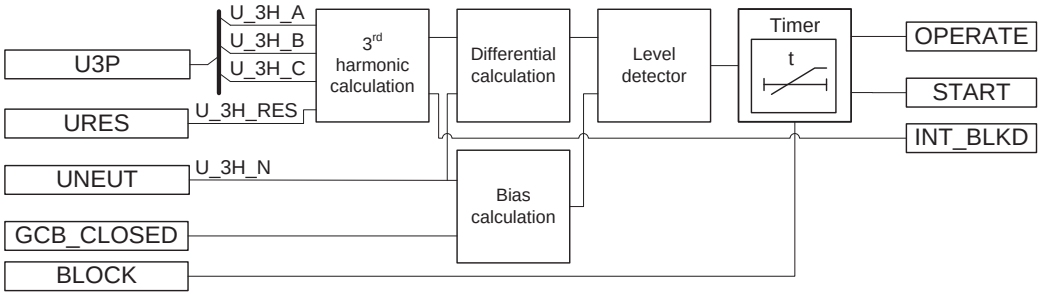

Figure 313: Functional module diagram

3rd harmonic calculation (terminal side)

3rd harmonic calculation calculates the magnitude and phase angle of the third harmonic voltage at the generator terminal $\bar{U}_{3H_T}$. Calculation of the third harmonic voltage depends on the availability of terminal side voltage and is specified by the *Voltage selection* setting.

- *Voltage selection* setting is set to "No voltage" if phase-to-earth voltages are not available at the terminal side. Even in a situation where only phase-to-phase voltages are available, *Voltage selection* is set to "No Voltage" because phase-to-phase voltages do not contain a third harmonic component. With *Voltage*

selection set to "No Voltage", third harmonic-based earth-fault protection is based on third harmonic neutral side undervoltage protection.

- *Voltage selection* setting is set to "Measured Uo" if the third harmonic voltage is measured directly from an open-delta voltage connection of the voltage transformer or the third harmonic voltage is calculated using all three phase-to-earth voltages. If the terminal side voltage is fed from an open-delta voltage connection of the voltage transformer, the terminal side third harmonic voltage Û3H_T is the same as the measured open-delta voltage Û3H_RES.

$$\overline{U}_{3H_T} = \overline{U}_{3H_RES}$$

(Equation 77)

If all three phase-to-earth voltages are available, the terminal side third harmonic voltage is calculated as a vector average of the third harmonic voltages of all three phases.

$$\overline{U}_{3H_T} = \frac{1}{3} \times (\overline{U}_{3H_A} + \overline{U}_{3H_B} + \overline{U}_{3H_C})$$

(Equation 78)

- If only one phase-to-earth voltage is available, the *Voltage selection* setting is set to the respective phase, that is, "Phase A" or "Phase B" or "Phase C" based on the available phase. In this case, the magnitude of the terminal side third harmonic voltage is assumed to be equal to the third harmonic voltage of the phase available.

$$\overline{U}_{3H_T} = \overline{U}_{3H_A} \text{ or } \overline{U}_{3H_B} \text{ or } \overline{U}_{3H_C}$$

(Equation 79)

The function is internally blocked if the magnitude of calculated $\bar{U}_{3H_T}$ is lower than the set *Voltage block value*. This also activates the `INT_BLKD` output.

Differential calculation

The amplitude of the third harmonic differential voltage can be calculated using the following equation.

$$UD_{3H} = \left| \overline{U}_{3H_T} + \overline{U}_{3H_N} \right|$$

(Equation 80)

UD_{3H}	Magnitude of the third harmonic differential voltage
$\bar{U}_{3H_T}$	Terminal side third harmonic voltage phasor
$\bar{U}_{3H_N}$	Neutral side third harmonic voltage phasor

The magnitude of the third harmonic differential voltage `UD_3H` and the phase angle difference between the terminal side and neutral side third harmonic voltage `U_3HANGL_T_N` are available in the Monitored data view.

Bias calculation

The amplitude of the third harmonic bias voltage can be calculated using the following equation.

$$UB_{3H} = Beta \times \left| \bar{U}_{3H_N} \right|$$

(Equation 81)

UB_{3H}	Magnitude of the third harmonic bias voltage
Beta	Setting to achieve the required degree of security under healthy conditions
$\bar{U}_{3H_N}$	Neutral side third harmonic voltage phasor

The third harmonic bias voltage calculation shown in *Equation 81* is valid under all operating conditions if there is no generator circuit breaker between generator and transformer. But if the generator circuit breaker is used, it is needed to reduce the sensitivity of the protection when it is open. The use of the generator circuit breaker is defined by *Generator CB used* setting set to "Yes" and the open position is sensed when the binary input GCB_CLOSED available is FALSE.

With the generator breaker in the open position, function desensitizes the protection by multiplying the value of the *Beta* setting with the set constant *CB open factor* setting.

$$UB_{3H} = CB\ open\ factor \times Beta \times \left| \bar{U}_{3H_N} \right|$$

(Equation 82)

Neutral side third harmonic voltage is measured via a voltage transformer between the generator neutral point and the earth. The magnitude of the third harmonic biased voltage UB_3H is available in the Monitored data view.

Level detector

In the third harmonic differential method, Level detector compares the third harmonic differential voltage with the third harmonic bias voltage. If the differential voltage exceeds the biased voltage, the module sends an enabling signal to start the timer.

If the terminal voltage is not available, that is, *Voltage selection* is set to "No voltage" the module compares the neutral side third harmonic voltage U_3H_N to the set *Voltage N 3.H Lim*.

Timer

Once activated, Timer activates the START output. The Timer characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

Timer calculates the start duration START_DUR value, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates all outputs and resets internal timers.

4.2.8.6 Application

Mechanical and thermal stress deteriorates stator winding insulation, which can eventually cause an earth fault between the winding and stator core.

The fault current magnitude in case of stator earth fault depends on the grounding type. Common practice in most countries is to earth the generator neutral side through a resistor. The resistor is selected such as to limit the maximum earth-fault current in the range of 5...10 A. The same can be done by connecting a single phase voltage transformer between the neutral side and earth, and with an equivalent resistor on the secondary side of the transformer.

In a normal operating condition, that is, when there is no earth fault, the residual voltage is close to zero with no zero-sequence current flowing in the generator. When a phase-to-earth fault occurs, the residual voltage increases and the current flows through the neutral. The simplest way to protect the stator winding against an earth fault is by providing residual overvoltage protection (or residual/neutral overcurrent protection). However, at best these simple schemes can protect only 95% of the stator winding, leaving 5% of the neutral end unprotected. This is because the voltage generated in the faulted winding decreases as the fault point becomes closer to the neutral point and it is not enough to drive the protection. Under certain unfavorable conditions, the blind zone may extend up to 20% from the neutral point.

An earth fault close to the neutral point is not dangerous, but an undetected fault may develop into an interturn fault or phase-to-phase fault. Also an undetected earth fault near the neutral point is bypassing the high-impedance grounding, and then another earth fault at the terminal results in a catastrophic situation.

Therefore, it is important to extend the protection to full 100%. The third harmonic voltage-based protection is one such protection which provides effective protection during an earth fault at the neutral point, and at least in the range up to 15...20% from the neutral point along the stator winding.

To achieve a complete stator earth-fault protection, two protection functions should always run in parallel.

- Fundamental frequency-based residual overvoltage protection ROVPTOV
- Third harmonic-based stator earth-fault protection H3EFPSEF

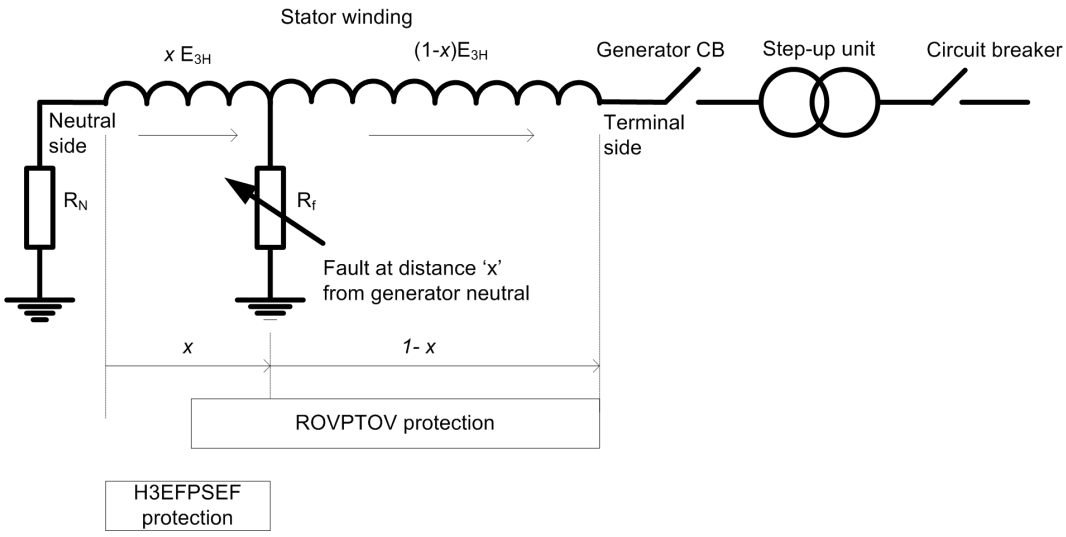

Figure 314: Complete stator earth-fault protection

Third harmonic voltage-based differential protection

The voltage generated by a generator is not a perfect sinusoidal wave but contains triplen harmonics voltages. These triplen harmonics appear in each phase with the same magnitude and angle, due to which they do not sum to zero and thus also appear in the neutral side of the generator as a zero-sequence quantity. Among all the triplen harmonics voltages generated, the third harmonic voltage has the highest magnitude with the magnitude varying between 1% and 10% of the terminal voltage, depending on the generator design philosophy. However, for a particular generator the magnitude of third harmonics on the neutral side and terminal side depends also on the active power generated.

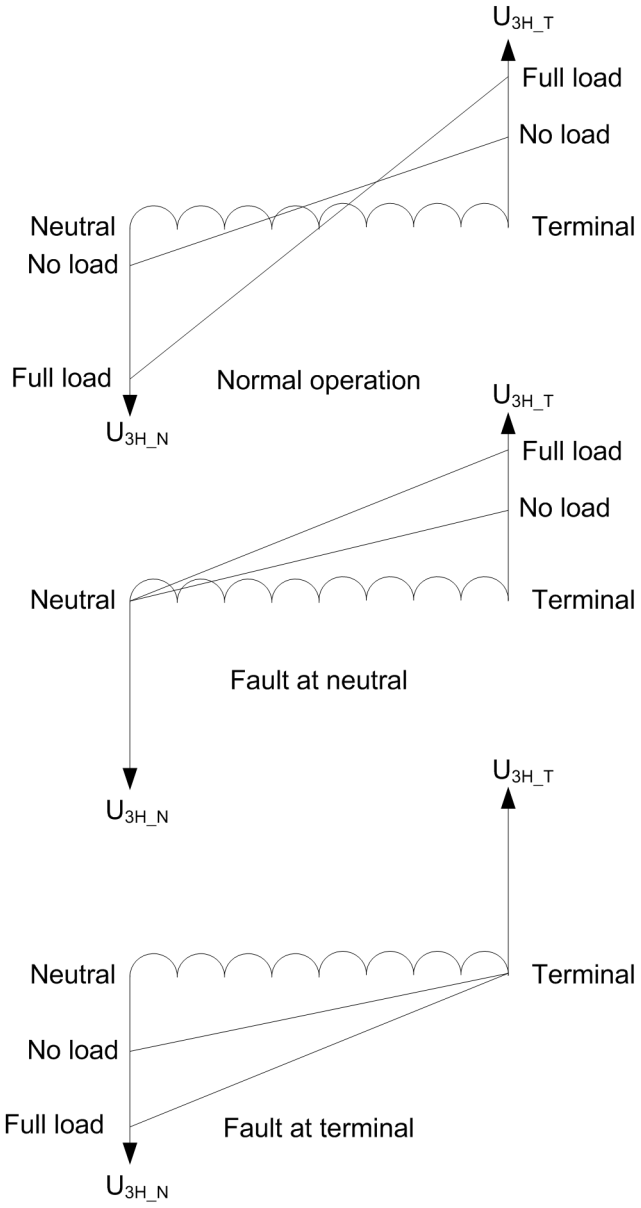

Figure 315: Typical example of the third-harmonic voltage measured at the generator neutral and terminals under different conditions

The operating equation of the protection is described in the following equation.

$$\left|\bar{U}_{3H_T} + \bar{U}_{3H_N}\right| - Beta \times \left|\bar{U}_{3H_N}\right| = 0$$

(Equation 83)

The third harmonic voltages $\bar{U}_{3H_T}$ and $\bar{U}_{3H_N}$ are the phasor with its real and imaginary parts. $\bar{U}_{3H_T}$ is approximately in the opposite direction to that of the $\bar{U}_{3H_N}$, however the actual no-fault angle between those two phasors depends on the type of generator earthing. For example, the angle is about 145 degrees for a high-resistance-earthed unit generator.

The equation defines the "operate" and "restrain" regions of the protection. The third harmonic differential protection operates according to the following equation.

$$\left|\bar{U}_{3H_T} + \bar{U}_{3H_N}\right| \geq Beta \times \left|\bar{U}_{3H_N}\right|$$

(Equation 84)

$\bar{U}_{3H_N}$	Neutral side third harmonic voltage phasor
$\bar{U}_{3H_T}$	Terminal side third harmonic voltage phasor
Beta	Setting to achieve a required degree of security under healthy conditions
$\lvert\bar{U}_{3H_T}+\bar{U}_{3H_N}\rvert$	Magnitude of the third harmonic differential voltage
$Beta \cdot \lvert\bar{U}_{3H_N}\rvert$	Magnitude of the third harmonic bias (restrain) voltage

Factor *Beta*, which is a setting, can be determined from the condition.

$$\frac{Beta \times \left|\bar{U}_{3H_N}\right|}{\left|\bar{U}_{3H_T} + \bar{U}_{3H_N}\right|} = K$$

(Equation 85)

K is the security factor, for example K = 1.5. *Equation 85* must be satisfied in the normal, healthy condition of the protected generator, with a high enough value for K, so that no unwanted operation of the protection should be expected, regardless the load on the generator.

To assure a reliable functioning of the protection, it is necessary that the generator produces third harmonic voltage which is at least 1% of the generator rated voltage.

As phase-to-phase voltages do not contain a third harmonic component, in situations where the VTs on the terminal side are connected between phase-to-phase, the differential protection in *Equation 85* cannot work. In such case, the *Voltage selection* setting is set to "No Voltage" and H3EFPSEF operates as a simple neutral side third harmonic undervoltage protection.

When H3EFPSEF is reduced to function as only a third harmonic neutral point undervoltage protection, it is necessary to block the function during start-up and shutdown of generator and also when there is no sufficient voltage.

Calculating Beta value

The setting *Beta* gives the proportion of the third harmonic voltage in the neutral point of the generator to be used as bias quantity. *Beta* must be set so that there

is no risk of trip during the normal, non-faulted operation of the generator. If *Beta* is set high, this limits the portion of the stator winding covered by the protection. In most cases, the default setting “3.00” gives an acceptable sensitivity for an earth fault near the neutral point of the stator winding. However, to assure the best performance, measurements during the normal operation of the generator are to be made during commissioning.

1. The value of the *Beta* setting must be set to “1.00”.
2. Loading of the generator is done at 5 to 10 different load points and the third harmonic differential and bias voltage are measured. Both quantities can be obtained from the Monitored data view of the function.
3. A graph indicating differential and bias voltages as a functions of the load on the generator must be plotted.
4. Based on the graph, such value of the *Beta* setting must be selected that the bias voltage, even in the worst condition, is at least 30% to 50% higher than the differential voltage.

The angle between the third harmonic voltage phasors $\bar{U}_{3H_T}$ and $\bar{U}_{3H_N}$ is 150°, and with the *Beta* setting value "1.0", protection guarantees a stability margin of 25%. This requires the value of *Beta* to be increased so as to increase the stability of protection. The recommended value of the *Beta* setting is at least “1.2”.

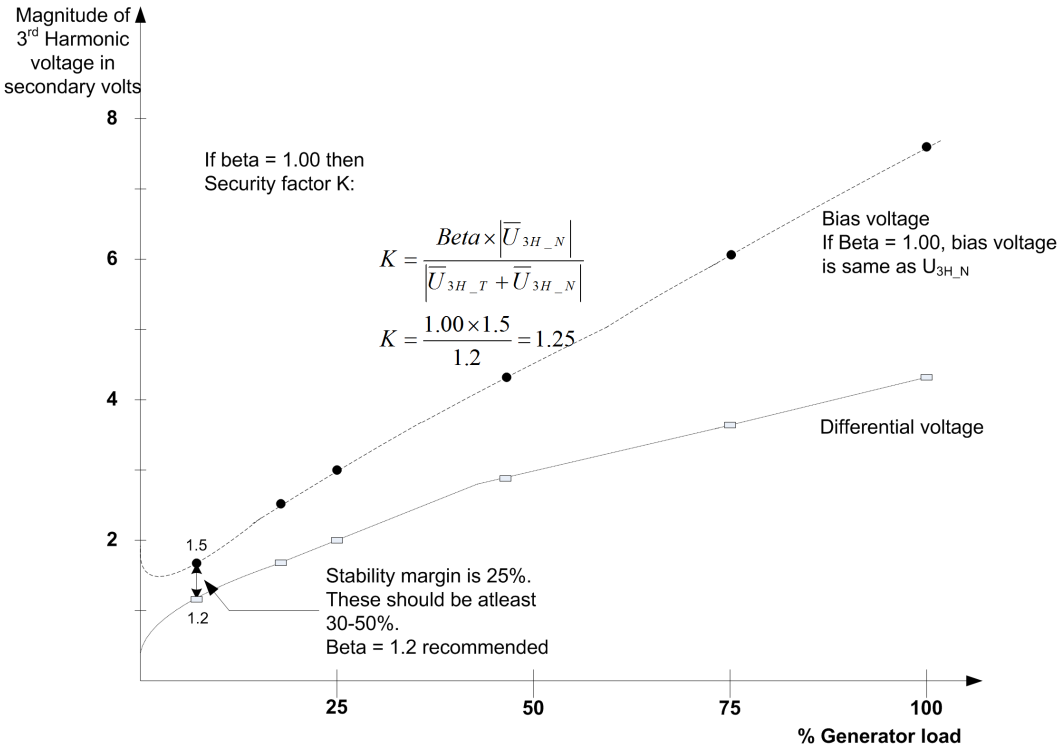

Figure 316: Typical example of variation of the bias voltage and differential voltage with a change in the active generated load (the angle between the third harmonic terminal and neutral voltage is 150°)

Calculating CB Open factor

One of the factors, though not major, governing the magnitude of the generated third harmonic voltage is the generator terminal capacitance. If there is no generator breaker, the capacitive coupling to earth is the same under all operating

conditions. However, the generator breaker normally exists between the protected generator and its power transformer.

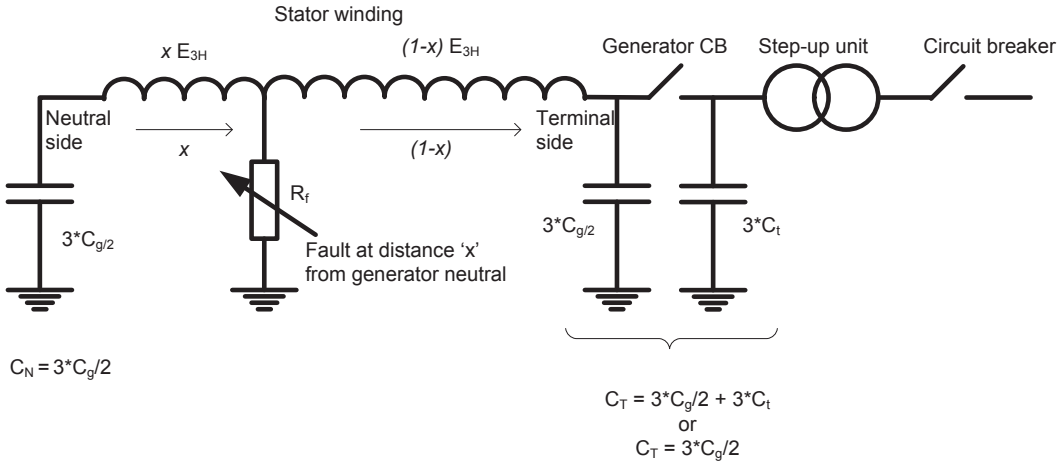

Figure 317: Capacitance seen at generator terminal and neutral side

C_g	Phase capacitance of generator stator winding
C_t	Total external phase capacitance of the system as seen from the generator
C_N	Phase-to-ground lumped capacitance of the generator stator winding, between the earth-fault location and the generator neutral
C_T	Phase-to-ground lumped capacitance of the generator stator winding, between the generator terminal and earth-fault location

When there is a generator breaker, the capacitive coupling to earth differs between the operating conditions when the generator is running with the generator breaker open (before synchronization) and with the circuit breaker closed.

With the generator breaker open, the total capacitance is smaller compared to normal operating conditions. This means that the neutral side third harmonic voltage is reduced compared to the normal operating condition. Therefore, there is a need to reduce the sensitivity of the protection. When generator breaker is open, H3EFPSEF desensitizes the protection by multiplying the *Beta* setting with a set constant *CB open factor* setting.

$$\left|\overline{U}_{3H_T} + \overline{U}_{3H_N}\right| \geq \text{CB open factor} \times \text{Beta} \times \left|\overline{U}_{3H_N}\right|$$

(Equation 86)

The *CB Open factor* setting is obtained during commissioning.

1. For a particular value of *Beta* the third harmonic neutral voltage is measured with the generator in the no-load condition and the circuit breaker in the closed position.
2. With the same condition, the third harmonic neutral voltage with the circuit breaker in the open position is measured.
3. *CB Open factor* should be set equal to the ratio of the third harmonic neutral voltage measured with the circuit breaker in the closed position to that in the open.

Multifrequency admittance-based earth-fault protection	MFADPSDE	Io> ->Y	67NYH

4.2.9.2 Function block

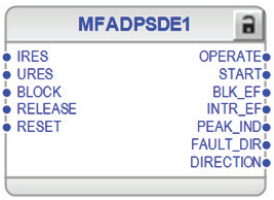

Figure 318: Function block

4.2.9.3 Functionality

The multifrequency admittance-based earth-fault protection function MFADPSDE provides selective directional earth-fault protection for high-impedance earthed networks, that is, for compensated, unearthed and high-resistance earthed systems. It can be applied for the earth-fault protection of overhead lines and underground cables, regardless of the earth-fault type (continuous, transient or

[1] f_n = 50 Hz, results based on statistical distribution of 1000 measurements
[2] Includes the delay of the signal output contact

intermittent) or the fault resistance value (low or high ohmic). MFADPSDE replaces traditional sensitive directional earth-fault protection (such as Iocos) and transient earth-fault protection (such as Wischer principle) combining the same functionality into a single function block (see *Table 612*).

Table 612: Comparison of the MFADPSDE functionality with traditional methods in resonant earthed networks

	Earth-fault type				
	Transient	**Continuous**	**Restriking/ Intermittent**	**Low-ohmic**	**High-ohmic**
Traditional Iocos		x		x	x
Traditional Wischer	x		x	x	
MFADPSDE	x	x	x	x	x

As shown by numerous practical field tests, MFADPSDE provides better sensitivity and selectivity compared with traditional methods with less complexity in settings and configuration. MFADPSDE provides enhanced earth-fault protection performance, especially in networks with cable feeders where distributed compensation coils are applied and the earth-fault type is typically intermittent. It is applicable in feeders with distributed compensation regardless of the size or localization of distributed coils. Selective protection can be achieved also in case of overcompensated feeders.

The neutral point in compensated networks is earthed via a controllable centralized arc suppression coil located typically in the primary substation. Additionally, (fixed) distributed compensation coils can be used, which are installed in relevant locations along the protected feeders.

In unearthed networks, the neutral point in the primary substation is not connected to earth. However, in unearthed networks (fixed) distributed compensation coils can also be used to compensate a part of the total capacitive earth-fault current. Typically, the resulting compensation degree is less than 50 percent. Thus, unearthed networks with or without distributed compensation coils are generally referred to as unearthed networks in this manual.

MFADPSDE operation is based on multifrequency neutral admittance measurement using the cumulative phasor summing technique. This concept provides extremely secure, dependable and selective earth-fault protection also when the residual quantities are highly distorted and contain non-fundamental frequency components.

The sensitivity that can be achieved is comparable with traditional fundamental frequency based methods such as IoCos/IoSin (DEFxPTOC), Watt/Varmetric (WPWDE) and neutral admittance (EFPADM).

MFADPSDE can detect faults with dominantly fundamental frequency content as well as transient, intermittent and restriking earth faults. The function can be used as an alternative solution to transient or intermittent function INTRPTEF.

MFADPSDE supports fault direction indication both in operate and in non-operate direction, which can be used during fault location process. The in-built transient detector can be used to identify restriking or intermittent earth faults, and discriminate them from permanent or continuous earth faults.

The operation characteristic is defined by a tilted operation sector, which is universally valid for unearthed and compensated networks.

The operating time characteristic is according to the definite time (DT).

MFADPSDE contains a blocking functionality to block function outputs, timers or the function itself.

4.2.9.4 Analog channel configuration

MFADPSDE has two analog group inputs which must be properly configured.

Table 613: Analog inputs

Input	Description
IRES	Residual current (measured or calculated)
URES	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 614: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected for calculating the residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.9.5 Operation principle

The *Operation* setting is used to enable or disable the function. The corresponding parameter values are "on" and "off".

The operation of MFADPSDE can be described using a module diagram. All the modules in the diagram are explained in the following sections.

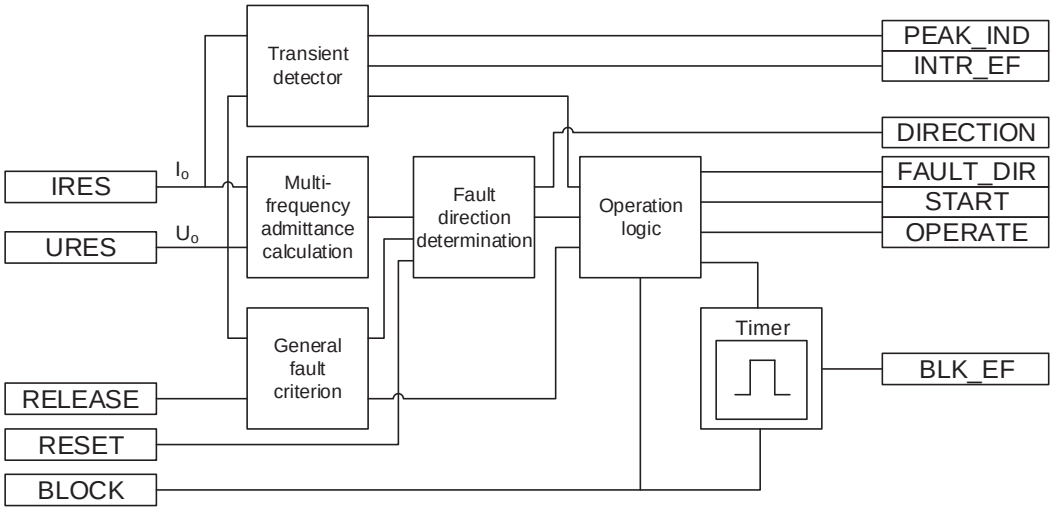

Figure 319: Functional module diagram

General fault criterion

The General fault criterion (GFC) module monitors the presence of earth faults in the network and it is based on the value of the fundamental frequency zero-sequence voltage defined as the vector sum of fundamental frequency phase voltage phasors divided by three.

$$\overline{U_0^1} = \frac{\left(\overline{U_A^1} + \overline{U_B^1} + \overline{U_C^1}\right)}{3}$$

(Equation 87)

MFADPSDE supports zero-sequence voltage monitoring based on measurement (from open-delta winding) or calculated (derived from phase-to-earth voltages).

When the magnitude of $\overline{U_o^1}$ exceeds setting *Voltage start value*, an earth fault is detected. The GFC module reports the exceeded value to the Fault direction determination module and Operation logic. The reporting is referenced as General Fault Criterion release.

The setting *Voltage start value* defines the basic sensitivity of MFADPSDE. To avoid unselective start or operation, *Voltage start value* must always be set above the maximum healthy-state zero-sequence voltage value, considering network topology changes, compensation coil and parallel resistor switching status and compensation degree variations. The setting *Voltage start value* can be easily selected based on the resonance curve calculated by the coil controller in corresponding network conditions (see *Figure 320*).

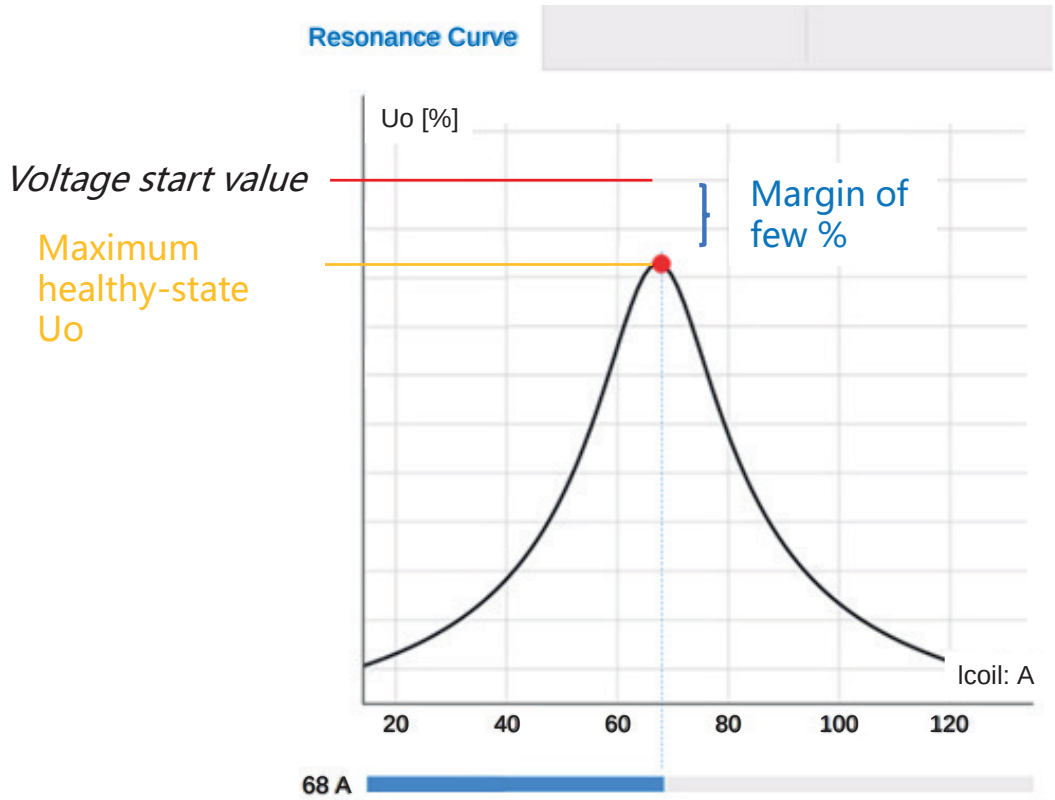

Figure 320: Example of selection of setting Voltage start value to maximize the earth-fault detection sensitivity based on the resonance curve calculated by the coil controller

There are three MFADPSDE instances (stages) available. The sensitivity of different stages should be selected differently. For example, stage 1 could have the highest *Voltage start value* and the shortest *Operate delay time*. Thus it would fulfill the requirements for protection operation speed by providing fast operation for low-ohmic earth faults. Stage 2 should have lower *Voltage start value* and longer *Operate delay time* compared with stage 1. This stage would fulfill the requirements for protection sensitivity (in terms of fault resistance value). Stage 3 could be used to detect high-ohmic earth faults and generate alarms for them. To maximize the earth-fault detection sensitivity of stage 3, *Voltage start value* should be selected based on the network's resonance curve (see *Figure 320*).

Such coordination of different protection stages enables:

- Indication (but no tripping) of transient, self-extinguishing earth faults, where the zero-sequence voltage may temporarily rise to a high value and then decay slowly away. This can be achieved by monitoring the START outputs. Delayed operation times of stages 1 and 2 avoid unnecessary breaker operations during self-extinguishing earth faults.
- Fast tripping of low-ohmic permanent earth faults regardless of their type (continuous or intermittent), stage 1
- Delayed tripping of higher-ohmic permanent earth faults regardless of their type (continuous or intermittent), stage 2

- Alarms (but no tripping) about high-ohmic earth faults in order to monitor the insulation status of the network and provide early indication of evolving faults before they cause tripping (by stages 1 or 2), stage 3.

Besides the internal start condition based on residual zero-sequence overvoltage, MFADPSDE can also be externally released by using the RELEASE input. In this case, the external release signal overrides the *Voltage start value* setting and sets the internal limit to the minimum value.

Multi-frequency admittance calculation

The Multi-frequency admittance calculation module calculates neutral admittances using fundamental frequency and the 2nd, 3rd, 5th, 7th and 9th harmonic components of residual current and zero-sequence voltage. The fundamental frequency admittance (conductance and susceptance) is calculated if the magnitude of a harmonic in residual current and zero-sequence voltage is measurable by the relay.

$$\overline{Y_0^1} = \frac{3 \cdot \overline{I_0^1}}{-\overline{U_0^1}} = G_o^1 + j \cdot B_o^1$$

(Equation 88)

$\overline{Y_0^1}$ Fundamental frequency neutral admittance phasor

$\overline{I_0^1}$ Fundamental frequency zero-sequence current phasor $(= \frac{(\overline{I_A^1} + \overline{I_B^1} + \overline{I_C^1})}{3})$

$\overline{U_0^1}$ Fundamental frequency zero-sequence voltage phasor $(= \frac{(\overline{U_A^1} + \overline{U_B^1} + \overline{U_C^1})}{3})$

G_o^1 Fundamental frequency conductance, $\mathrm{Re}\left(\overline{Y_0^1}\right)$

B_o^1 Fundamental frequency susceptance, $\mathrm{Im}\left(\overline{Y_0^1}\right)$

$$\mathrm{Im}\left[\overline{Y_0^n}\right] = \mathrm{Im}\left[\frac{3 \cdot \overline{I_0^n}}{-\overline{U_0^n}}\right] = j \cdot B_o^n$$

(Equation 89)

where n = 2, 3, 5, 7 and 9

$\overline{Y_0^n}$ nth harmonic frequency neutral admittance phasor

$\overline{I_0^n}$ nth harmonic frequency zero-sequence current phasor

Table continues on the next page

$\overline{U_0^n}$ nth harmonic frequency zero-sequence voltage phasor

B_o^n nth harmonic frequency susceptance, $\mathrm{Im}\left(\overline{Y_0^n}\right)$

For fault direction determination, the fundamental frequency admittance and harmonic susceptances are summed together in phasor format. The result is the sum admittance phasor defined as

$$\overline{Y}_{osum} = \mathrm{Re}\left[\overline{Y_0^1}\right] + j \cdot \mathrm{Im}\left[\overline{Y_0^1} + \sum_{n=2}^{9} \overline{Y_0^n}\right] = G_o^1 + j \cdot B_{osum}$$

(Equation 90)

The polarity of the polarizing quantity (residual voltage) can be changed (rotated by 180 degrees) by setting the *Pol reversal* parameter to "True" or by switching the polarity of the residual voltage measurement wires.

Fault direction determination

If an earth fault is detected by the GFC module, the fault direction is evaluated based on the calculated sum admittance phasor $\overline{Y}_{osum}$ obtained from the Multi-frequency admittance calculation module. To obtain dependable and secure fault direction determination regardless of the fault type (transient, intermittent, restriking, permanent, high or low ohmic), the fault direction is calculated using a special filtering algorithm, Cumulative Phasor Summing (CPS) technique. This filtering method is advantageous during transient, intermittent and restriking earth faults with dominantly non-sinusoidal or transient content. It is equally valid during continuous (stable) earth faults.

The concept of CPS is illustrated in *Figure 321*. It is the result of adding the values of the measured sum admittance phasors together in phasor format in chronological order during the fault. Using the discrete sum admittance phasors $\overline{Y}_{osum}$ in different time instants (t_1...t_5), the corresponding accumulated sum admittance phasor $\overline{Y}_{osum_CPS}$ is calculated. This phasor is used as directional phasor in determining the direction of the fault.

$$\overline{Y}_{osum_CPS}(t_1) = \overline{Y}_{osum}(t_1)$$

(Equation 91)

$$\overline{Y}_{osum_CPS}(t_2) = \overline{Y}_{osum}(t_1) + \overline{Y}_{osum}(t_2)$$

(Equation 92)

$$\overline{Y}_{osum_CPS}(t_3) = \overline{Y}_{osum}(t_1) + \overline{Y}_{osum}(t_2) + \overline{Y}_{osum}(t_3)$$

(Equation 93)

$$\overline{Y}_{osum_CPS}(t_4) = \overline{Y}_{osum}(t_1) + \overline{Y}_{osum}(t_2) + \overline{Y}_{osum}(t_3) + \overline{Y}_{osum}(t_4)$$

(Equation 94)

$$\overline{Y}_{osum_CPS}(t_5) = \overline{Y}_{osum}(t_1) + \overline{Y}_{osum}(t_2) + \overline{Y}_{osum}(t_3) + \overline{Y}_{osum}(t_4) + \overline{Y}_{osum}(t_5)$$

(Equation 95)

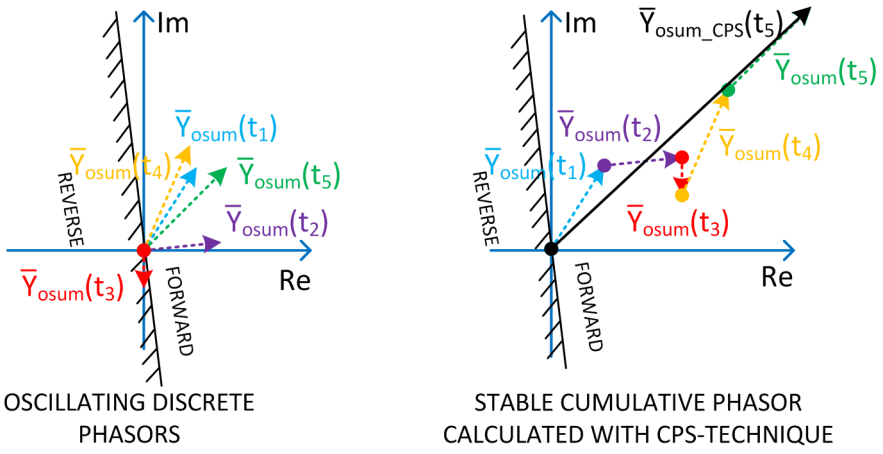

Figure 321: Principle of Cumulative Phasor Summing (CPS)

The CPS technique provides a stable directional phasor quantity despite individual phasors varying in magnitude and phase angle in time due to an unstable fault type such as a restriking or intermittent earth fault. This is also true for harmonic components included in the sum admittance phasor. Harmonics typically have a highly fluctuating character.

Harmonic components provide a more distinctive directional determination in compensated networks than the fundamental frequency component. With higher frequencies, the compensation coil appears as very high impedance and the harmonics are not affected by compensation coil and degree of compensation. When harmonics are present, they cause the sum admittance phasor to behave as in case of an unearthed network, where directional phasors point in opposite directions in the faulty and healthy feeder.

The direction of MFADPSDE is defined with setting *Directional mode* as "Forward" or "Reverse". The operation characteristic is defined by a tilted operation sector as illustrated in *Figure 322*. The characteristic provides universal applicability, that is, it is valid in both compensated and unearthed networks even if the compensation coil is temporarily switched off. The tilt of the operation sector is defined with setting *Tilt angle* to compensate the measurement errors of residual current and voltage transformers. The typical setting value of 5 degrees is recommended, but it should always reflect the maximum expected measurement errors.

In case of unearthed network operation, adequate tilt angle must be allowed to ensure dependable operation of MFADPSDE.

In *Figure 322*, phasors 1...4 demonstrate the behavior of the directional phasor in different network fault conditions.

- Phasor 1 depicts the direction of the accumulated sum admittance phasor in case of earth fault outside the protected feeder (assuming that the admittance of the protected feeder is dominantly capacitive). The result is valid regardless of the fault type (low ohmic, high(er) ohmic, permanent, intermittent or restriking). If harmonic components are present in the fault quantities, they turn the phasor alignment to the negative Im(Yo) axis.
- Phasor 2 depicts the direction of accumulated sum admittance phasor in case of earth fault inside the protected feeder when the network is unearthed. The result is also valid in compensated networks when there are harmonic components in the fault quantities (typically low-ohmic permanent, intermittent or restriking fault). In this case, the result is valid regardless of network's actual compensation degree. Harmonics would turn the phasor align to the positive Im(Yo) axis.
- Phasors 3 and 4 depict the direction of accumulated sum admittance phasor in case of higher-ohmic earth fault in the protected feeder without harmonics in the fault quantities when the network is compensated. As no harmonic components are present, the phase angle of the accumulated phasor is determined by the compensation degree of the network. With a high degree of overcompensation, the phasor turns towards the negative Im(Yo) axis (as phasor 4).

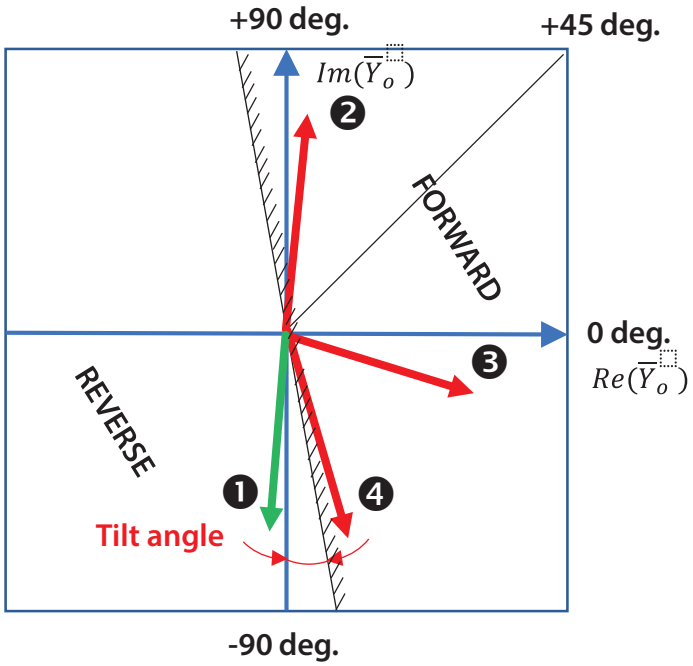

Figure 322: Directional characteristic of MFADPSDE

The residual current should be measured with accurate Core Balance Current Transformer (CBCT) to minimize the measurement errors, especially phase displacement. This is especially important when high sensitivity of protection is targeted.

The characteristic *Tilt angle* should reflect the measurement errors, that is, the larger the measurement errors, the higher the *Tilt angle* setting should be. A typical setting value of 5 degrees is recommended.

The maximum value for characteristic *Tilt angle* depends on the ratio of the resistive and reactive component in the measured residual current Io. The operation point moves away from the operation sector mid-point; the lower is the ratio of the resistive and reactive component in the

measured residual current Io. The phase angle of operation point in the faulted feeder can be approximated with equation

$$\varphi = atan\left(\frac{I_{EFFd} + I_{detuning}}{I_{damping}}\right)$$

(Equation 96)

I_{EFFd}	Earth-fault current produced by the protected feeder [A]
$I_{detuning}$	Detuning of the arc suppression coil [A]
$I_{damping}$	System damping [A]

Example 1:

I_{EFFd} = 30 A, $I_{detuning}$ = +10 A and $I_{damping}$ = 10 A. From *Equation 96*, j = 76 deg. Thus *Tilt angle* should not exceed ~10 deg.

Example 2:

I_{EFFd} = 50 A, $I_{detuning}$ = +10 A and $I_{damping}$ = 5 A. From *Equation 96*, j = 85 deg. Thus *Tilt angle* should not exceed ~3 deg. However, such a low Tilt angle setting may endanger the security of protection due to measurement errors of the CBCTs. In this case, the phase angle of operation point should be increased by considering:

1. System damping increase by increasing the current value of the parallel resistor of the coil.
2. Reduction of the earth-fault current produced by the protected feeder by, for example, installation of distributed compensation coils or by change of the feeder topology.
3. Reduction of overcompensation of the network. The recommendation is to use the undercompensation mode.

The DIRECTION output indicates on which operating sector the current is measured. The FAULT_DIR output indicates in which operation sector the fault current is measured. The output is operational once the function is started.

To adapt the fault direction determination to possible fault direction change during the fault, for example, during manual fault location process, a cyclic accumulation of sum admittance phasors is conducted. The duration of this directional evaluation cycle is 1.2 · *Reset delay time* (minimum of 600 ms). If the fault direction based on the cyclic phasor accumulation is opposite to the function direction output for *Reset delay time* or 500 ms (minimum of 500 ms), the function is reset and fault direction calculation of MFADPSDE is restarted.

If the earth-fault protection generates alarms, MFADPSDE also includes a RESET input which can be used to externally re-trigger the fault direction determination if reevaluation of fault direction during a persistent earth fault is required.

It is also recommended to connect the start signal of non-directional earth fault protection (EFxPTOC), set to operate in case of a cross-country fault, to RESET input or BLOCK input of MFADPSDE to reset phasor accumulation during a cross-country fault. MFADPSDE can then adapt to a fault direction change more rapidly if a singlephase earth fault persists in the system after the other faulty feeder has been tripped (the cross-country fault has been transformed into a single-phase earth fault).

The direction of MFADPSDE is supervised by a settable current magnitude threshold, setting *Min operate current*. The operate current used in the magnitude supervision is measured with a special filtering method, which provides a stable

residual current estimate regardless of the fault type. This estimate is the result of the fundamental frequency admittance calculation using the CPS technique. The stabilized current value is obtained (after conversion) from the corresponding admittance value by multiplying it by the system nominal phase-to-earth voltage value. The equations for calculating the stabilized values of the fundamental frequency admittance and the corresponding current are given below.

$$\overline{Y^1_{o\ stab}} = \frac{3 \cdot \overline{I^1_{0\,CPS}}}{-\overline{U^1_{0\,CPS}}} = \mathrm{Re}\left[\overline{Y^1_{o\ stab}}\right] + j \cdot \mathrm{Im}\left[\overline{Y^1_{o\ stab}}\right] = G^1_{ostab} + j \cdot B^1_{ostab}$$

(Equation 97)

$\overline{Y^1_{o\ stab}}$ Stabilized fundamental frequency admittance estimate, which is result from fundamental frequency admittance calculation utilizing the Cumulative Phasor Summing (CPS) technique.

$\overline{I^1_{0\,CPS}}$ Fundamental frequency zero-sequence current phasor calculated utilizing the Cumulative Phasor Summing (CPS) technique.

$\overline{U^1_{0\,CPS}}$ Fundamental frequency zero-sequence voltage phasor calculated utilizing the Cumulative Phasor Summing (CPS) technique.

G^1_{ostab} Real-part of stabilized fundamental frequency conductance estimate.

B^1_{ostab} Imaginary part of stabilized fundamental frequency susceptance estimate.

$$\overline{I^1_{o\ stab}} = (G^1_{ostab} + j \cdot B^1_{ostab}) \cdot U_{baseres} = I^1_{oCosstab} + j \cdot I^1_{oSinstab}$$

(Equation 98)

$\overline{I^1_{o\ stab}}$ Stabilized fundamental frequency residual current estimate, which is obtained (after conversion) from the corresponding admittance value by multiplying it with the system nominal phase-to-earth voltage value.

$\overline{I^1_{o\ Cosstab}}$ Real-part of stabilized fundamental frequency residual current estimate.

$\overline{I^1_{o\ Sinstab}}$ Imaginary part of stabilized fundamental frequency residual current estimate.

$U_{baseres}$ System nominal phase-to-earth voltage value.

The main advantage of the filtering method is that due to the admittance calculation, the resulting current value does not depend on the fault resistance value, that is, the estimated current magnitude equals the value that is measured during a solid earth fault (Rf = 0 Ω). Another advantage of the method is that it can estimate correct current magnitude also during intermittent or restriking faults.

The setting *Min operate current* defines the minimum operate current which must be exceeded for the function to start or operate.

Setting *Operating quantity* defines whether the current magnitude supervision is based on the “Adaptive”, “Amplitude” or “Resistive” methods.

Table 615: Comparison of Operating quantity of MFADPSDE with traditional methods

Traditional method	Setting Operating quantity of MFADPSDE		
	Adaptive	Amplitude	Resistive
Iosin		x	
Iocos			x
Iosin/Iocos	x		

When Operating quantity is set to "Adaptive", the method adapts the principle of current magnitude supervision to the system earthing condition. This is done by monitoring the phase angle of accumulated sum admittance phasor, (see *Figure 323*).

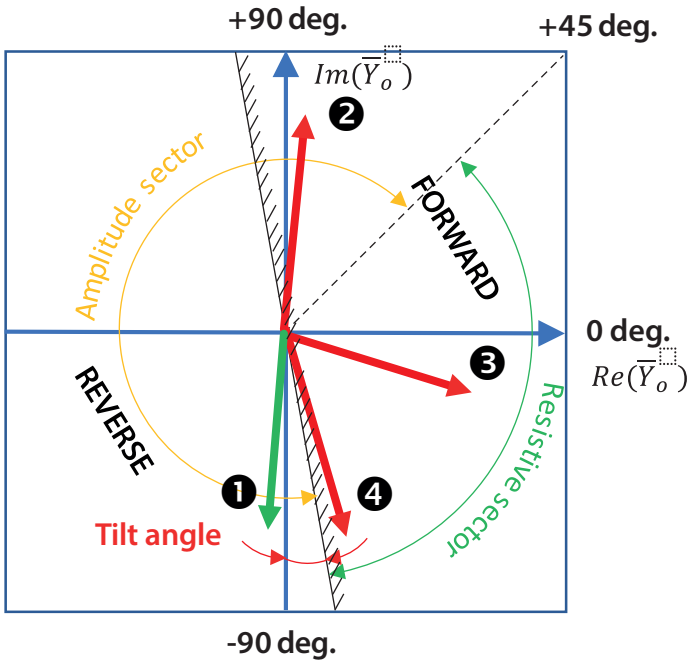

Figure 323: Automatic adaptation of current magnitude supervision condition (setting Min operate current) to either resistive part or amplitude of I1 ostab based on the phase angle of accumulated sum admittance phasor, when setting Operating quantity = “Adaptive”. Directional mode = “Forward”

If the phase angle of accumulated sum admittance phasor is greater than 45 degrees, current magnitude supervision is based on the amplitude of $\overline{I^1_{o\,stab}}$, which must exceed the set minimum operate current threshold. If the phase angle of accumulated sum admittance phasor is below 45 degrees, current magnitude supervision is based on the resistive part of $\overline{I^1_{o\,stab}}$, which must exceed the set minimum operate current threshold. This automatic adaptation of the magnitude supervision condition enables secure and dependable directional determination in compensated networks, and it is also valid when the network is unearthed (compensation coil is switched off).

If operation direction is set to reverse, the resistive and amplitude sectors are mirrored in the operation characteristics.

Setting *Operating quantity* should be set to "Adaptive" in resonant earthed systems, except when protected feeders are overcompensated by distributed coils. In such a case, *Operating quantity* should be set to "Resistive".

Setting *Operating quantity* to "Adaptive" enables secure and dependable directional determination in compensated networks, which is also valid when the compensation coil is switched off and the network becomes unearthed. In case of an unearthed network, *Min operate current* is automatically compared to the amplitude of $\overline{I^{1}_{o\ stab}}$. In case of restriking earth-faults, harmonics created by the fault type make the accumulated sum admittance phasor behave as in case of an unearthed network. Therefore, operation can be achieved without the need for resistive part of $\overline{I^{1}_{o\ stab}}$. This also means that in compensated networks during earth faults with rich harmonic content in residual quantities, operation can be achieved without the parallel resistor of the centralized compensation coil.

When *Operating quantity* is set to "Resistive", the set minimum operate current threshold (setting Min operate current) is compared to the resistive component of $\overline{I^{1}_{o\ stab}}$ in the whole defined operate sector (see *Figure 324*).

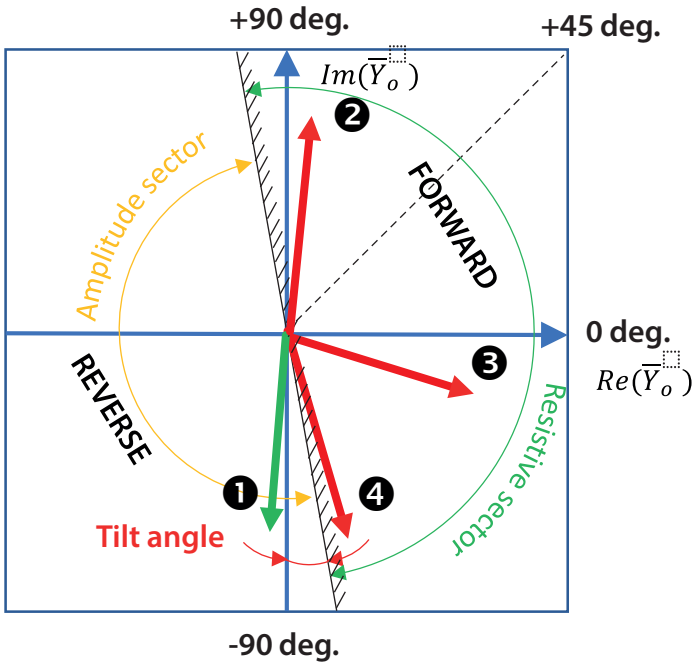

Figure 324: Operating quantity = "Resistive" and Directional mode = "Forward"

The resistive mode is valid for resonant earthed networks and high-resistance earthed systems, but not in case of unearthed networks. The resistive mode must be selected when there is a risk of local overcompensation of a protected feeder, that is, when the earth-fault current is compensated with distributed compensation coils and their inductive current exceeds the amount of capacitive current produced by the phase-to-earth capacitances of the feeder.

In compensated networks, where distributed compensation coils are also used to compensate earth-fault current, setting *Operating quantity* should be set to "Resistive". This enables secure and dependable directional determination also in case of local overcompensation where the earth-fault current produced by the healthy feeder can become inductive.

When *Operating quantity* is set to "Amplitude", the set minimum operate current threshold (setting *Min operate current*) is compared to the amplitude of $\overline{I}^{1}_{o\ stab}$ in the whole defined operate sector (see *Figure 325*). This selection can be used in unearthed networks.

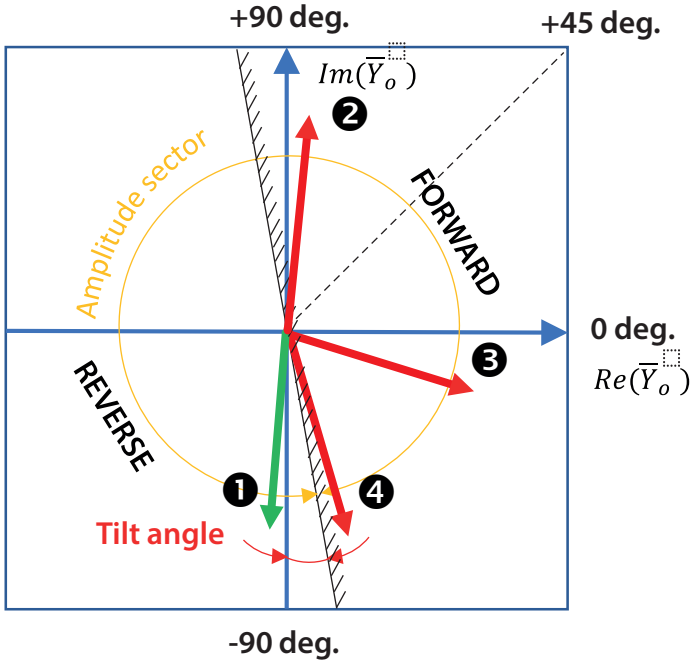

Figure 325: Operating quantity = "Amplitude" and Directional mode = "Forward"

If the “Adaptive” or “Resistive” operating quantity is selected, the setting *Min operate current* should be set to value:

$$[pu] < p \cdot IRtot$$

(Equation 99)

[pu]	Min operate current
IRtot	Total resistive earth-fault current of the network corresponding to the resistive current of the parallel resistor of the coil and the natural losses of the system (typically in order of 1...5 % of the total capacitive earth-fault current of the network).
p	security factor = 0.5…0.7

It must be set to a value which is lower than the total resistive earth-fault current in order to enable dependable operation.

Estimation of the total resistive earth-fault current of the network including the parallel resistor of the coil and the network losses can be obtained from the

network calculation results of the coil controller in resonant earthed networks. In Petersen coil controller, this value is denoted as 'I_DAMPING' [A]. When evaluating this numerical value, the connection status of the parallel resistor of the coil must be considered. See the example in *Figure 326*. In this case, the parallel resistor of the coil has value 8.6 A and it is permanently connected. The total system damping is calculated as 11.29 A. Thus the natural network losses including the losses of the coil are 11.29 A - 8.6 A = 2.69 A.

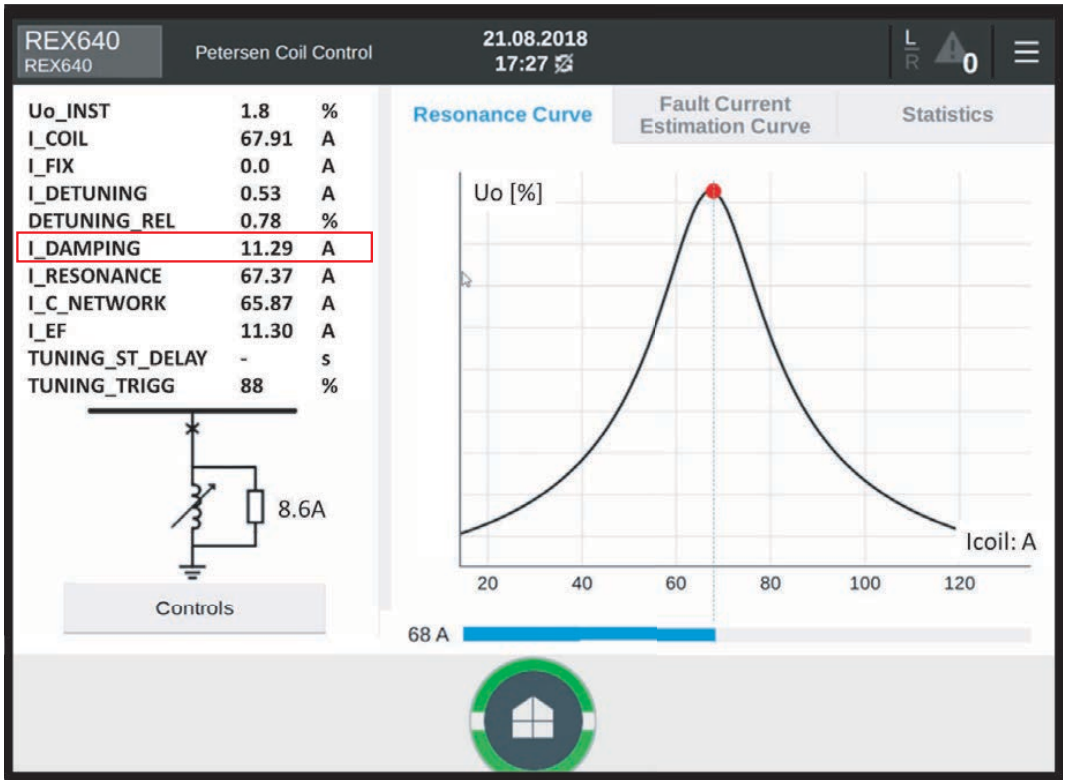

Figure 326: Example of interpretation of network damping value, I_DAMPING, calculated by the coil controller

For example, if the resistive current of the parallel resistor is 10 A (at primary voltage level), then a value of 0.5 · 10 A = 5 A could be used for setting *Min operate current*.

The network damping value, I_DAMPING, calculated by the coil controller can be used as a base for setting *Min operate current*.

If *Operating quantity* is set to "Adaptive", the setting value *Min operate current* is also applicable if the coil is disconnected and the network becomes unearthed. In this case, the current magnitude supervision is automatically based on the amplitude of $\overline{I^{1}_{o\,stab}}$). The selected setting value must never exceed the ampere value of the parallel resistor in order to allow operation in the faulty feeder. In case of smaller ampere value of the parallel resistor, for example 5 A, the recommended security factor should be higher, for example 0.7, so that sufficient margin for CT and VT errors can be achieved.

If *Operating quantity* is set to "Amplitude", the *Min operate current* setting should be selected based on the capacitive earth-fault current values produced by the background network in case of a solid earth fault with a security margin.

The main task of the current magnitude supervision module is to secure the correct directional determination of an earth fault so that only the faulty feeder is disconnected or generates alarms. Therefore, the threshold value *Min operate current* should be selected carefully and should not be set too high as this can inhibit the disconnection of the faulty feeder.

The residual current should be measured with an accurate CBCT to minimize the measurement errors, especially phase displacement.

The parallel resistor should be kept connected during the healthy state so that in case of a fault, earth-fault protection can immediately see sufficient value of resistive component for operation. If the parallel resistor is kept disconnected during the healthy state, it should be immediately connected when the earth fault is detected. This enables the earth-fault protection to operate without delay.

Transient detector

The Transient detector module is used for detecting transients in the residual current and zero-sequence voltage signals. Whenever transient is detected, this is indicated with the `PEAK_IND` output. When the number of detected transients equals or exceeds the *Peak counter limit* setting (without the function being reset, depending on the drop-off time set with the *Reset delay time* setting), `INTR_EF` output is activated. This indicates detection of restriking or intermittent earth fault in the network.

Transient detector affects the operation of MFADPSDE (`START` and `OPERATE` outputs) when operation mode is “Intermittent EF”. For other operation modes, (“General EF”, “Alarming EF”), `PEAK_IND` and `INTR_EF` outputs can be used for monitoring purposes. The operation of the Transient detector is illustrated in *Figure 327*.

Several factors affect the magnitude and frequency of fault transients, such as the fault inception angle on the voltage wave, fault location, fault resistance and the parameters of the feeders and the supplying transformers. If the fault is permanent (non-transient), the initial fault transient in current and voltage can be measured, whereas the intermittent fault creates repetitive transients. The practical sensitivity of transient detection is limited to approximately a few hundreds of ohms of fault resistance. Therefore the application of transient detection is limited to low-ohmic earth faults.

Transient detector is a non-directional function. Thus, if detection of restriking or intermittent earth faults is wanted only in the faulted feeder, the `START` and `INTR_EF` outputs must be ANDed in the configuration.

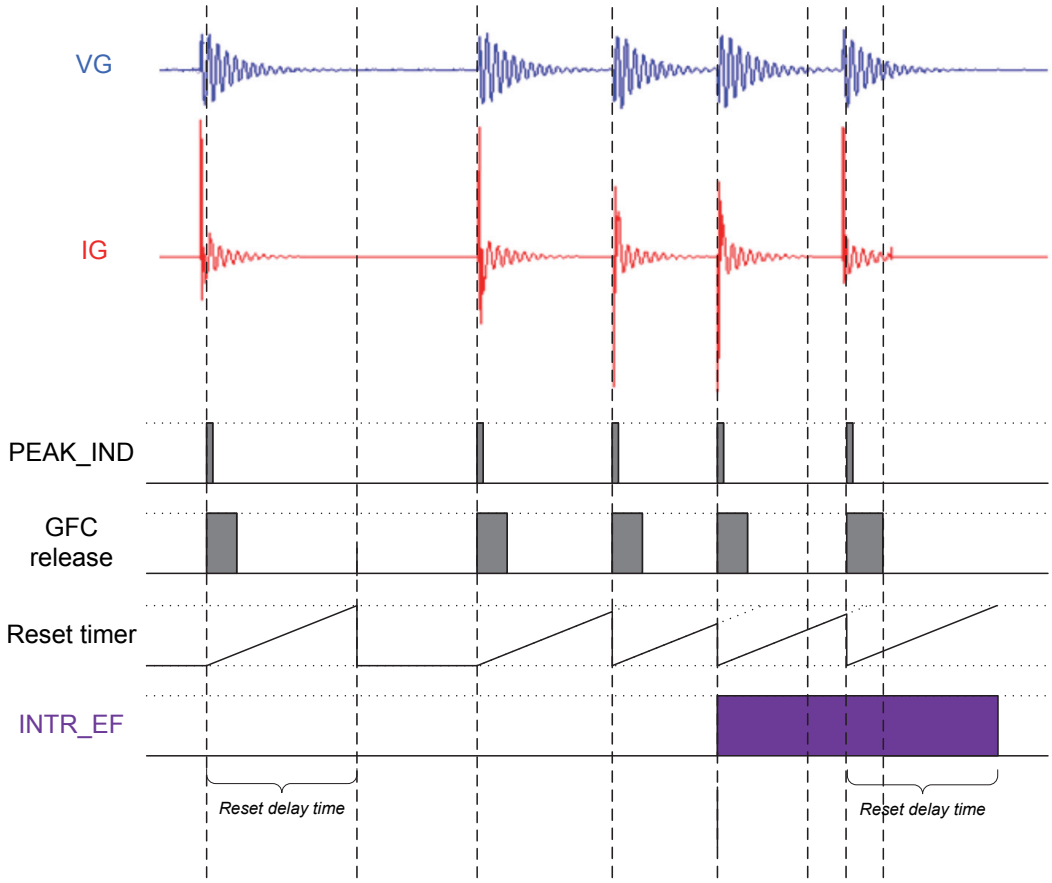

Figure 327: Example of operation of Transient detector: indication of detected transient by PEAK_IND output and detection of restriking or intermittent earth fault by INTR_EF output (setting Peak counter limit = 3)

Operation logic

MFADPSDE supports four operation modes selected with setting Operation mode: "General EF", "Alarming EF", "Intermittent EF" and "Transient EF".

General EF

Operation mode “General EF” is applicable to various earth faults in high-impedance earthed networks, that is, in compensated, unearthed and high-resistance earthed networks. It detects earth faults regardless of their type (transient, intermittent or restriking, permanent, high or low ohmic) and provides definite operate time for protection regardless of the fault type.

In “General EF” mode, the operate timer is started in the following conditions.

- Earth fault is detected by the GFC
- Fault direction equals *Directional mode* setting
- Estimated stabilized fundamental frequency residual current $\overline{I^{1}_{o\,stab}}$ exceeds the set *Min operate current* level which is applied in current magnitude threshold supervision, and which is further defined with setting *Operating quantity* (available options are "Adaptive", "Amplitude" and "Resistive").

The START output is activated once *Start delay time* has elapsed. OPERATE output is activated once *Operate delay time* has elapsed and the above three conditions are valid. Reset timer is started if any of the above three conditions is not valid. If the fault is transient and self-extinguishes, START output stays activated until the elapse of reset timer (setting Reset delay time). After OPERATE output activation, START and OPERATE outputs are reset immediately, if any of the above three conditions is not valid. The start duration value START_DUR, available in the Monitored data view, indicates the percentage ratio of the start situation and the set operating time.

If detection of temporary earth faults is not desired, the activation of START output can be delayed with setting *Start delay time*. The same setting can also be used to avoid restarting of the function during long lasting post-fault oscillations, if time constant of post-fault oscillations is very long (network losses and damping is low).

To keep the operate timer activated between current spikes during intermittent or restriking earth fault, the *Reset delay time* should be set to a value exceeding the maximum expected time interval between fault spikes (obtained at full resonance condition). Recommended value is at least 300 ms.

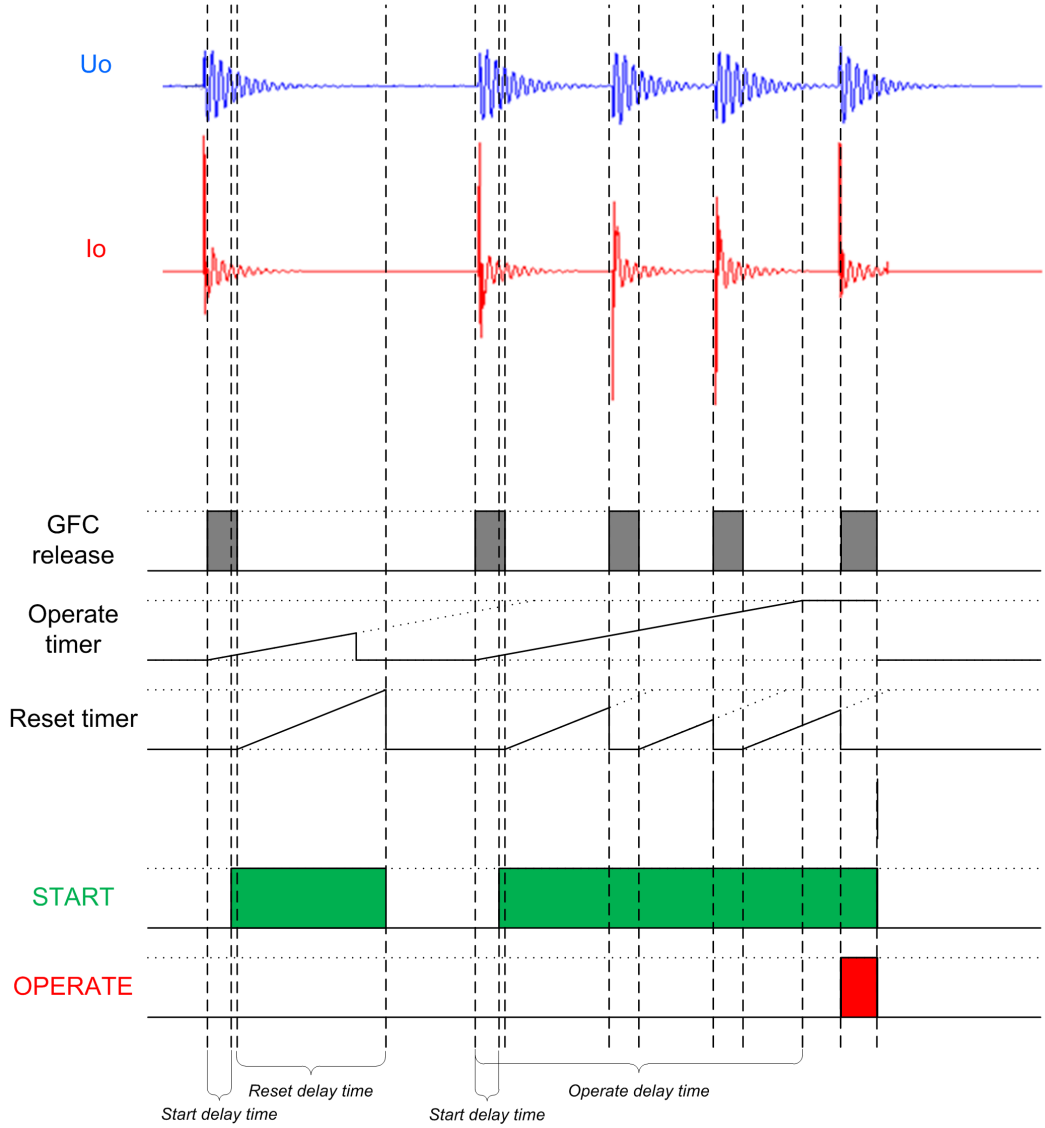

Figure 328: Operation in "General EF" mode

Alarming EF

Operation mode "Alarming EF" is applicable in all kinds of earth faults in high-impedance earthed networks, that is, in compensated, unearthed and high resistance earthed networks, where fault detection is only alarming. It is intended to detect earth faults regardless of their type (transient, intermittent or restriking, permanent, high or low ohmic).

In "Alarming EF" mode, the operate timer is started during the following conditions.

- Earth fault is detected by the GFC
- Fault direction equals *Directional mode* setting
- Estimated stabilized fundamental frequency residual current $\overline{I^{1}_{o\,stab}}$ exceeds the set *Min operate current* level, which is applied in current magnitude threshold supervision, and which is further defined with setting *Operating quantity* (available options are "Adaptive", "Amplitude" and "Resistive").

The START output is activated once *Start delay time* has elapsed. OPERATE output is not valid in the “Alarming EF” mode. Reset timer is started if any of the above three conditions are not valid. In case the fault is transient and self-extinguishes, START output stays activated until the elapse of reset timer (setting *Reset delay time*).

If detection of temporary earth faults is not desired, the activation of START output can be delayed with setting *Start delay time*.

To keep the operate timer activated between current spikes during intermittent or restriking earth fault, the *Reset delay time* should be set above the maximum expected time interval between fault spikes (obtained at full resonance condition). The recommended value is at least 300 ms.

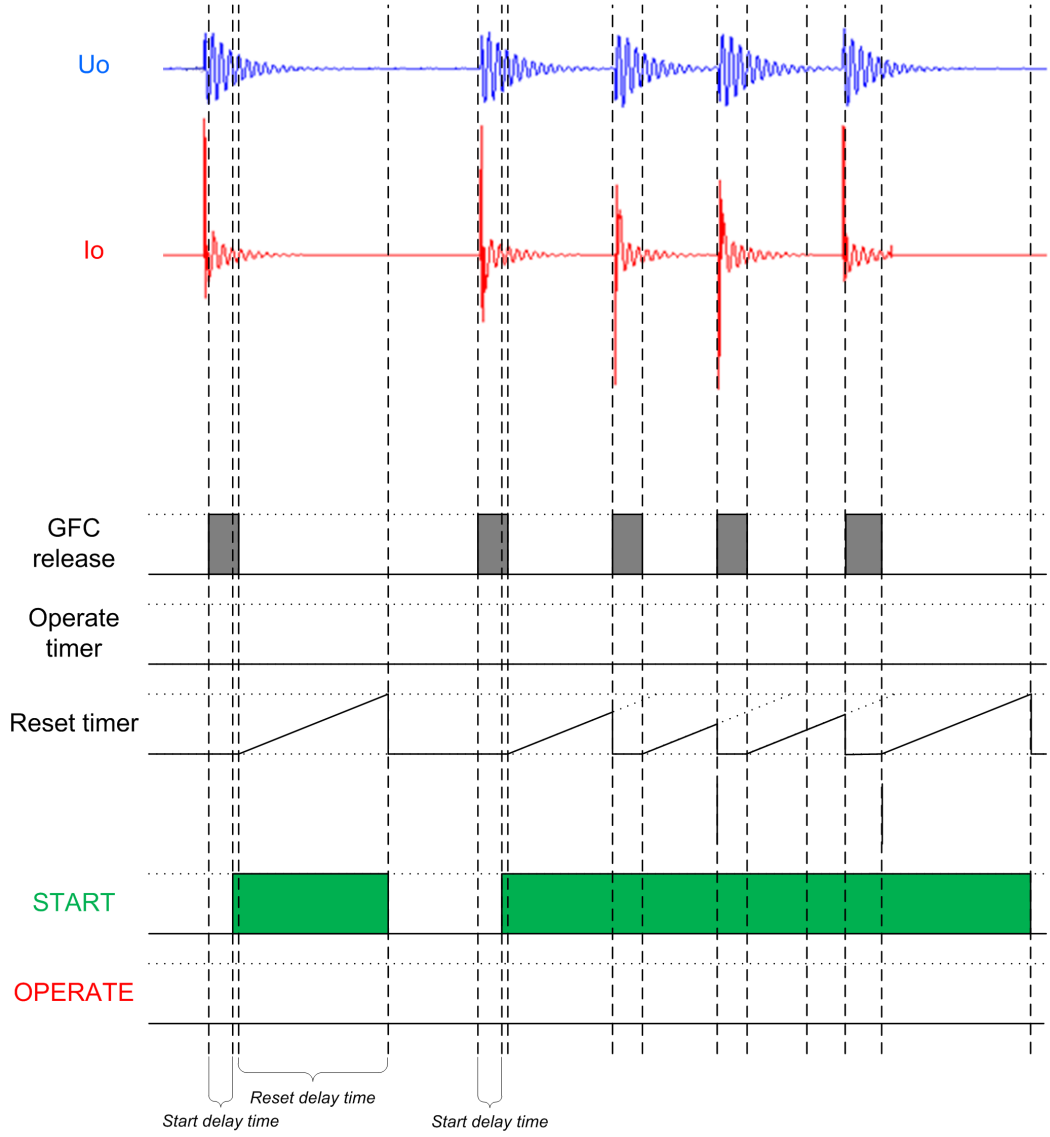

Figure 329: Operation in “Alarming EF” mode

Intermittent EF

Operation mode “Intermittent EF” is used to detect restriking or intermittent earth faults. A required number of intermittent earth fault transients set with the *Peak counter limit* setting must be detected for operation. Therefore, transient faults or permanent faults with only initial fault ignition transient are not detected in this mode. The application of “Intermittent EF” mode is limited to low ohmic intermittent or restriking earth faults.

In the “Intermittent EF” mode, the operate timer is started when the following conditions are met.

- Transient is detected by the Transient detector (indicated with PEAK_IND output)
- Earth fault is detected by the GFC at time of transient
- Fault direction equals *Directional mode* setting
- Estimated stabilized fundamental frequency residual current $\overline{I^{1}_{o\,stab}}$ exceeds the set *Min operate current* level, which is applied in current magnitude threshold supervision, and which is further defined with setting *Operating quantity* (available options are "Adaptive", "Amplitude" and "Resistive").

When a required number of intermittent earth-fault transients set with the *Peak counter limit* setting are detected without the function being reset (depends on the drop-off time set with the *Reset delay time* setting), the START output is activated. The INTR_EF output is activated to indicate the fault type is intermittent or restriking earth fault. The operate timer is kept activated as long as transients occur during the drop-off time defined by setting *Reset delay time*.

The OPERATE output is activated when *Operate delay time* has elapsed, required number of transients has been detected, earth fault is detected by the GFC, fault direction matches the *Directional mode* setting and estimated stabilized fundamental frequency residual current exceeds set *Minimum operate current* setting.

Reset delay time starts to elapse from each detected transient. Function is reset if time between current peaks is more that *Reset delay time* or if the General Fault Criterion release is reset. After OPERATE output activation, START and OPERATE outputs are reset immediately at the falling edge of General Fault Criterion release, that is, when zero-sequence voltage falls below *Voltage start value*. This should be considered if “Intermittent EF" mode is applied in case earth faults are only alarmed to avoid repetitive start and operate events.

Peak counter limit setting should not be set below 3 in order to provide secure indication of intermittent/restriking earth faults. This is due to the fact that sometimes the fault ignition transient is characterized by highly distorted waveform, which may result in multiple transient detection at time of fault ignition. By increasing the value of *Peak counter limit* setting, the security of correct fault type identification is increased.

To keep the operate timer activated between current spikes during intermittent or restriking earth faults, *Reset delay time* should be set above the maximum expected time interval between fault spikes (obtained at full resonance condition). The recommended value is at least 300 ms.

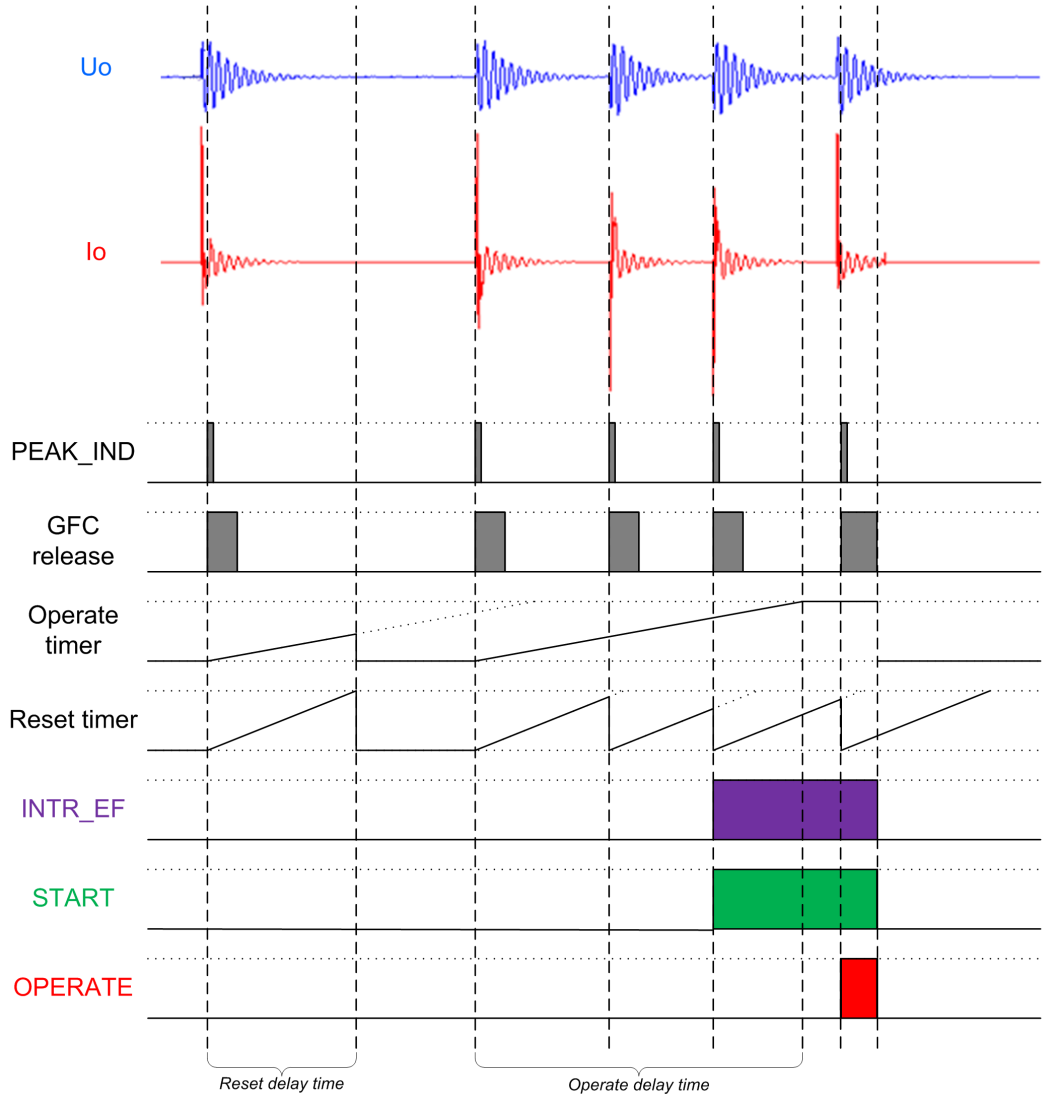

Figure 330: Operation in "Intermittent EF" mode, Peak counter limit = 3

Transient EF

Operation mode "Transient EF" is dedicated for detecting fast transient faults where the fault current stays on only for a very short time. It is recommended method in networks, where network damping has very small value or when parallel resistor of the coil is not used, for example in sub-transmission networks.

In the "Transient EF" mode, the fault direction is determined from the beginning of the fault and is held until earth-fault is detected by GFC.

In the "Transient EF" mode, the operate timer is started when the following conditions are met.

- Earth fault is detected by the GFC
- Fault direction equals Directional mode setting and fault direction detection is done only at the beginning of the fault

- Estimated stabilized fundamental frequency residual current $\overline{I^{1}_{o\,stab}}$ exceeds the set Min operate current level, which is applied in current magnitude threshold supervision, and which is further defined with setting Operating quantity (available options are "Adaptive", "Amplitude" and "Resistive").

In the “Transient EF” mode, the START output is activated immediately when start conditions are met.

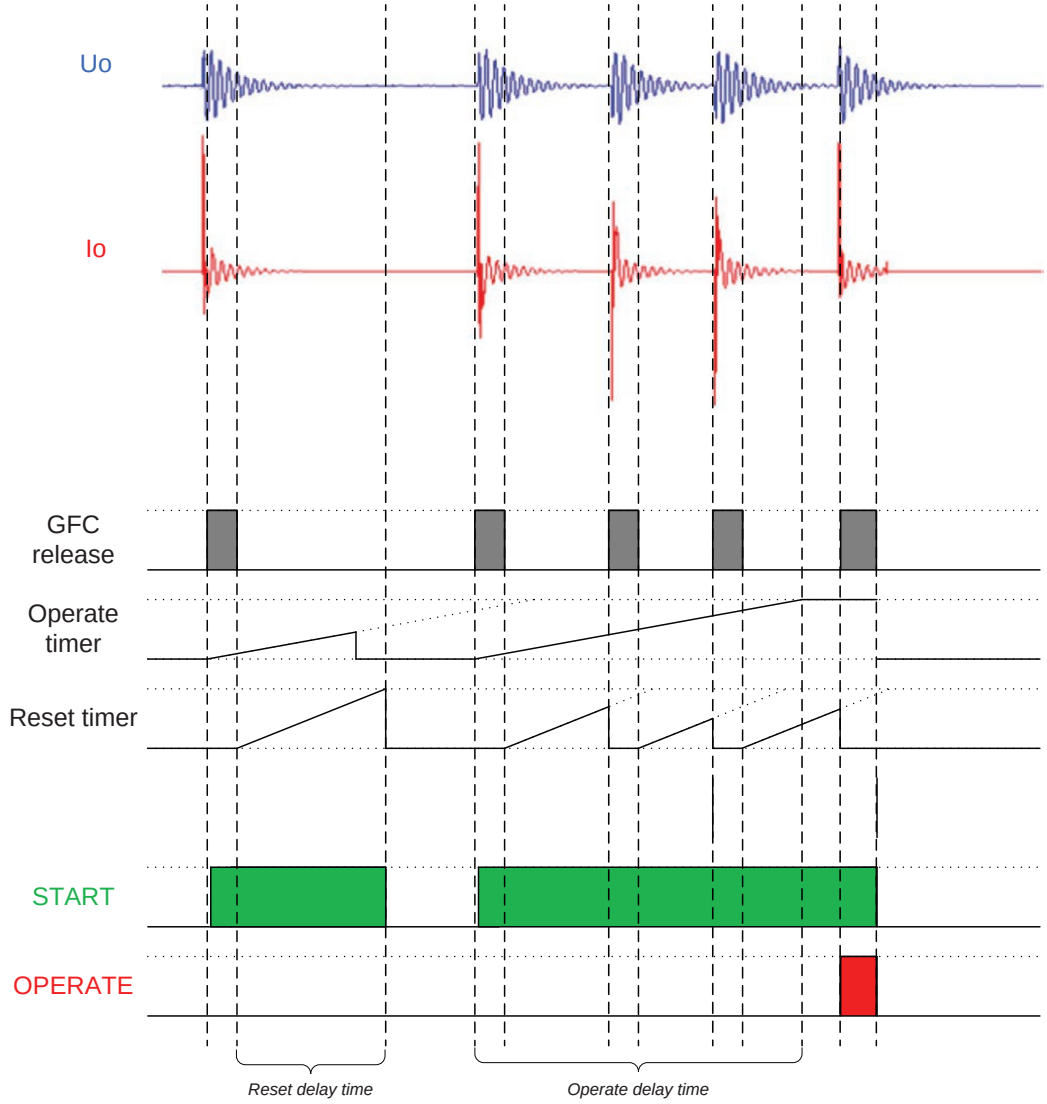

Figure 331: Operation in “Transient EF” mode

When operation mode “Transient EF” is selected, *Operating quantity* should be set to "Resistive" and *Min operate current* to the minimum value. *Tilt angle* should be 10 degrees especially if the residual current is measured with Holmgreen (sum) connection of phase current CTs.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be

controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

If the BLOCK input of MFADPSDE is used in the configuration, then "Block all" mode is recommended.

Recommended uses of the BLOCK input of MFADPSDE are:

1. Connecting the start signal of non-directional earth fault protection (EFxPTOC), set to operate in case of a cross-country fault, to BLOCK input of MFADPSDE to reset phasor accumulation during a cross-country fault. MFADPSDE can then adapt to a fault direction change more rapidly if a single-phase earth fault persists in the system after the other faulty feeder has been tripped (the cross-country fault has been transformed into a single-phase earth fault).
2. Connecting the 'Auto-Reclose in progress' output (INPRO) from DARREC to BLOCK input of MFADPSDE to allow faster reset of MFADPSDE during high-speed auto-reclosing cycle HSAR when setting *Reset delay time* equals or is higher than the dead time of high-speed auto-reclosing cycle HSAR.
3. In case of a network with distributed coils but no centralized arc suppression coil at the primary substation (unearthed network), it is recommended to add an additional logic to protection configuration, which blocks MFADPSDE if the frequency of measured Uo and Io becomes lower than nominal. Such condition is valid in network when earth fault becomes disconnected and a phenomenon called 'post-fault oscillation' is initiated.
4. If the parallel resistor of the coil has long connection delay, it is recommended to add an additional logic to protection configuration to enable the release of MFADPSDE at the time of the parallel resistor switching.

The logic to release MFADPSDE at time of resistor (re)connection is illustrated in *Figure 332*.

- Detection of earth fault from residual overvoltage, ROVPTOV
- Delay of release MFADPSDE using TONGAPC connected to the BLOCK input of MFA (inversed)
- Delay of release (TONGAPC: On delay time (ms)) based on known time delays in resistor connection
- Protection operate delay time to be set smaller than the resistor connection duration.

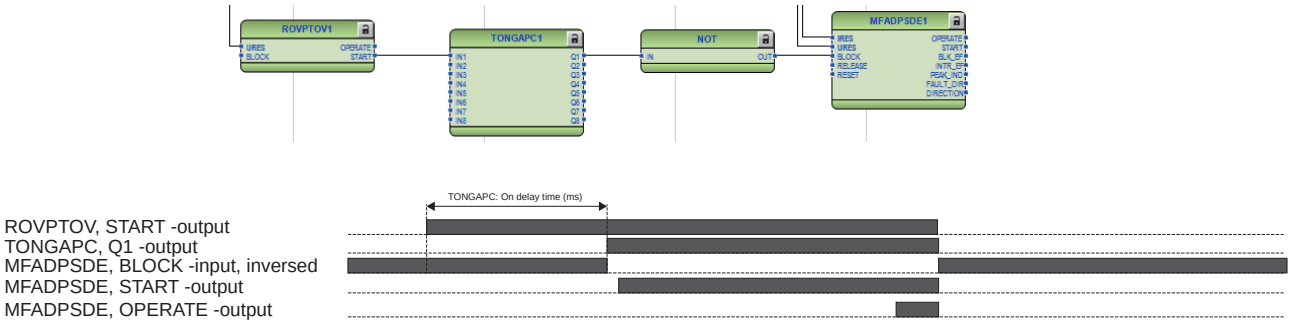

Figure 332: Logic to release MFADPSDE at the time of resistor (re)connection

The logic enables exact operate time of MFADPSDE elapsed from time of resistor (re)connection.

In the configuration, equal *Reset delay time* and *Voltage start value* must be used for ROVPTOV and MFADPSDE.

The release delay should be based on known delays in resistor (re)connection:

- Logic OFF-ON-OFF: *Switch on delay* of the parallel resistor.
- Logic ON-OFF-ON: *Switch off delay* + *Time off* time of the parallel resistor.

The resulting total protection operate time is defined as follows:

- Logic OFF-ON-OFF: *Switch on delay* of the parallel resistor + set *Operate delay time* of MFADPSDE.
- Logic ON-OFF-ON: *Switch off delay* + *Time off* time of the parallel resistor + set *Operate delay time* of MFADPSDE.
- Set *Operate delay time* of MFADPSDE smaller than the connection duration time of the resistor.

If earth faults are only alarmed, the external logic is not needed.

When the proposed logic is used and indication of transient earth faults is needed, the START output from INTRPTEF can be used.

Timer

If the detected fault direction is opposite to the set directional mode and GFC release is active, BLK_EF output is activated once *Start delay time* has elapsed. Reset timer is activated at the falling edge of GFC release, that is, when zero-sequence voltage falls below *Voltage start value*. BLK_EF is reset once the reset delay time elapses. Activation of the BLOCK input deactivates the BLK_EF output and resets Timer.

BLK_EF output is activated when the following conditions are met:

- Earth fault is detected by the GFC
- Fault direction is opposite to *Directional mode* setting

The estimated stabilized fundamental frequency residual current $\overline{I^{1}_{o\,stab}}$ exceeds the internally fixed threshold, which is 1% of In. This current magnitude threshold supervision is based on the “Amplitude” method.

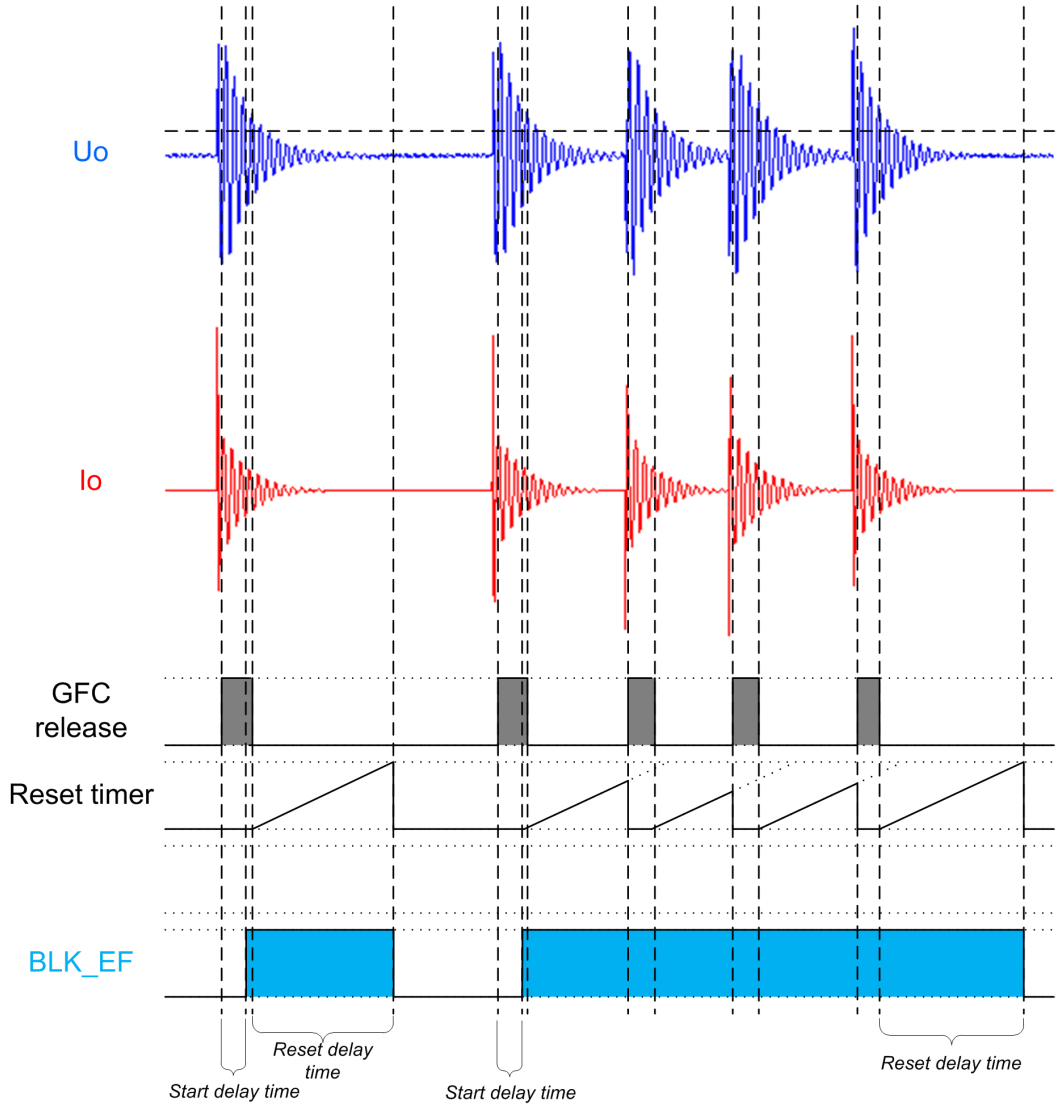

Figure 333: Activation of BLK_EF output (indication that fault is located opposite to the set operate direction)

4.2.9.6 Application

MFADPSDE provides selective directional earth-fault protection for high-impedance earthed networks, that is, for compensated, unearthed and high-resistance earthed systems. It can be applied for the earth-fault protection of overhead lines and underground cables, regardless of the earth-fault type (continuous, transient or intermittent) or the fault resistance value (low or high ohmic). MFADPSDE replaces traditional sensitive directional earth-fault protection (such as Iocos) and transient earth-fault protection (such as Wischer principle) combining the same functionality into a single function block (see *Table 616*).

Table 616: Comparison of the MFADPSDE functionality with traditional methods in resonant earthed networks

	Earth-fault type				
	Transient	**Continuous**	**Restriking / Intermittent**	**Low-ohmic**	**High-ohmic**
Traditional Iocos		x		x	x
Traditional Wischer	x		x	x	
New MFADPSDE	x	x	x	x	x

As shown by numerous practical field tests, MFADPSDE provides better sensitivity and selectivity compared with traditional methods with less complexity in settings and configuration. MFADPSDE provides enhanced earth-fault protection performance, especially in networks with cable feeders where distributed compensation coils are applied and earth-fault type is typically intermittent. It is applicable in feeders with distributed compensation regardless of the size or localization of distributed coils. Selective protection can be achieved also in case of overcompensated feeders.

MFADPSDE operation is based on multifrequency neutral admittance measurement using the cumulative phasor summing technique. This concept provides extremely secure, dependable and selective earth-fault protection also when the residual quantities are highly distorted and contain non-fundamental frequency components. MFADPSDE is well-suited for compensated networks where measurement signals may have such characteristics, for example, during intermittent earth faults.

MFADPSDE can operate with both low-ohmic and higher-ohmic earth faults, where the sensitivity limit is defined with the residual overvoltage condition. This allows earth faults with several kilohms of fault resistance to be detected in a symmetrical system. The achieved sensitivity is comparable with traditional fundamental frequency based methods such as the IoCos/IoSin (DEFxPTOC), Watt/Varmetric (WPWDE) and neutral admittance (EFPADM).

MFADPSDE can detect faults with dominantly fundamental frequency content as well as transient, intermittent or restriking earth faults. MFADPSDE can be used as an alternative solution to transient or intermittent function INTRPTEF.

MFADPSDE supports fault direction indication in operate and non-operate directions which can be used during fault location process. The in-built transient detector can be used to identify restriking or intermittent earth faults, and discriminate them from permanent or continuous earth faults.

The direction of MFADPSDE can be set as forward or reverse. The operation characteristic is defined by a tilted operation sector, which is universally valid both in unearthed and compensated networks. The tilt of the operation sector should be selected based on the measurement errors of the applied residual current and voltage measurement transformers.

The operating time characteristic is according to the definite time (DT).

The function contains a blocking functionality to block function outputs, timers or the function itself.

MFADPSDE supports both tripping and alarming operation modes. For the alarming earth-fault protection application, the function contains a dedicated operation mode. MFADPSDE provides reliability and sensitivity of protection with a single function. This enables a protection scheme implementation that is simpler than

separate fault type dedicated earth-fault functions which need to be coordinated. Other advantages of MFADPSDE include versatile applicability, good selectivity, good sensitivity and easy setting principles.

Three instances (stages) of MFADPSDE are available.

4.2.9.7 Signals

MFADPSDE Input signals

Table 617: MFADPSDE Input signals

Name	Type	Default	Description
IRES	SIGNAL	-	Residual current
URES	SIGNAL	-	Residual voltage
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode
RELEASE	BOOLEAN	0=False	External trigger to release neutral admittance protection
RESET	BOOLEAN	0=False	External trigger to reset direction calculatio

MFADPSDE Output signals

4.2.10.3 Functionality

The touch voltage-based earth-fault current protection function IFPTOC provides selective earth-fault protection for single-phase earth faults in high-impedance earthed networks, that is, in compensated, unearthed and high resistance earthed

[1] Includes the delay of the signal output contact, results based on statistical distribution of 1000 measurements.

systems. It can be applied for the earth-fault protection of overhead lines and underground cables, regardless of actual earth-fault type (continuous or intermittent) or fault resistance value (low or high ohmic). Operation time of IFPTOC can either be definite time or inverse time. In case of inverse time operation, operation time becomes automatically adapted to estimated single-phase earth-fault current or touch-voltage magnitude.

Traditional directional, sensitive earth-fault protection functions applied in high-impedance earthed networks are typically based on residual quantities (U_o, I_o). In high-impedance earthed networks residual current does not accurately match the fault current flowing at fault location. This is since the capacitive current contribution of the faulted feeder itself is not measurable using residual current. The higher is the capacitive current contribution of the faulted feeder, the greater is the mismatch of true fault current and residual current (I_o). This is the root reason, why operate time cannot be based on measured magnitude of current (I_o). Therefore, in traditional directional sensitive earth-fault protection functions operate time must be pre-defined and it is thus based on *assumed* magnitude of fault current. *Actual* fault current magnitude depends on e.g. the prevailing detuning degree of the network during an earth fault, which depends on the actual values of network shunt capacitance and coil inductance. In modern networks with increased degree of cabling, switching operations may result into large variations of network capacitance. On the other hand, typical practical arrangement for adjustment of coil inductance involves mechanical movement of air gap in the iron core, which is a time-consuming process. In case there is great mismatch between the assumed and true fault current magnitude, the fulfillment of electrical safety regulations is questionable. It should be noted that the time constant of coil tuning is much longer than requirements for protection operate time. In modern networks, high temporary detuning conditions are possible due to increase of use of underground cables, which increase feeder total phase-to-earth capacitance enormously.

However, operation of IFPTOC is not based on traditional residual quantities (U_o, I_o), but on accurate estimation of earth-fault (EF) current flowing at the fault location. Estimation of earth-fault current is done in real-time utilizing changes in phase currents measured at the beginning of the feeder due to a single-phase earth fault.

Thanks to its novel operation principle, the method has several advantages over the traditional state-of-art earth-fault protection methods such as the wattmetric method:

- The method enables automatic, real-time adaptation of protection operation speed according to the prevailing (estimated) single-phase earth-fault current magnitude. The estimated earth-fault current magnitude can be converted into corresponding touch voltage or earth potential rise (EPR) value, which enables direct compliance of protection operation speed according to standard EN50522. As another option, IFPTOC enables protection operation speed according to standard IEEE80. This operation mode can also be used when maximum allowed earth potential rise vs. operation speed follows a relationship such as 750V/ $\sqrt{t}$[*sec*].
- The harmonic content of fault current can be included into fault current magnitude estimate, which further enhances the accuracy and practicality of the novel protection method.
- IFPTOC enables significant improvement on safety and overall dependability of the protection schemes used today in compensated networks. IFPTOC provides unique advantages, for example during the following practical network conditions:
  - On feeders with high capacitive earth-fault current contribution (e.g. long cable feeders), where traditional earth-fault protection is challenged by the

fact that the phase angle difference between U_o and I_o increases as the capacitive earth-fault current contribution increases. Phase angle difference may become so high that correct operation of traditional protection functions is endangered. This is not the case for IFPTOC, as fault current estimate is not affected by the capacitive earth-fault current contribution of the protected feeder itself.
  - In case earth fault occurs during abnormal network topologies, or when fault current compensation is temporarily not effective or when network is operated heavily over- or under-compensated.
- Magnitude of true fault current is estimated without need on any pre-defined information on the network topology.
- Also, the effect of fault resistance can be considered and compensated in the estimated earth-fault current magnitude applying dedicated fault resistance compensation method. This functionality allows acceleration of protection operation speed during high(er) ohmic earth fault when actual fault current magnitude is low.

IFPTOC includes also dedicated protection functionality for important practical earth-fault scenarios such as switch onto fault (SOTF) condition, for intermittent earth faults and for high current cross-country earth-faults. Each of such fault condition can be tripped with individually defined operation criteria enabling high application flexibility and reliability.

4.2.10.4 Analog channel configuration

IFPTOC has four analog group inputs which must be properly configured.

Table 625: Analog inputs

Input	Description
I3P	Three phase currents
IRES	Residual current (measured or calculated)
U3P	Three phase voltages
URES	Measured or calculated residual voltage

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 626: Special conditions

Condition	Description
U3P connected real measurements	Recommendation to connect all three phase-to-earth voltage channels. Alternative is at least two phase-to-earth / phaseto-phase voltages and measured residual voltage (URES).
URES calculated	Three phase-to-earth voltages must be connected for calculating the residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. check the contents of this chapter and also the preprocessing blocks in this

document. The configuration can be written to the protection relay once the mismatch is corrected.

4.2.10.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected “on” the function is enabled and respectively “off” means function is disabled.

The operation of *Touch voltage-based earth-fault current protection IFPTOC* can be described by using a module diagram (see figure below). All the modules in the diagram are explained in the next sections.

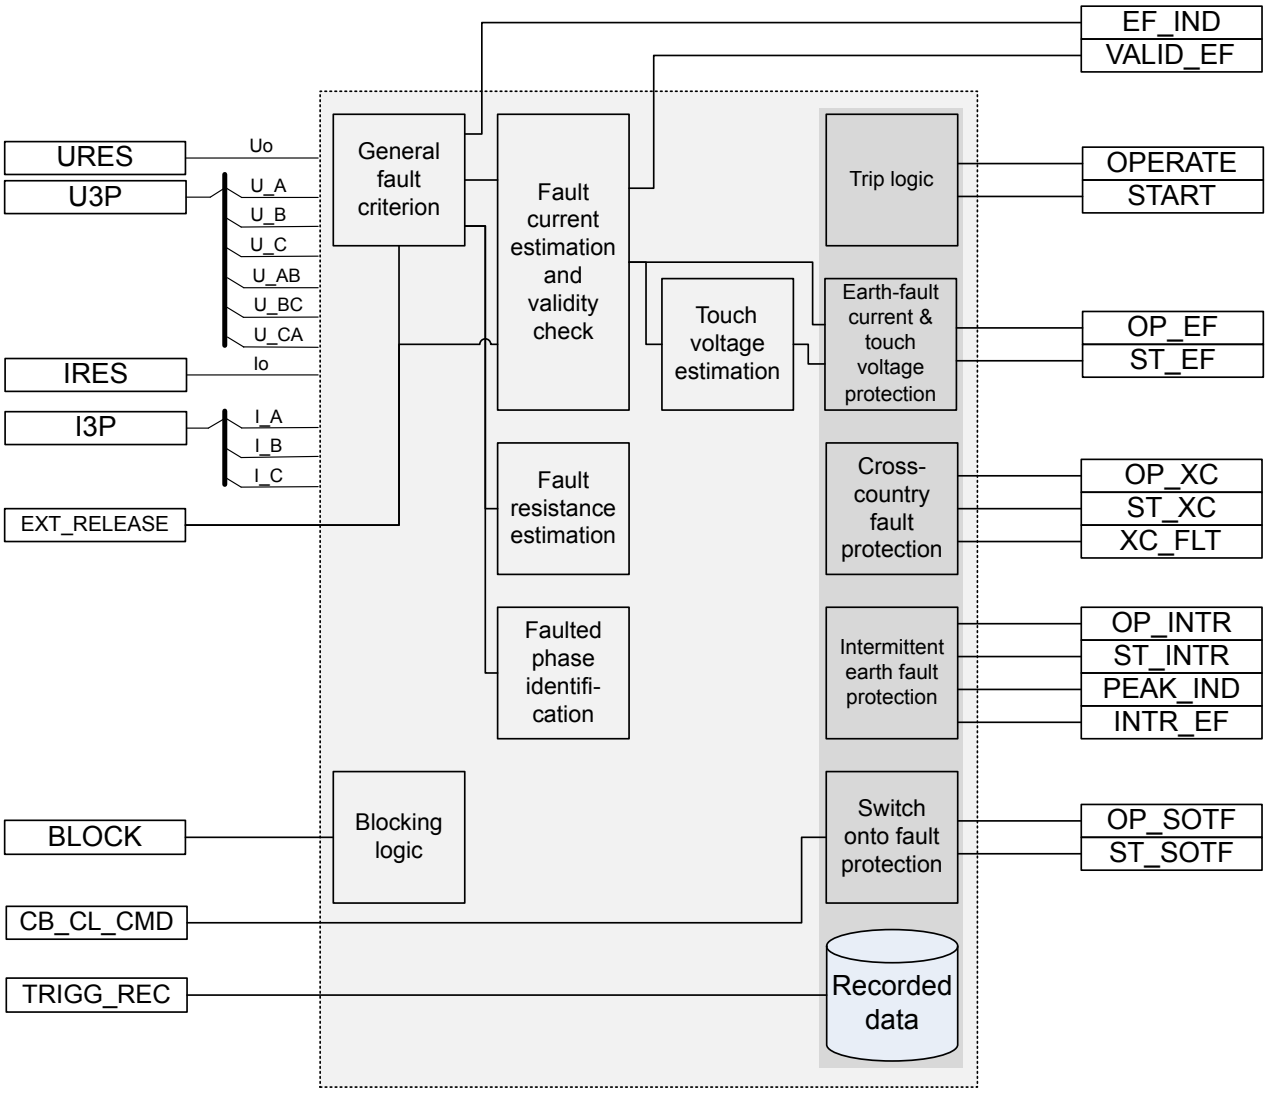

Figure 335: Functional module diagram

General fault criterion

The General fault criterion (GFC) module monitors the presence of earth fault in the network. It is based on the value of the fundamental frequency residual voltage $\overline{U}_o$

defined as the vector sum of fundamental frequency phase voltage phasors divided by three.

$$\underline{U_o} = (\underline{U_A} + \underline{U_B} + \underline{U_C})/3$$

(Equation 100)

When the magnitude of U_o exceeds setting *Voltage start value*, an earth fault is detected and EF_IND output is set to TRUE. Setting value *Voltage start value* is given in per unit format with system nominal phase-to-earth value (U_{n_PE}) as reference.

IFPTOC supports fundamental frequency residual voltage monitoring based on measured U_o from open-delta winding or internally calculated U_o derived from connected phase-to-earth voltages.

Input EXT_RELEASE is alternative method for internal GFC and validity check modules to indicate the presence of earth fault in the protected feeder and to release the calculation of IFPTOC function. Activation of EXT_RELEASE will also override earth-fault validity check criterion i.e. earth-fault current estimate is considered as valid when EXT_RELEASE is activated. It is therefore mandatory that EXT_RELEASE is based on start of directional earth-fault detection function, such as MFADPSDE or DEFxPDEF.

The setting *Voltage start value* defines the basic sensitivity of the IFPTOC function in terms of fault resistance. Fault detection sensitivity in terms of fault resistance can be estimated using the equation below:

$$R_F[ohm] \leq \frac{U_{PE}\cdot\left(\sqrt{I_d^2+I_v^2-I_v^2\cdot U_{o_pu}^2}-I_d\cdot U_{o_pu}\right)}{(I_d^2+I_v^2)\cdot U_{o_pu}}$$

(Equation 101)

where U_{PE} is the system phase-to-earth voltage [V], I_d is the total system damping [A], I_v is the network detuning value [A] and U_{o_pu} is setting *Voltage start value* in per unit.

In compensated networks the minimum value for the setting *Voltage start value* can be easily selected based on the resonance curve calculated by the coil controller considering different network topologies and conditions, refer to *Figure 336*.

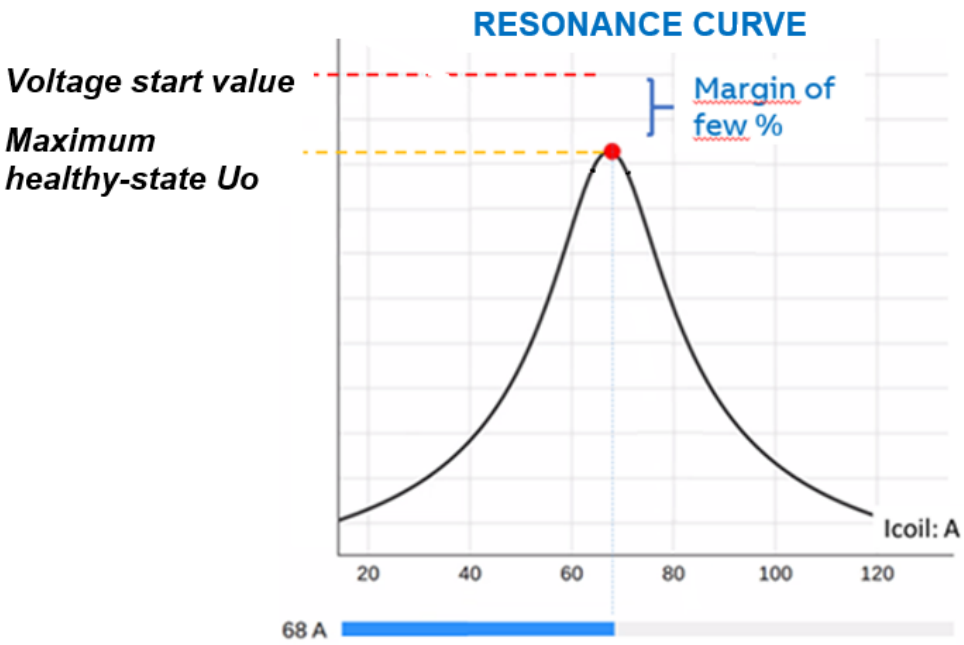

Figure 336: Example of selection of setting Voltage start value in order to maximize the earth-fault detection sensitivity of IFPTOC based on the resonance curve calculated by the coil controller

To avoid unselective start or operation of IFPTOC, *Voltage start value* must always be set to a value which exceeds the maximum healthy-state residual voltage value, taking into consideration of possible network topology changes (variation in unbalance), compensation coil and parallel resistor switching status (variation in damping) and compensation degree variations (variation in detuning).

Activation of `EF_IND` output is determined to be the time instant when the earth fault is detected. This information is needed as the IFPTOC utilizes “delta” calculation i.e. changes in phase currents due to earth fault. For example, the change of phase A current phasor due to earth fault can be written as:

$$\Delta \underline{I}_A = \underline{I}_A(t_{FLT}) - \underline{I}_A(t_{PRE_FLT})$$

(Equation 102)

Where:

t_{FLT} is the time during the detected earth fault

t_{PRE_FLT} is the time prior to detected earth fault occurrence and it represents time during pre-fault or healthy-state conditions. This pre-fault operation point is determined based on user setting *Revert time* as follows:

$$t_{PRE_FLT} = t_{FLT}(1) - \text{Revert time}$$

(Equation 103)

where $t_{FLT}(1)$ equals the first time instant, when earth fault is detected by the GFC-module. Pre-fault time moment is at least *Revert time* before earth fault occurrence moment.

Revert time setting should be set high enough (default value is 300 ms), because during a high(er) ohmic fault the increase speed (gradient) of the magnitude of U_o may be slow, refer to example in *Figure 337*, where earth-fault occurs at time 0 ms. Earth fault is detected by GFC module slightly after that, at time instant $t_{FLT}(1)$ marked with red dot, when magnitude of U_o exceeds setting *Voltage start value*. As an indication of detected earth-fault output `EF_IND` is activated.

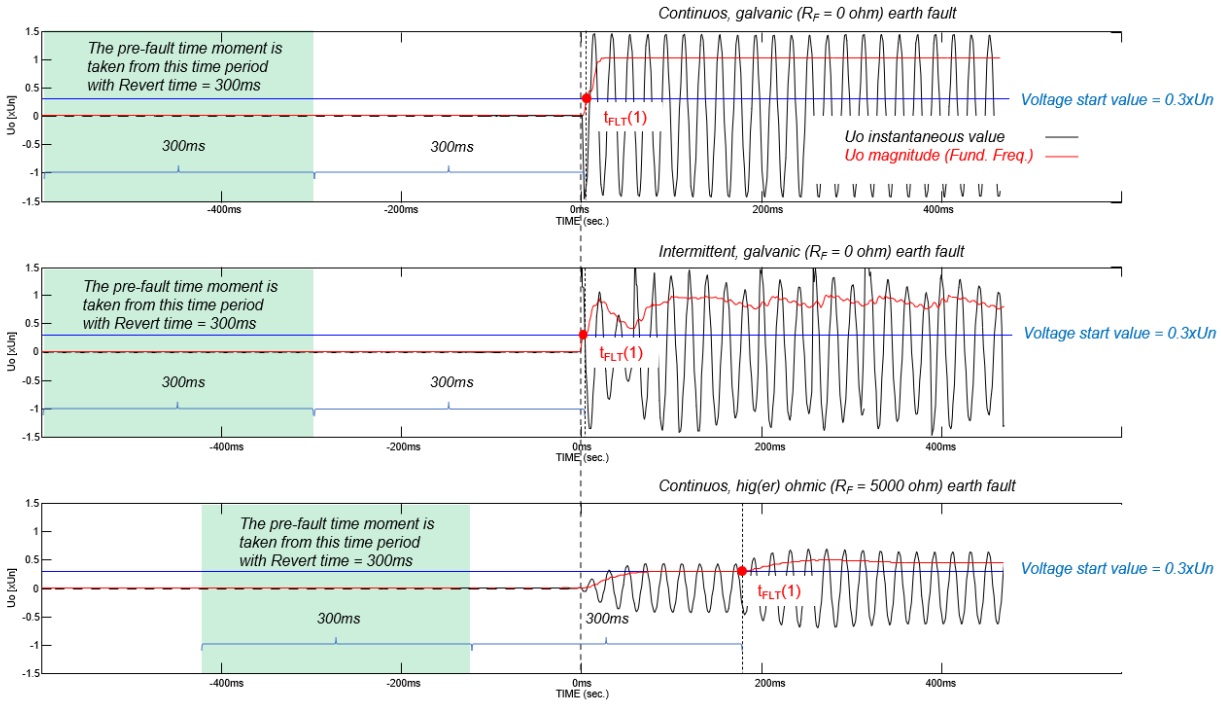

Figure 337: Illustration of operation of General Fault Criterion (GFC) module and the meaning of setting Revert time

In case of secondary testing of IFPTOC function, the pre-fault time in the test file must be longer than *2xRevert time*. For example, if *Revert time* = 300 ms, then pre-fault time in the test file must be longer than 600 ms.

Indication of detected earth fault is available in Recorded data: *EF indication*.

Fault current estimation and validity check

Operation of IFPTOC is based on estimating the magnitude of earth-fault current flowing in the fault spot, or on touch voltage magnitude derived from the earth-fault current estimate.

In compensated network, the magnitude of fundamental frequency earth-fault current depends on the network damping (I_d), detuning (I_v), voltage (U_{PE}) and fault resistance (R_F) and can be written as:

$$I_F^1 = \sqrt{\frac{(I_d^2+I_v^2)\cdot U_{PE}^2}{(I_d^2+I_v^2)\cdot R_F^2+2\cdot I_d\cdot R_F\cdot U_{PE}+U_{PE}^2}}$$

(Equation 104)

Maximum fault current value is obtained when fault resistance (R_F) is zero, in case of *Equation 104* can be written as:

$$\max(I_F^1) = \sqrt{I_d^2 + I_v^2}$$

(Equation 105)

Interpretation of *Equation 105* is that fault current has resistive part due to network damping and imaginary part due to network detuning. Fault current magnitude increases when damping or detuning increases.

The effect of fault resistance to fault current magnitude can be written as:

$$I_F^1 = \max(I_F^1) \cdot U_{o_{pu}} = \sqrt{I_d^2 + I_v^2} \cdot U_{o_{pu}}$$

(Equation 106)

where

$$U_{o_{pu}} = \left| \frac{U_{PE}}{R_F\cdot(I_d - j\cdot I_v)+U_{PE}} \right|$$

(Equation 107)

Interpretation of *Equation 106* is that effect of fault resistance to fault current magnitude is proportional to scaling the fault current magnitude at zero fault resistance with the per unit value of residual voltage ($U_{o_{pu}}$) due to fault resistance.

Minimum fault current magnitude is always obtained at resonance, when detuning (I_v) is zero, in case *Equation 104* can be written as:

$$\min(I_F^1) = \sqrt{\frac{I_d^2\cdot U_{PE}^2}{(I_d\cdot R_F + U_{PE})^2}}$$

(Equation 108)

At resonance, fault current is only due to system resistive shunt losses i.e. due to network damping (I_d) and possible harmonic components.

In case of unearthed network, detuning value (I_v) equals the uncompensated earth-fault current due to total network phase-to-earth capacitance value. In case of high resistance earthed network detuning value (I_v) equals the uncompensated earth-

fault current due to total network phase-to-earth capacitance value and the network damping (I_d) value includes losses due to the neutral point resistor.

Estimation of earth-fault current and methods for ensuring its validity are explained next.

Fault current estimation

In IFPTOC the estimation of earth-fault current flowing at the fault location is done utilizing changes in phase currents measured due to an earth fault.

To estimate the earth-fault current magnitude, change in threefold negative-sequence component due to earth fault is calculated (phase A as reference, phase rotation: ABC):

$$\underline{I}_F^{est} = 3 \cdot \underline{I}_2 = \underline{I}_A + \underline{a}^2 \cdot \underline{I}_B + \underline{a} \cdot \underline{I}_C$$

(Equation 109)

$$\underline{I}_F^{est} = 3 \cdot \Delta \underline{I}_2 = \Delta \underline{I}_A + \underline{a}^2 \cdot \Delta \underline{I}_B + \underline{a} \cdot \Delta \underline{I}_C$$

(Equation 110)

$$I_F^{est} = abs(\underline{I}_F^{est})$$

(Equation 111)

Where

$\underline{I}_F^{est}$ = Earth-fault current estimate (phasor)

I_F^{est} = Earth-fault current estimate (magnitude)

$\Delta \underline{I}_A = \underline{I}_A(t_{FLT}) - \underline{I}_A(t_{PRE_FLT})$ = change of phase A current phasor due to earth fault

$\Delta \underline{I}_B = \underline{I}_B(t_{FLT}) - \underline{I}_B(t_{PRE_FLT})$ = change of phase B current phasor due to earth fault

$\Delta \underline{I}_C = \underline{I}_C(t_{FLT}) - \underline{I}_C(t_{PRE_FLT})$ = change of phase C current phasor due to earth fault

$\Delta \underline{I}_2 = \underline{I}_2(t_{FLT}) - \underline{I}_2(t_{PRE_FLT})$ = change of negative sequence-current phasor due to earth fault

$\underline{a}$ = Phase rotation operator = cos(120°) + j·sin(120°)

Applying the “delta” calculation i.e. change in phase currents due to earth fault removes the healthy-state negative-sequence component from earth-fault current estimate, which may exist due to the practical unbalances in load currents and capacitive charging currents. Pre-fault negative-sequence current value is typically rather low in magnitude and constant in time domain, which enables good estimation accuracy regardless of load current level variations, or in case of uncertainty in the exactness of the pre-fault value (e.g. during auto-reclosing cycle).

The validity of memorized pre-fault negative-sequence component value that is utilized in delta calculation becomes poorer in time. There is thus a maximum time defined by the user that delta calculation is valid. This is given with setting

Max Dur delta Calc (maximum duration for delta calculation). After this time is elapsed from initial fault detection moment, then the validity of delta-calculation is not considered to be valid anymore and thus fault current estimation is done without delta calculation i.e. based on real time measurement of threefold negative-sequence component (*Equation 109*). The memorized pre-fault negative-sequence component values are reset when function is reset.

In practical compensated networks, earth-fault current may include a large share of harmonic components, especially during low ohmic faults. In IFPTOC the estimation of earth-fault (EF) current can be done with or without harmonic components. Refer to Figure 5 for illustrating the effect of harmonics on earth-fault current estimate. Measurement of harmonic components can be enabled with setting *Enable harmonics* = “Enable”, “Disable”.

Fundamental frequency component is always included into fault current magnitude estimation, even when setting *Enable harmonics* = “Disable”.

When setting *Enable harmonics* = “Enable”, the included harmonics are (if their magnitudes are sufficient for an accurate measurement): 2nd, 3rd, 5th, 7th and 9th.

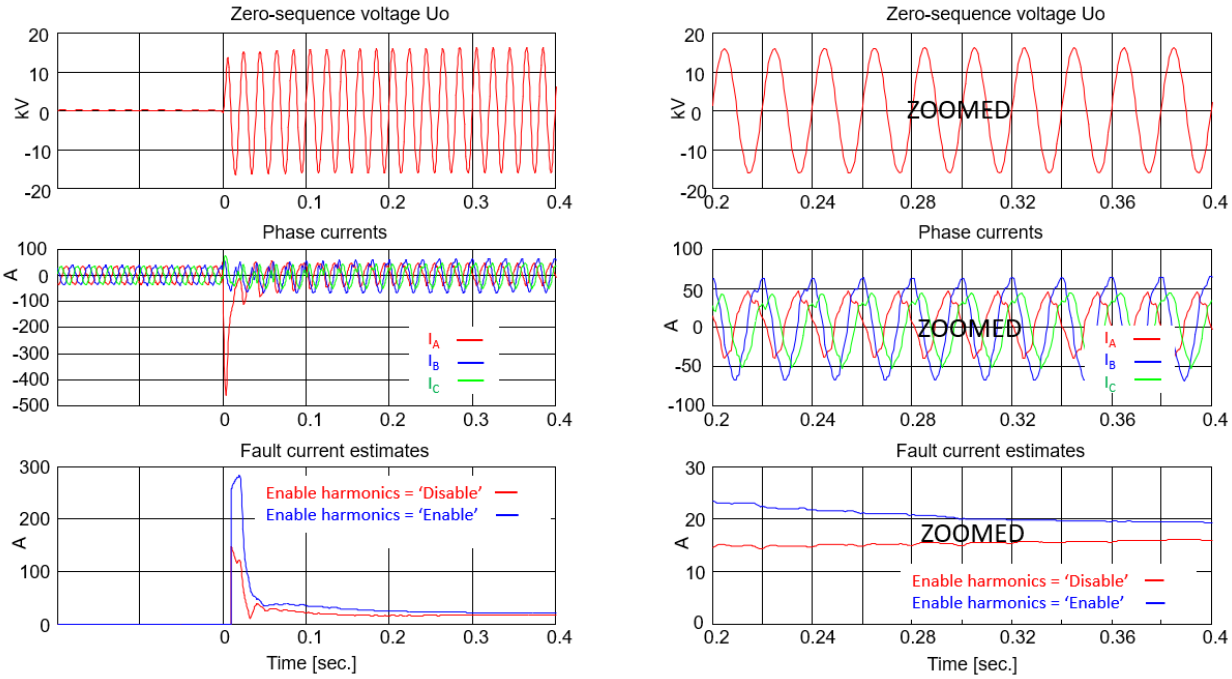

Figure 338: Illustration of earth-fault current estimate with and without harmonics calculation enabled (zoomed view on right hand column)

The harmonic components are only included in the earth-fault current estimate if their magnitudes are sufficient for an accurate measurement i.e. their values exceed minimum predefined value (0.3% from I_n). Also, the effect of harmonics is only taken into account, if the magnitude of fundamental frequency fault current estimate or touch voltage exceeds set start thresholds.

For the earth-fault current estimate magnitude, I_F^{est}, can be written:

When setting *Enable harmonics* = “Disable”:

$$I_F^{est} = \Delta 3I_2^1$$

(Equation 112)

When setting *Enable harmonics* = “Enable”:

$$I_F^{est} = \sqrt{(\Delta 3I_2^1)^2 + (\Delta 3I_2^2)^2 + (\Delta 3I_2^3)^2 + (\Delta 3I_2^5)^2 + (\Delta 3I_2^7)^2 + (\Delta 3I_2^9)^2}$$

(Equation 113)

Where I_2^n is the magnitude of the nth harmonic negative-sequence current component (n = 1, 2, 3, 5, 7 and 9).

In case of frequency adaptive system measurements, only 2nd, 3rd and 5th harmonics are calculated.

In case there is fault resistance included in the fault current path, the effect of fault resistance is to decrease the value of earth-fault current as shown by *Equation 106*.

The downscaling of fault current magnitude can be estimated to be proportional to the magnitude of per unit value of residual voltage, refer to *Equation 106*. With setting *Ena RF Compensation* = “Enable”, user can compensate the effect of fault resistance and then earth-fault current estimate becomes independent of actual fault resistance value. This is done by dividing the fault current estimate with per unit value of residual voltage (< 1pu):

Estimate for “fault resistance compensated” earth-fault current, $I_F^{est_Rfcomp}$:

$$I_F^{est_Rfcomp} = I_F^{est}[A]/Uo[pu]$$

(Equation 114)

This means that with setting *Ena RF Compensation* = “Enable”, regardless of actual fault resistance magnitude, the earth-fault current estimate matches the value that would be valid if the fault would be a galvanic one (fault resistance equals zero). Thanks to this feature the fault is always seen and treated as a galvanic fault regardless of possible fault resistance. This functionality allows acceleration of protection operation speed during high(er) ohmic earth fault when fault current magnitude is low.

In case IFPTOC is used to detect high(er) ohmic earth faults, all start thresholds (*Voltage start value*, *EF current Str Val* or *Touch Vol Str Val*) must be set according to sensitivity requirements. Otherwise *Ena RF Compensation* may not be effective during actual high(er) ohmic earth fault.

In case of setting *Ena RF Compensation* = “Enable”, the effect of harmonics are not taken into account i.e. fault current estimation is based only on fundamental frequency component.

Figure 339 illustrates this concept: In the left-hand column is shown residual voltage, phase currents and fault current estimate during a galvanic earth fault (R_F = 0 ohm). During a galvanic fault U_o equals system nominal phase-to-earth voltage

and has thus value of 1. 0pu (xU_{n_PE}, U_{n_PE} = Nominal phase-to-earth voltage). In the middle column is shown residual voltage, phase currents and fault current estimate during a higher ohmic earth fault (R_F = 3000 ohm). During a higher ohmic earth fault U_o reduces and thus also the magnitude of fault current is reduced. But the magnitude of fault current is reduced proportionally to residual voltage. In the right-hand column the effect of fault resistance is compensated by scaling the fault current estimate by dividing it with the per unit value of residual voltage. With fault resistance compensation, the operation speed of IFPTOC can be accelerated during high(er) ohmic earth faults.

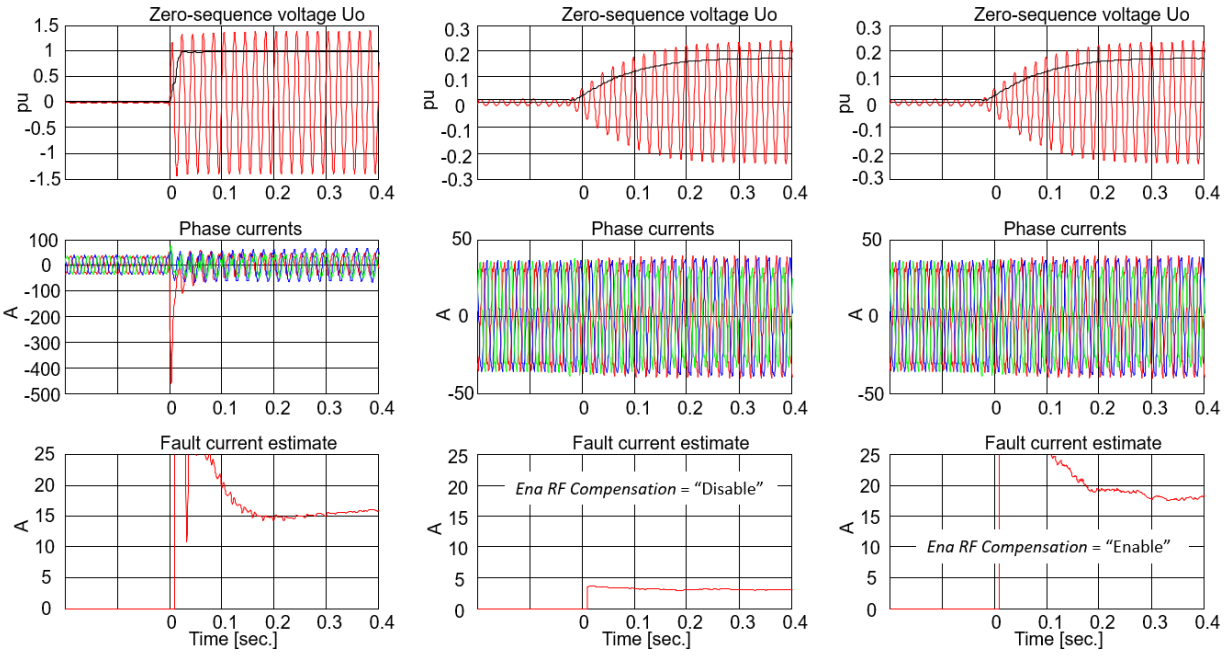

Figure 339: Illustration of fault resistance compensation functionality in IFPTOC. Left-hand column: galvanic earth fault (R_F = 0 ohm). Middle column: a higher ohmic earth fault (R_F = 3000 ohm) with setting Ena R_F Compensation = "Disable". Right-hand column: a higher ohmic earth fault (R_F = 3000 ohm) with setting Ena R_F Compensation = "Enable".

Note that it is the "effective" earth-fault current estimate which determines operation of IFPTOC. "Effective" earth-fault current includes the effect of user setting *Reduction factor*.

Effective earth-fault current estimate, $I_F^{est_eff}$:

$$I_F^{est_eff} = I_F^{est} \cdot Reduction\ factor$$

(Equation 115)

Setting *Reduction factor* is a user defined reduction factor, which can be used to scale down the estimated earth-fault current magnitude. Setting *Reduction factor* allows e.g. consideration that not all the earth-fault current (I_F) will flow back through "remote" earth. See illustration in Figure 7. A portion of the earth-fault current (I_{SCR}) may have alternative return paths, e.g. through cable sheaths/screens. Only current which flows through earth (I_E) will introduce rise of earth potential (earth potential rise, EPR, also called as ground potential rise GPR), which must

be considered from electrical safety perspective. Setting *Reduction factor* = 1.00 means that 100% of earth-fault current flows back through “remote” earth and thus 100% of earth-fault current will introduce rise of earth potential.

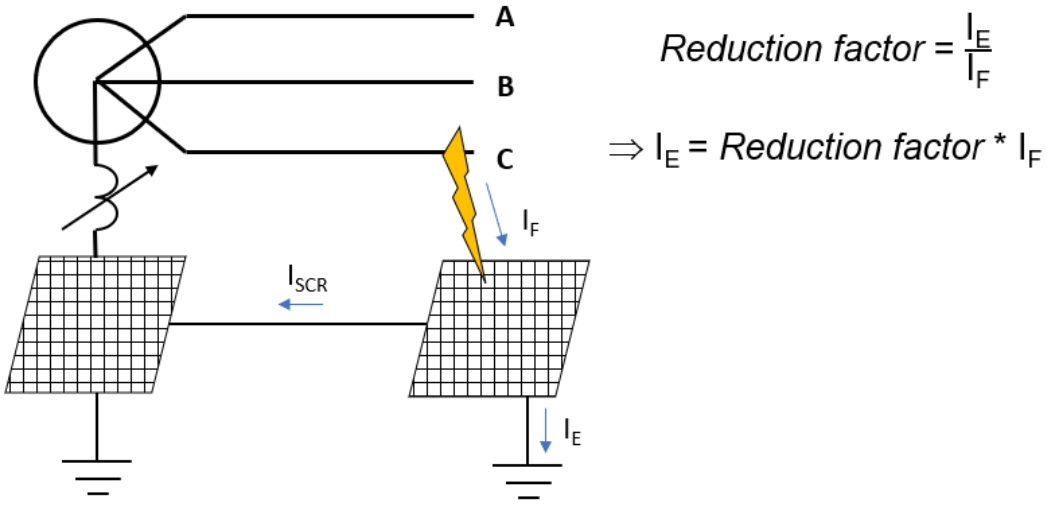

Figure 340: Simplified illustration and explanation of setting Reduction factor. Only fault current which flows through earth (I_E) will introduce rise of earth potential (earth potential rise, EPR, also called as ground potential rise, GPR).

Magnitude of the estimated effective earth-fault current is given in Recorded data:

- *Fault current* (fundamental frequency magnitude)
- *Fault current rms* (rms-value).

In Monitored data the magnitude of estimated effective earth-fault current is given in as:

- *FLT_CURRENT* (fundamental frequency magnitude)
- *FLT_CURR_RMS* (rms-value).

In case of setting *Ena RF Compensation* = “Enable”, actual earth-fault current value affected by fault resistance is then not available in Monitored/Recorded data, but the monitored/recorded current value is fault resistance compensated.

Validity check

Validity of earth-fault current estimate is defined with settings *EF validity Op mode* and *EF validity Min Curr*. *EF validity Op mode* has three options “Resistive”, “Resistive, Reactive” and “No Validity”.

Validity of earth-fault current estimate is based on evaluating the polarity of the measured admittance ($\underline{Y}_o = \underline{I}_o/\underline{U}_o$) at fault ignation. The accuracy of $\underline{I}_o$ and $\underline{U}_o$ should be therefore as good as possible. Especially the measurement of $\underline{I}_o$ should be based on accurate Core Balance CT (CBCT).

The validity of earth-fault current estimate is based on evaluating the polarity of the measured admittance ($\underline{Y}_o = \underline{I}_o/\underline{U}_o$) during the fault ignition moment (during the transient phase of fault). Admittance is calculated utilizing cumulative phasor summing technique (CPS). The measured “transient admittance” is converted into equivalent current value by multiplying it with nominal phase-to-earth voltage value

and then compared with setting *EF validity Min Curr*. The current values used in validity check are called as transient resistive and reactive components and noted as *Transient Ris Comp* and *Transient React Comp* in Recorded data and TR_RIS_COMP and TR_REACT_COMP in Monitored Data.

Validity of earth-fault current estimate is indicated by VALID_EF = TRUE.

In case *EF validity Op mode* = 'Resistive', then validity of earth-fault current estimate is confirmed by evaluating the polarity of the resistive part of measured admittance (real($\underline{Y}_o$) = real($\underline{I}_o/\underline{U}_o$)) during the fault ignition moment (during the transient phase of fault). The measured "transient admittance" is converted into equivalent current value by multiplying it with nominal phase-to-earth voltage value and then compared with setting *EF validity Min Curr*. *EF validity Op mode* = 'Resistive' is valid in compensated systems regardless of compensation degree and also in high resistance earthed systems. Note that situation, when the compensation coil becomes unintentionally disconnected, may result to condition where measured resistive component is not sufficient for validity confirmation. In such case *EF validity Op mode* should be selected as 'Resistive, Reactive'.

In case *EF validity Op mode* = 'Resistive, Reactive', then validity of earth-fault current estimate is confirmed by evaluating the polarity of the resistive (real($\underline{Y}_o$) = real($\underline{I}_o/\underline{U}_o$)) and reactive (imaginary) part (imag($\underline{Y}_o$) = imag($\underline{I}_o/\underline{U}_o$)) of measured admittance during the fault ignition moment (during the transient phase of fault). The measured "transient admittance" is converted into equivalent current value by multiplying it with nominal phase-to-earth voltage value and then compared with setting *EF validity Min Curr*. Either one, resistive or reactive part of measured admittance is used to confirm validity of earth-fault current estimate. *EF validity Op mode* = 'Resistive, Reactive' is valid in compensated, unearthed and in high resistance earthed systems. In compensated systems this criterion is applicable unless the protected feeder is over-compensated i.e. earth-fault current produced by protected feeder is inductive. In such case *EF validity Op mode* must be set to 'Resistive'.

In case *EF validity Op mode* = 'No validity", then validity of earth-fault current estimate is not confirmed and protection operates based on estimated earth-fault current or touch voltage magnitude. *EF validity Op mode* = 'No validity' can be applied e.g. when current measurement is at incomer and when compensation coil with parallel resistor is located at dedicated earthing transformer bay. In this case, during an earth fault in the network, residual current at incomer is zero and thus validity evaluation based on resistive or reactive component is not possible. Thus in order to apply IFPTOC at the incomer, *EF validity Op mode* = 'No validity', must be selected.

Setting *EF validity Min Curr* is given in per unit format with residual current channel primary current as base value. The value should be selected based on following principles:

- In compensated networks *EF validity Min Curr* should be selected based on the known system damping value, in practice e.g. based on the ampere value of the parallel resistor of the coil. For example, if parallel resistor of the coil has rating of 10A, then *EF validity Min Curr* should be smaller than this value with margin, for example 5A. Based on practical experience, value of 3A is found to be suitable for most applications. The value of *EF validity Min Curr* should also be set higher than the transient resistive component generated by the protected feeder during post-fault oscillation to avoid false activations of validity check module in healthy feeders during an earth fault.

  Transient resistive component can be approximated with following equation:

$$real(\underline{Y}_o^{Tr}) = real\left(\frac{I_o}{-\underline{U}_o}\right) = G_{oTot} \cdot \frac{|B_{oFdTot}|}{|B_{oTot}|} - G_{oFdTot}$$

(Equation 116)

where

G_{oTot} = Conductance representing the total system shunt losses, i.e. losses of the coil(s), the parallel resistor and the total network shunt losses.

$|B_{oFdTot}|$ = The sum of absolute values of capacitive and inductive susceptances of the protected feeder. This term represents the energy stored in the LC-branches of the feeder. For example, if the capacitive susceptance of the feeder equals $20A^{cap}$ and the inductive susceptance of the distributed coils at the feeder equal $20A^{ind}$, then the sum of absolute values of susceptances of the feeder equal 40A.

$|B_{oTot}|$ = The sum of absolute values of capacitive and inductive susceptances of the network. This term represents the energy stored in the LC-branches of the total network. For example if capacitive susceptance of the network equal $100A^{cap}$ and the inductive susceptance of the central and distributed coils equal $100A^{ind}$, then the sum of absolute values of susceptances of the network equal 200A.

G_{oFdTot} = Conductance representing the total shunt losses of protected feeder i.e. losses of the coil(s) located at the feeder and natural shunt losses of the feeder.

- In unearthed networks *EF validity Min Curr* should be selected based on the earth-fault current of connected feeders. Value must be smaller than the capacitive earth-fault current due to parallel feeders. Based on practical experience, value of 3A is found to be suitable for most applications.
- In resistance earthed networks *EF validity Min Curr* should be selected based on the value of earthing resistor. Value must be smaller than the ampere value of earthing resistor.

To adapt the earth-fault current validity determination to a possible fault direction change during the fault, for example during manual fault location process, a cyclic accumulation of admittance phasor can be enabled with setting *Ena cyclic reset* = “Enable”. The duration of this evaluation cycle is only few fundamental cycles so that function can rapidly adapt to changes in fault direction. Evaluation is based on monitoring the sign of the accumulation of admittance phasor compared with sign of transient admittance stored at fault ignation. In case change of polarity is detected, and duration of polarity change exceeds setting *Intr EF reset time* and a cyclic accumulation of admittance (real- or imaginary part converted into equivalent current value) exceeds *EF validity Min Curr*, the validity evaluation of earth-fault current estimate is reset and restarted. As default, setting *Ena cyclic reset* = “Enable”.

Information about the validity of earth-fault current estimate is also available in *Recorded data: Valid EF detection*.

Magnitude of transient resistive or reactive current component used in evaluation of earth-fault current validity is given in recorded data as *Transient Ris Comp* and *Transient React Comp* (fundamental frequency magnitude) and in Monitored data as `TR_RIS_COMP` and `TR_REACT_COMP`

(fundamental frequency magnitude). Positive value means that fault is seen inside the protected feeder, negative value means that fault is seen outside the protected feeder.

Touch voltage estimation

After estimate for earth-fault current is calculated and its validity confirmed, then conversion of fault current estimate I_F^{est} into earth potential rise estimate U_{EPR}^{est} is derived using equations below:

Effective earth potential rise estimate:

$$U_{EPR}^{est} = Maximum\ earthing\ Ris \cdot Reduction\ factor \cdot I_F^{est}$$

(Equation 117)

with *Equation 115*, *Equation 117* can also be written as:

$$U_{EPR}^{est} = Maximum\ earthing\ Ris \cdot I_F^{est_eff}$$

(Equation 118)

Where

Setting *Maximum earthing Ris* is a user defined maximum earthing resistance value encountered in the earthings located at the protected feeder. Higher earthing resistance results in higher earth potential rise and touch voltage during the fault.

For estimating the hazardous touch voltage at fault location, U_{TF}^{est}, the estimate of the effective earth potential rise is used:

$$U_{TF}^{est} = U_{EPR}^{est}$$

(Equation 119)

Setting *Reduction factor* enables down scaling of the estimated earth potential rise, which determines operation speed of IFPTOC:

- In case *Reduction factor* = 1, it is assumed that touch voltage equals 100% of earth potential rise.
- In case *Reduction factor* < 1, then it is assumed that touch voltage equals only part of earth potential rise. In this case the value of setting *Reduction factor* depends e.g. on actual reduction effect in the return path of earth-fault current and properties of earthing systems in the protected feeder.

Magnitude of estimated touch voltage is given in Recorded data:

- *Touch voltage* (fundamental frequency magnitude)
- *Touch voltage rms* (rms-value).

In Monitored data the magnitude of estimated touch voltage is given in as:

- `TCH_VOLTAGE` (fundamental frequency magnitude)
- `TCH_VOLT_RMS` (rms-value).

Earth-fault current and touch voltage protection

Based on the practical experience from real earth faults, some faults have re-striking/intermittent characteristics, where the voltage and current waveforms generated by earth fault are rich with harmonics and non-sinusoidal content. In such fault type the operation of IFPTOC can alternatively be based on the counted number of transients instead of estimated fault current or touch voltage. Dedicated functionality to allow this type of operation is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.

Principle based on earth fault current estimate

The operation of IFPTOC based on earth-fault current estimate is described next. In case *Operation principle* = “EF current based”, then operation is based on the estimated effective earth-fault current magnitude taking account the effect of *Reduction factor*. The harmonic content of fault current can be included into estimate with setting *Enable harmonics* = “Enable”.

Operation time can be either definite time or inverse time, selected with setting *Operating curve type* = “Definite time”, “Inverse time EN50522” or “Inverse time IEEE80”.

When *Operating curve type* = “Definite time” is selected, then

- Operate time is according to definite time (DT) operation
- START and ST_EF outputs are activated when estimated earth-fault current magnitude (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *EF current Str Val* and earth fault is detected, and earth-fault current estimate is validated. Note that *Ena RF Compensation* = “Enable” does not affect this start condition. It is important to set setting *EF current Str Val* according to required protection sensitivity.
- OPERATE and OP_EF outputs are activated after operation timer has elapsed, defined with setting *DT stage Op time*.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting *Reset delay time*). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid.
- During re-striking/intermittent earth faults, in case operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms, thus definite time operation is ineffective during re-striking/intermittent earth faults as DT-timer becomes reset between re-strikes. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, EF current Str Val, DT stage Op time* and *Reset delay time*.
- Note that setting *CB Delay Comp* (circuit breaker delay compensation) is not applicable in definite time operation, but it must be taken into account in setting *DT stage Op time*.

Minimum practical value for setting *EF current Str Val* is 0.5% from CT primary current. For example, in case CT primary current is 200 A, then minimum practical value for setting *EF current Str Val* is 0.5%*200A = 1 A. For CT with 400 A primary current, then minimum practical value for setting *EF current Str Val* is 0.5%*400A = 2 A. The lower setting *EF current Str Val* is used, the higher sensitivity in terms of fault resistance

can be obtained. Sensitivity in terms of fault resistance depends also on the network parameters (nominal voltage, damping and detuning) as described by equation below:

$$R_F[ohm] \leq \frac{U_{PE} \cdot \left(\sqrt{I_d^4 + 2I_d^2 \cdot I_v^2 - I_F^2 \cdot I_v^2 + I_v^4} - I_d \cdot I_F \right)}{(I_d^2 + I_v^2) \cdot I_F}$$

(Equation 120)

where U_{PE} is the nominal phase-to-earth voltage [V], I_d is the total system damping [A], I_v is the detuning [A], I_F is setting *EF current Str Val* in primary amperes.

Consider next the following example:

Example 1. Definite time operation of IFPTOC, when Operation principle = “EF current based”, *Operating curve type* = “Definite time” is illustrated in *Figure 341*. In the example, setting *EF current Str Val* = 0.04*In (4 A with primary 100 A) and *DT stage Op time* = 400 ms. *Reduction factor* =1.0. IFPTOC starts when estimated fault current exceeds 4 A and operates after 400 ms, if start conditions are met. For illustrating possible operating speed requirements of protection, limits of touch voltage and earth potential rise durations defined in standard EN50522 scaled into corresponding earth-fault current requirements using the maximum earthing resistance R_{Emax} (setting *Maximum earthing Ris*) encountered in protected feeder are shown for reference.

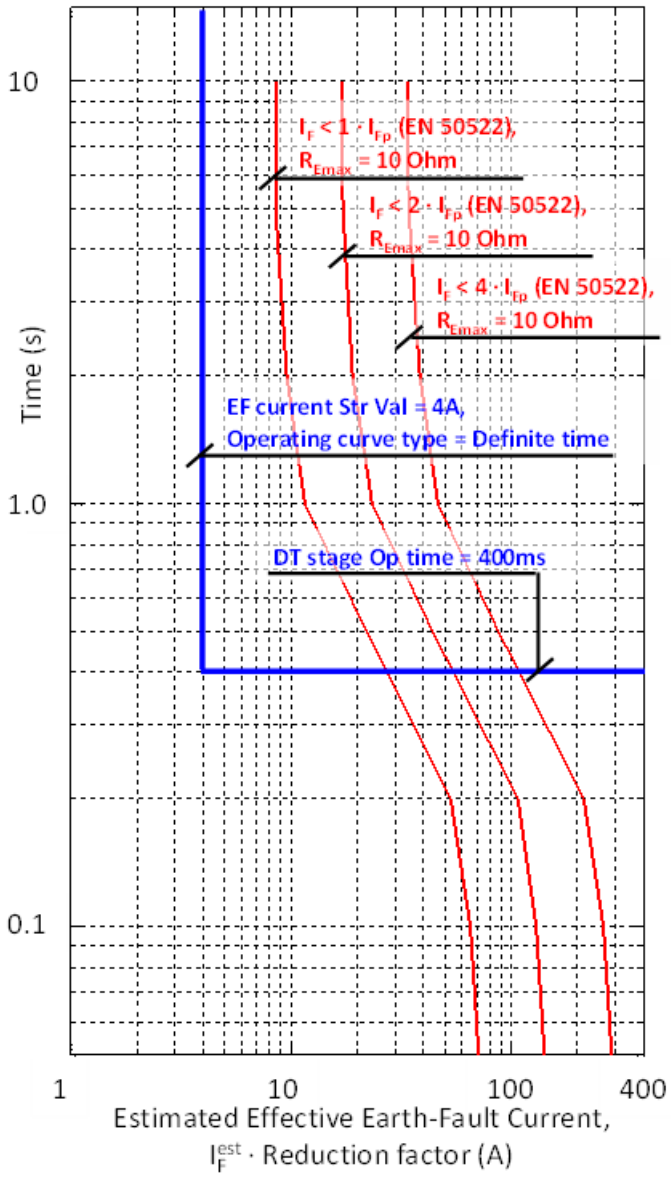

*Figure 341: Example of definite time operation of IFPTOC, when Operation principle = "EF current based", Operating curve type = "Definite time". Settings EF current Str Val = 0.04*In (4A) and DT stage Op time = 400ms. Reduction factor = 1.0. Maximum earthing Ris = 10ohm.*

When *Operating curve type* = "Inverse time EN50522" is selected, then

- Operate time is inverse time according to standard EN50522:

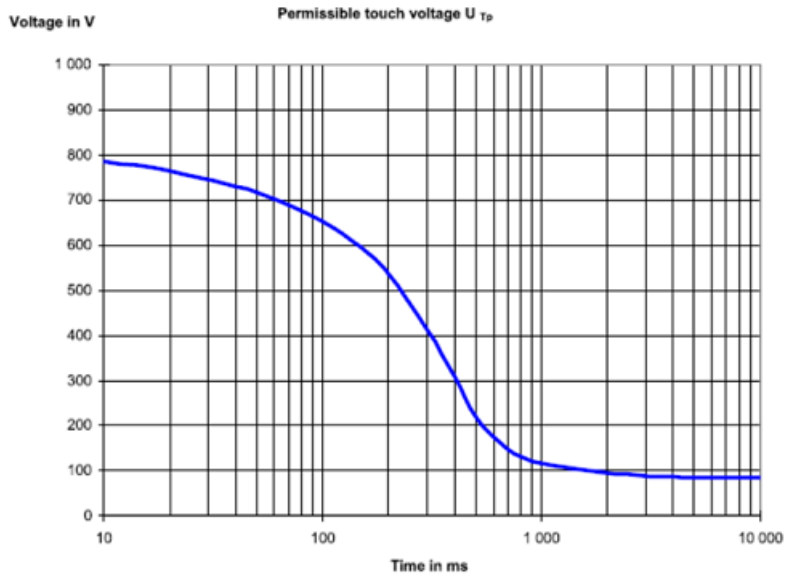

Figure 342: Permissible time-touch voltage characteristics given in standard EN 50522

- Time margin for practical circuit-breaker operate time can be applied with setting *CB delay Comp*. Default time margin is 0 ms.
- START and ST_EF outputs are activated when estimated effective earth-fault current magnitude (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *EF current Str Val* and earth fault is detected, and earth-fault current estimate is validated. Note that *Ena RF Compensation* = “Enable” does not affect this start condition.
- OPERATE and OP_EF outputs are activated according to the operate time - touch voltage and earth potential rise requirements defined in standard EN 50522. i.e. operate time is inversely proportional to the estimated fault current.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting *Reset delay time*). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid. During re-striking/intermittent earth faults, the very high current transient may result to very fast operation times. In case longer operation time during re-striking/intermittent earth faults is preferred and operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, EF current Str Val, CB delay Comp, UTp multiplier, Maximum earthing Ris, IDMT stage Min Op Tm, IDMT stage Max Op Tm, Reset delay time*.

It is important to note, that:

1. Setting *Maximum earthing Ris* is used to scale the touch voltage and earth potential rise requirements defined in standard EN 50522 into corresponding earth-fault current requirements.
2. Setting *UTp multiplier* enables operation based on permissible earth potential rise U_E, by scaling of the permissible time-touch voltage characteristics given in standard EN 50522 with Setting *UTp multiplier*, see table below.

Table 627: Permissible touch voltages U_{Tp} and earth potential rise U_E values given in standard EN50522 converted into equivalent permissible earth-fault current I_{Fp} values as a function of the fault duration t_f. Conversion is made with parameter R_{Emax}, which is the setting *Maximum earthing Ris* in primary ohms i.e. the maximum earthing resistance encountered in protected feeder.

Fault duration t_f [sec.]	Permissible touch voltage, U_{Tp} converted into corresponding permissible fault current, I_{Fp}, U_{Tp} multiplier = 1.0 [A]	Permissible earth potential rise, U_E converted into corresponding permissible fault current, I_{Fp}, U_{Tp} multiplier = 2.0 [A]	Permissible earth potential rise, U_E converted into corresponding permissible fault current, I_{Fp}, U_{Tp} multiplier = 4.0 [A]
0.05	716 V/R_{Emax}	1432 V/R_{Emax}	2864 V/R_{Emax}
0.10	654 V/R_{Emax}	1308 V/R_{Emax}	2616 V/R_{Emax}
0.20	537 V/R_{Emax}	1074 V/R_{Emax}	2148 V/R_{Emax}
0.50	220 V/R_{Emax}	440 V/R_{Emax}	880 V/R_{Emax}
1.00	117 V/R_{Emax}	234 V/R_{Emax}	468 V/R_{Emax}
2.00	96 V/R_{Emax}	192 V/R_{Emax}	384 V/R_{Emax}
5.00	86 V/R_{Emax}	172 V R_{Emax}	344 V/R_{Emax}
10.00	85 V/R_{Emax}	170 V/R_{Emax}	340 V/R_{Emax}

3. Minimum effective earth-fault current magnitude (considering the effect of setting *Reduction factor*), which must be exceeded for the function to start, is defined with setting *EF current Str Val*. It is important to set this value according to required protection sensitivity.
4. With *IDMT stage Min Op Tm* setting user can define minimum allowed operate time for IFPTOC i.e. this is the minimum allowed operate time of IFPTOC.
5. With *IDMT stage Max Op Tm* setting user can define maximum allowed operate time for IFPTOC i.e. this is the maximum allowed operate time of IFPTOC although IDMT timer would define slower operate time.

Parameter defining maximum earthing resistance, setting *Maximum earthing Ris* must be always set in case *Operation principle* = “EF current based” and *Operating curve type* = “Inverse time EN50522” is selected. Setting *Maximum earthing Ris* is needed to scale the touch voltage and earth potential rise requirements defined in standard EN 50522 into corresponding earth-fault current requirements.

Setting *Reduction factor* considers the fact that only part of the earth-fault current (I_F) will flow back through “remote” earth and introduces earth potential rise and touch voltages.

Minimum practical value for setting *EF current Str Val* is 0.5% from CT primary current. For example, in case CT primary current is 200A, then minimum practical value for setting *EF current Str Val* is 0.5%*200 A = 1 A. For CT with 400 A primary current, then minimum practical value

for setting *EF current Str Val* is 0.5%*400 A = 2 A. The lower setting *EF current Str Val* is used, the higher sensitivity in terms of fault resistance can be obtained. Sensitivity in terms of fault resistance depends also on the network parameters (nominal voltage, damping and detuning) as described by *Equation 120*.

When *Operating curve type* = “Inverse time EN50522” is selected, then the protection operate time as a function of estimated effective earth-fault current I_F^{est} (taking into account the effect of settings *Reduction factor* and *Enable harmonics*) is according to equation below:

$$t = 0.29 \times e^{ln\left(-\frac{722.8-\left(\frac{I_F^{est} \times Reduction\ factor \times Maximum\ earthing\ Ris}{UTp\ multiplier}\right)}{85.3-\left(\frac{I_F^{est} \times Reduction\ factor \times Maximum\ earthing\ Ris}{UTp\ multiplier}\right)}\right)/2.39} - CB\ delay\ Comp\ [s]$$

(Equation 121)

In IFPTOC function, the preferred presentation of operation timer characteristics is by plotting the protection operate time as a function of permissible/estimated earth-fault current as illustrated in figures from *Figure 343*, *Figure 344* and *Figure 345*.

Consider next three examples with *Operating curve type* = “Inverse time EN50522”:

Table 628: Comparison of operation times given in EN50522 with IFPTOC. The theoretical operate time of IFPTOC has been calculated assuming CB delay Comp = 0 s

EN50522, U_{tp} [V]	EN50522, t_f [sec]	IFPTOC, t_f Theoretical [sec]
716	0.05	0.04
654	0.1	0.12
537	0.2	0.20
220	0.5	0.50
117	1	1.00
96	2	1.59
86	5	5.02
85	10	8.48

Example 2a. Inverse time operation of IFPTOC, when *Operation principle* = “EF-current based” and *Operating curve type* = “Inverse time EN50522” is illustrated in *Figure 343*. Start value for operation is set to be 0.02*In (2 A if primary 100 A). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms. Setting *UTp multiplier* is 1.0 and setting *Maximum earthing Ris* is 10 ohms. Reduction factor = 1.0. For illustrating the operating speed requirement of protection, limits of touch voltage durations defined in standard EN50522 scaled the into corresponding earth-fault current requirements using the maximum earthing resistance R_{Emax} (setting *Maximum earthing Ris*) encountered in protected feeder are shown for reference.

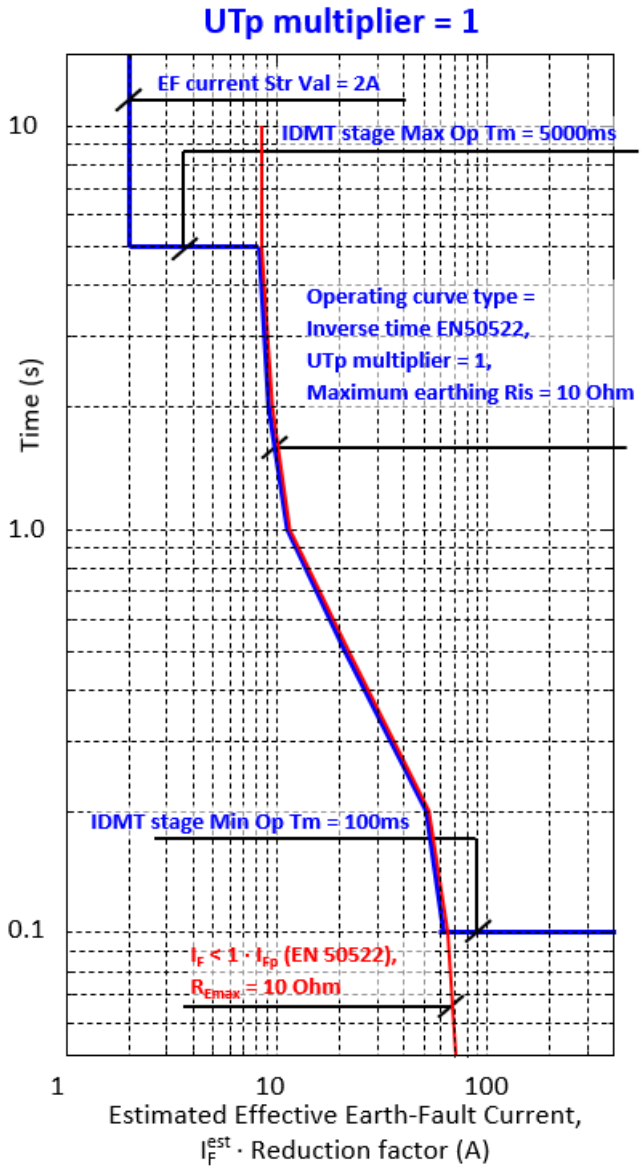

*Figure 343: Operation timer characteristic of IFPTOC function when Operation principle = "EF-current based" and Operating curve type = "Inverse time EN50522". Setting UTp multiplier is 1.0, Maximum earthing Ris = 10ohms, EF current Str Val = 0.02*In (2A), IDMT stage Min Op Tm = 100 ms and IDMT stage Max Op Tm = 5000 ms. Reduction factor = 1.0. Characteristics are according to standard EN50522.*

Example 2b. Inverse time operation of IFPTOC, when *Operation principle* = "EF-current based" and *Operating curve type* = "Inverse time EN50522" is illustrated in *Figure 344*. Start value for operation is set to be 0.04*In (4 A). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms. Setting *UTp multiplier* is 2.0 and setting *Maximum earthing Ris* is 10 ohms. Reduction factor = 1.0. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in standard EN50522 scaled into corresponding earth-fault current requirements using the maximum earthing resistance R_{Emax} (setting *Maximum earthing Ris*) encountered in protected feeder are shown for reference.

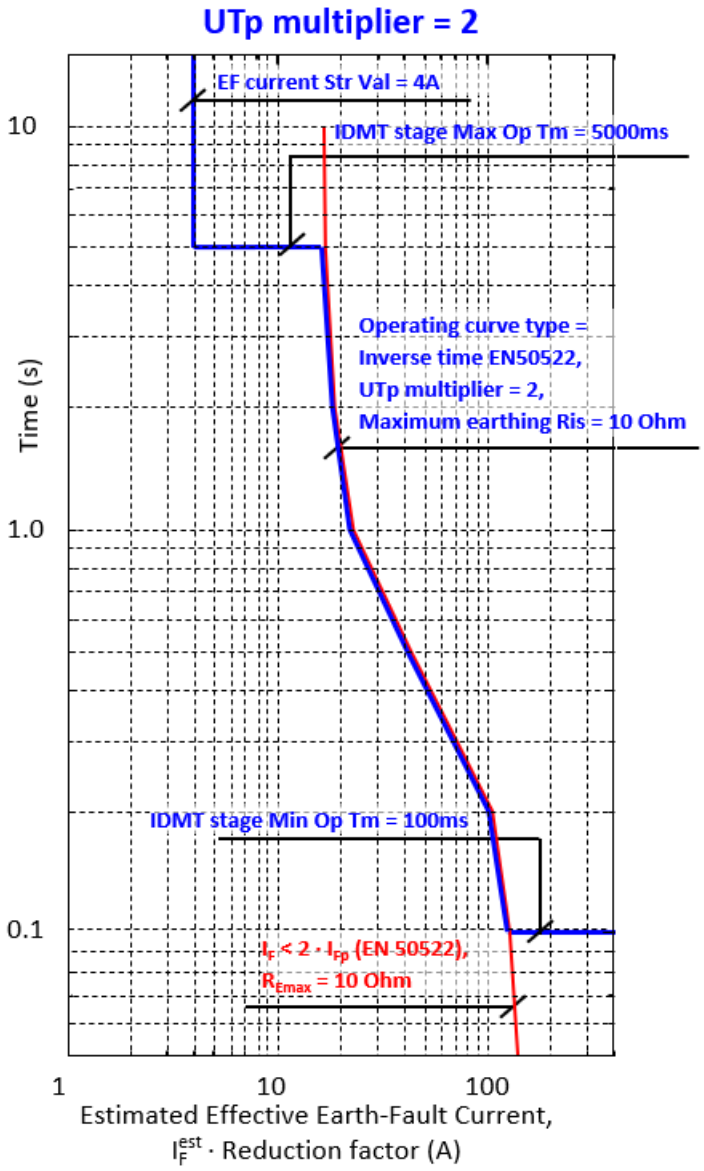

*Figure 344: Operation timer characteristic of IFPTOC function when Operation principle = "EF-current based" and Operating curve type = "Inverse time EN50522". Setting UTp multiplier is 2.0, Maximum earthing Ris = 10 ohms, EF current Str Val = 0.02*In (4 A), IDMT stage Min Op Tm = 100 ms and IDMT stage Max Op Tm = 5000 ms. Reduction factor = 1.0. Characteristics are according to standard EN50522.*

Example 2c. Inverse time operation of IFPTOC, when *Operation principle* = "EF-current based" and *Operating curve type* = "Inverse time EN50522" is illustrated in *Figure 345*. Start value for operation is set to be 0.06*In (6 A). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms. Setting *UTp multiplier* is 4.0 and setting *Maximum earthing Ris* is 10 ohms. Reduction factor = 1.0. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in standard EN50522 scaled into corresponding earth-fault current requirements using the maximum earthing resistance R_{Emax} (setting *Maximum earthing Ris*) encountered in protected feeder are shown for reference.

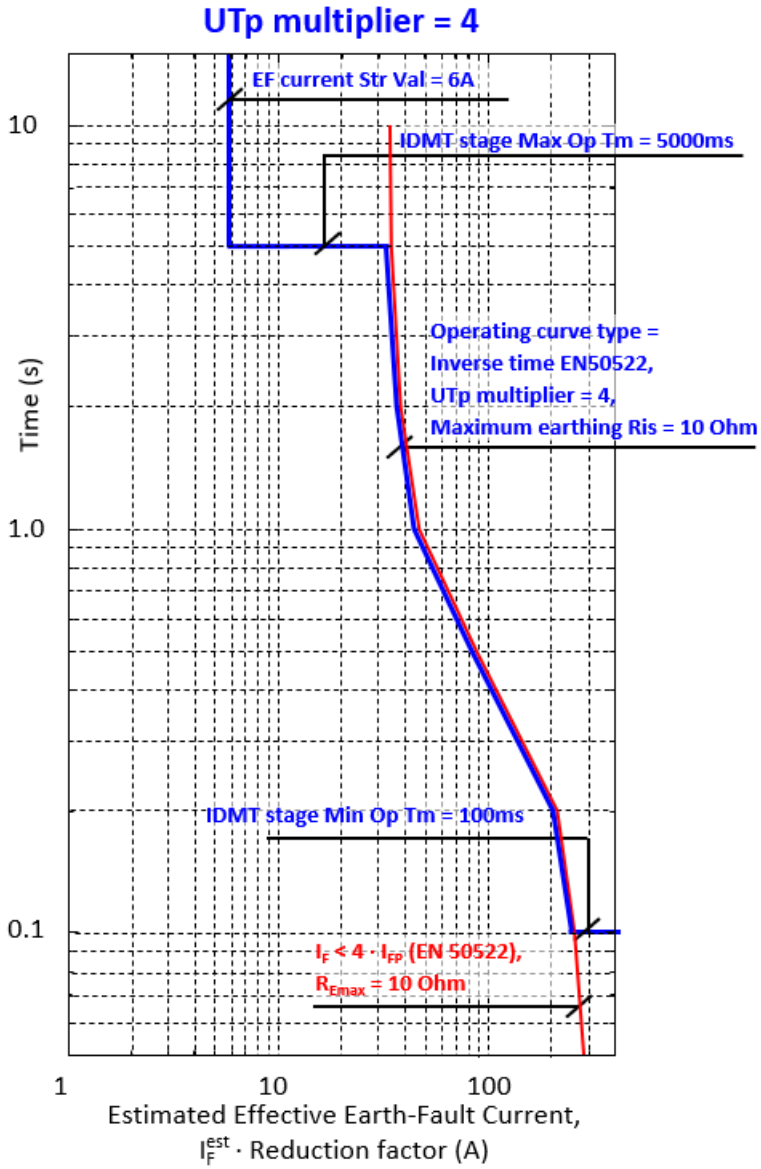

*Figure 345: Operation timer characteristic of IFPTOC function when Operation principle = "EF-current based" and Operating curve type = "Inverse time EN50522". Setting UTp multiplier is 4.0, Maximum earthing Ris = 10 ohms, EF current Str Val = 0.06*In (6 A), IDMT stage Min Op Tm = 100 ms and IDMT stage Max Op Tm = 5000 ms. Reduction factor = 1.0. Characteristics are according to standard EN50522.*

When Operating curve type = "Inverse time IEEE80" is selected, then

- Operate time is inverse time according to standard IEEE80:

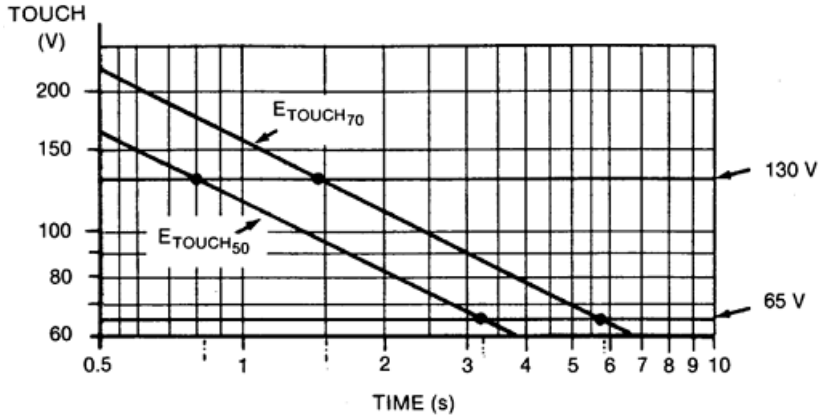

Figure 346: Permissible time-touch voltage characteristics given in standard IEEE80 (metal-to-metal contact)

- This operation mode can be also used when maximum allowed earth potential rise vs. operation speed follows a relationship such as 750 V/√*t*[*sec*].
- Time margin for practical circuit-breaker operate time can be applied with setting *CB delay Comp*. Default setting is 0 ms.
- START and ST_EF outputs are activated when estimated effective earth-fault current magnitude (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *EF current Str Val* and earth fault is detected, and earth-fault current estimate is validated. Note that *Ena RF Compensation* = "Enable" does not affect this start condition. It is important to set setting *EF current Str Val* according to required protection sensitivity.
- OPERATE and OP_EF-outputs are activated so that the operate time is according to the touch voltage requirements defined in standard IEEE80. i.e. operate time is inversely proportional to the estimated fault current.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting *Reset delay time*). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid.
- During re-striking/intermittent earth faults, the very high current transient may result to very fast operation times. In case longer operation during re-striking/ intermittent earth faults is preferred and operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, EF current Str Val, CB delay Comp, IEEE multiplier, Maximum earthing Ris, IDMT stage Min Op Tm, IDMT stage Max Op Tm, Reset delay time*.

According to the standard IEEE80, the values of the permissible touch voltage U_{Tp} as a function of the fault duration t_f are defined as follows:

For body weight of 50kg:

$$U_{Tp} = (1000 + 1.5 \cdot C_s \cdot \rho_s) \cdot \frac{0.116}{\sqrt{t_s}}$$

(Equation 122)

For body weight of 70kg:

$$U_{Tp} = (1000 + 1.5 \cdot C_s \cdot \rho_s) \cdot \frac{0.157}{\sqrt{t_s}}$$

(Equation 123)

where

C_s is the surface layer derating factor

ρ_s is the surface material resistivity in Ω·m

ρ is the resistivity of the earth beneath the surface material in Ω·m

If no protective surface layer is used, then C_s =1 and $\rho_s = \rho$.

The equations of IEEE Std 80-2013 are in IFPTOC-function modelled with following simplified equation, with only one setting *IEEE multiplier*:

$$U_{TF}^{est} = IEEE\ multiplier \cdot \frac{1}{\sqrt{t_s}}$$

(Equation 124)

With setting *IEEE multiplier* the operate time as a function of estimated touch voltage magnitude can be adjusted. For body weight of 70kg, C_s =1, $\rho_s = \rho$ = 0 Ω·m, then *IEEE multiplier* equals 157.0.

In case *Operation principle* = “EF current based”, setting *Maximum earthing Ris* is used to scale the touch voltage and earth potential rise requirements defined in standard IEEE80 into corresponding earth-fault current requirements. When *Operating curve type* = “Inverse time IEEE80” is selected, then the protection operate time as a function of estimated effective earth-fault current I_F^{est} (taking into account the effect of settings *Reduction factor* and *Enable harmonics*) is according to equation below:

$$t = \left(\frac{IEEE\ multiplier}{Maximum\ earthing\ Ris * Reduction\ factor * I_F^{est}} \right)^2 - CB\ delay\ comp\ [s]$$

(Equation 125)

Example numerical values of the permissible touch voltage U_{Tp} converted into corresponding earth-fault current requirements as a function of the fault duration t_f according to standard IEEE80 are shown in table below.

Table 629: Numerical example of the values of the permissible touch voltages U_{Tp} as a function of the fault duration t_f according to standard IEEE80 converted into corresponding permissible earth-fault current values. The numerical values assume body weight of 70 kg, C_s =1, $\rho_s = \rho$ = 0 Ω·m, then IEEE multiplier equals 157. Conversion is made with parameter R_{Emax}, which is the setting *Maximum*

earthing Ris **in primary ohms i.e. the maximum earthing resistance encountered in protected feeder.**

Fault duration t_f [sec.]	Permissible touch voltage, U_{Tp} converted into corresponding permissible fault current, I_{Fp} [A]
0.05	702 V/R_{Emax}
0.10	496 V/R_{Emax}
0.20	351 V/R_{Emax}
0.50	222 V/R_{Emax}
1.00	157 V/R_{Emax}
2.00	111 V/R_{Emax}
5.00	70 V/R_{Emax}
10.00	50 V/R_{Emax}

In some countries, safety during an earth fault is defined in terms of highest allowed earth potential rise (EPR) as a function of fault duration. As an example, in Finnish national Electrical Safety Regulations 89 define highest allowed earth potential rise as a function of fault duration as shown in table below.

Table 630: Highest allowed EPR values based on Electrical Safety

Group	Highest allowed EPR [V], when earth fault is automatically disconnected within time *t* [sec]
a	750V/√*t*
b	2000V/√*t*
c	3000V/√*t*
d	500V/√*t*
e1	750V/√*t*
e2	1000V/√*t*

The regulations of *Table 630* are implemented into IFPTOC. In case *Operation principle* = “EF current based”, setting *Maximum earthing Ris* is used to convert the highest allowed earth potential risevalues into corresponding earth-fault current values. Setting *IEEE multiplier* is set to equal the highest allowed voltage value, for example for group d, *IEEE multiplier* = 500. Conversion of the highest allowed earth potential rise value to the highest allowed earth-fault current magnitude with setting *Maximum earthing Ris* is shown in *Table 631*.

Setting *Maximum earthing Ris* in primary ohms is selected based on the maximum earthing resistance encountered in protected feeder.

Table 631: Conversion of the highest allowed earth potential rise value into corresponding earth-fault current values according to the Electrical Safety Regulations

89 with setting *Maximum earthing Ris* in primary ohms i.e. the maximum earthing resistance encountered in protected feeder.

Group	Highest allowed EPR values [V] converted into corresponding permissible fault current, I_{Fp} [A],when earth fault is automatically disconnected within time t [sec]
a	(750 V/ *Maximum earthing Ris*)/√t
b	(2000 V/ *Maximum earthing Ris*)/√t
c	(3000 V/ *Maximum earthing Ris*)/√t
d	(500 V/ *Maximum earthing Ris*)/√t
e1	(750 V/ *Maximum earthing Ris*)/√t
e2	(1000 V/ *Maximum earthing Ris*)/√t

It is important to note, that:

1. Minimum effective earth-fault current magnitude (considering the effect of *Reduction factor*), which must be exceeded for the function to start, is defined with setting *EF current Str Val*. It is important to set this value according to required protection sensitivity.
2. With *IDMT stage Min Op Tm* setting user can define minimum allowed operate time for IFPTOC i.e. this is the minimum allowed operate time of IFPTOC.
3. With *IDMT stage Max Op Tm* setting user can define maximum allowed operate time for IFPTOC i.e. this is the maximum allowed operate time of IFPTOC although IDMT timer would define slower operate time.

Parameter defining maximum earthing resistance, setting *Maximum earthing Ris* must be always set in case *Operation principle* = “EF current based” and *Operating curve type* = “Inverse time IEEE80” is selected. Setting *Maximum earthing Ris* is needed to scale the touch voltage and earth potential rise requirements defined in standard IEEE80 into corresponding earth-fault current requirements.

Setting *Reduction factor* considers the fact that only part of the earth-fault current (I_F) will flow back through “remote” earth and introduces earthing and touch voltages.

When *Operating curve type* = “Inverse time IEEE80” is selected, then setting *UTp multiplier* is not effective.

Consider next the following example with *Operating curve type* = “Inverse time IEEE80”:

Example 3. Inverse time operation of IFPTOC, when *Operation principle* = “EF-current based” and *Operating curve type* = “Inverse time IEEE80” is illustrated in *Figure 347*. Start value for operation is set to be 0.02*In (2 A). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms. Setting *IEEE multiplier* is 500 and setting *Maximum earthing Ris* is 10 ohms. *Reduction factor* = 1.0. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in Finnish national Electrical Safety Regulations 89 scaled the into corresponding earth-fault current requirements using the maximum earthing resistance R_{Emax} (setting *Maximum earthing Ris*) encountered in protected feeder are shown for reference.

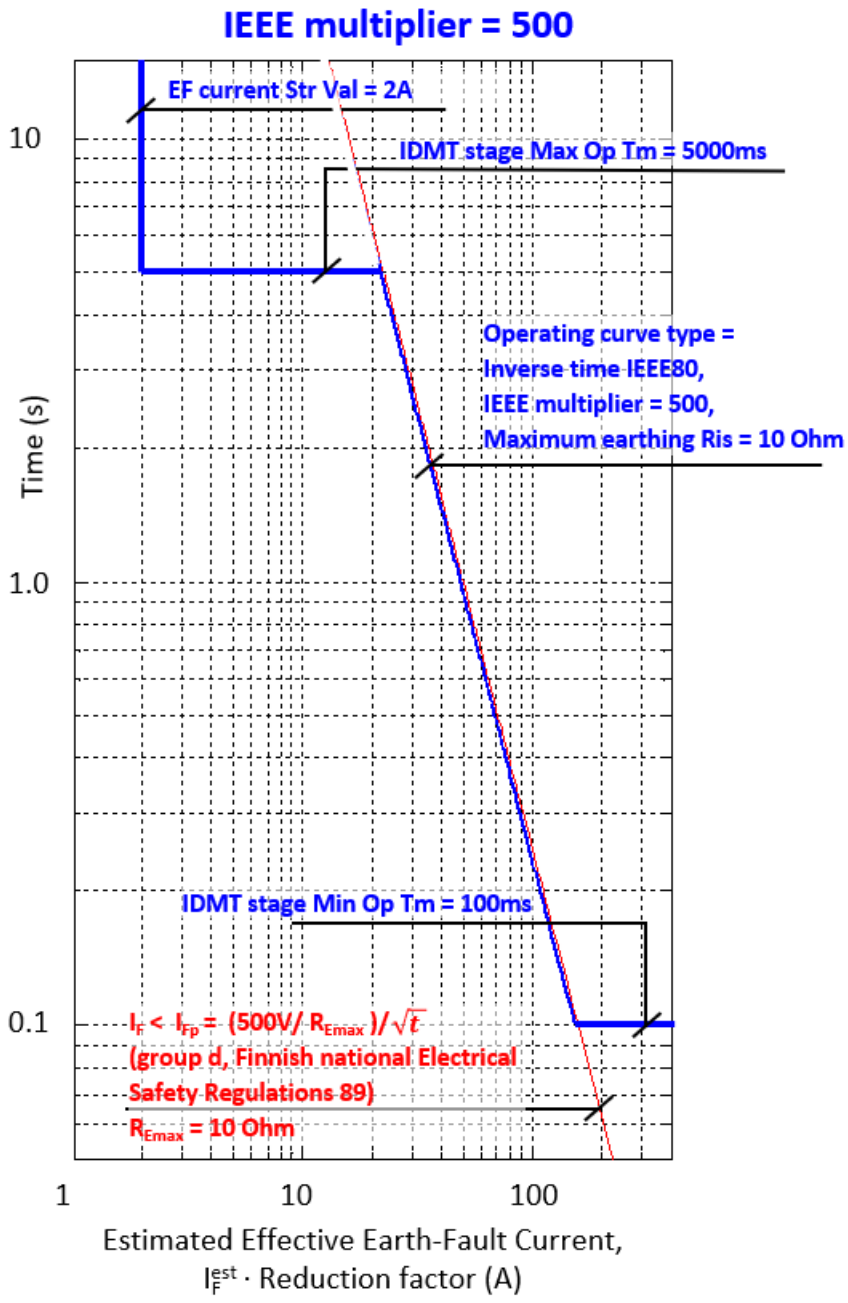

*Figure 347: Operation timer characteristic of IFPTOC-function when Operation principle = "EF-current based" and Operating curve type = "Inverse time IEEE80". Setting IEEE multiplier is 500,Maximum earthing Ris is 10 ohms, EF current Str Val = 0.02*In (2 A), IDMT stage Min Op Tm = 100 ms and IDMT stage Max Op Tm = 5000 ms. Reduction factor = 1.0. Characteristics are according to standard IEEE80.*

Principle based on touch voltage estimate

The operation of IFPTOC based on touch voltage estimate is described next. In case *Operation principle* = "Touch voltage based", then operation is based on the estimated touch voltage magnitude according to *Equation 119*. The harmonic content of touch voltage can be included into estimate with setting *Enable harmonics* = "Enable".

Operation time can be either definite time or inverse time, selected with setting *Operating curve type* = “Definite time”, “Inverse time EN50522” or “Inverse time IEEE80”.

When *Operating curve type* = “Definite time” is selected, then

- Operate time is according to definite time (DT) operation.
- START and ST_EF outputs are activated when estimated touch voltage (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *Touch Vol Str Val* and earth fault is detected and earth-fault current estimate is validated. Note that *Ena RF Compensation* = “Enable” does not affect this start condition. It is important to set setting *Touch Vol Str Val* according to required protection sensitivity.
- OPERATE and OP_EF outputs are activated after *Operation timer* has elapsed, defined with setting *DT stage Op time*.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting Reset delay time). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid.
- During re-striking/intermittent earth faults, in case operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms, thus definite operation is ineffective during re-striking/intermittent earth faults. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, Maximum earthing Ris, Touch Vol Str Val, DT stage Op time, Reset delay time*.
- Note that setting *CB Delay Comp* (circuit breaker delay compensation) is not applicable in definite time operation.

Consider next the following example:

Example 4. Setting *Touch Vol Str Val* = 40 V and *DT stage Op time* = 400 ms. IFPTOC starts when estimated touch voltage exceeds 40 V and operates after 400 ms, if start conditions are met. Maximum earthing resistance value encountered in the protected feeder is set to be 10 ohms (setting *Maximum earthing Ris*) and *Reduction factor* = 1. For illustrating possible operating speed requirements of protection, limits of touch and earth potential rise durations defined in standard EN50522 are shown for reference.

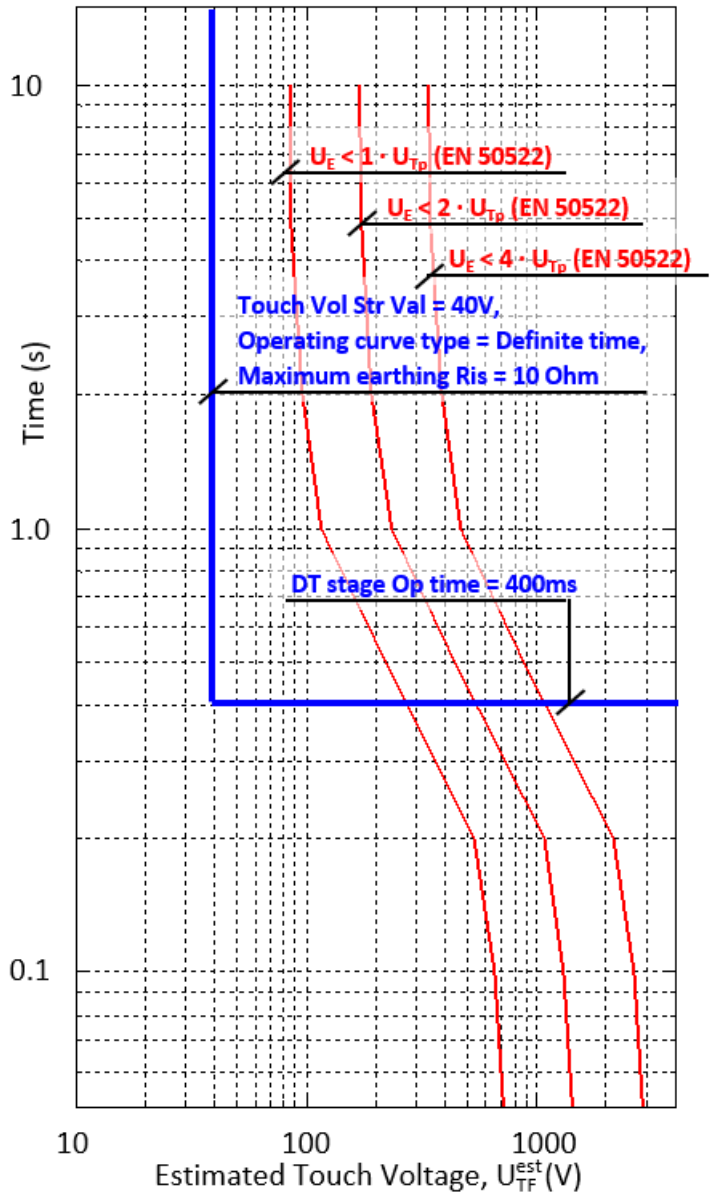

Figure 348: Example of definite time operation of IFPTOC, when Operation principle = "Touch voltage based", Operating curve type = "Definite time". Setting Touch Vol Str Val = 40 V and DT stage Op time = 400 ms. Maximum earthing Ris = 10 ohm

Parameter defining maximum earthing resistance, setting *Maximum earthing Ris* must be always set in case *Operation principle* = "Touch voltage based" and *Operating curve type* = "Definite time" is selected. Setting *Maximum earthing Ris* is needed to scale the estimated earth-fault current value into corresponding touch voltage or earth potential rise value.

When *Operating curve type* = "Inverse time EN50522" is selected, then

- Operate time is inverse time according to standard EN50522:

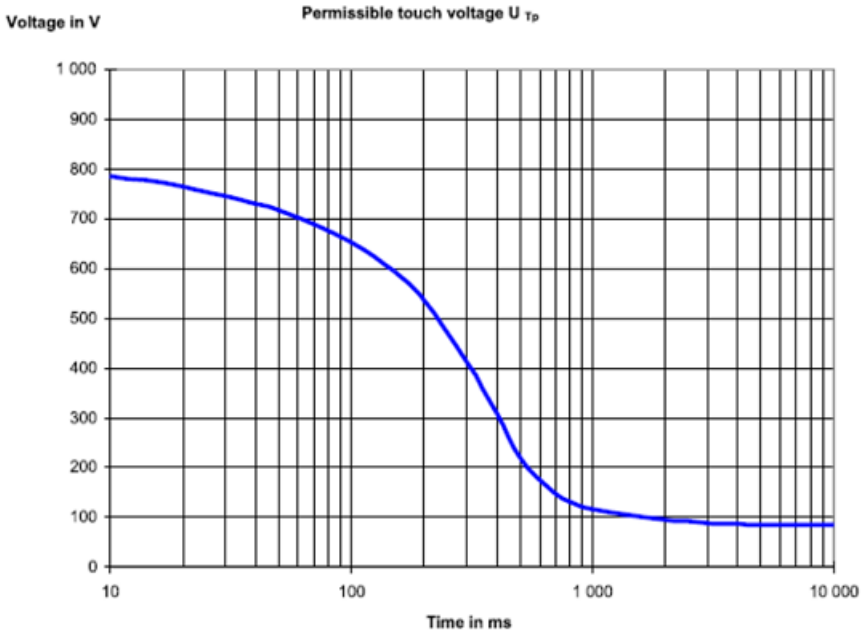

Figure 349: Permissible time-touch voltage characteristics given in standard EN 50522

- Time margin for practical circuit-breaker operate time can be applied with setting *CB delay Comp*. Default setting is 0 ms.
- START and ST_EF outputs are activated when estimated touch voltage (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *Touch Vol Str Val* and earth fault is detected and earth-fault current estimate is validated. Note that *Ena RF Compensation* = “Enable” does not affect this start condition.
- OPERATE and OP_EF outputs are activated according to time-touch voltage characteristics given in standard EN 50522 i.e. operate time is inversely proportional to the estimated touch voltage.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting Reset delay time). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid.
- During re-striking/intermittent earth faults, the very high current transient may result to very fast operation times. In case longer operation during re-striking/intermittent earth faults is preferred and operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, Maximum earthing Ris, Touch Vol Str Val, CB delay Comp, UTp multiplier, IDMT stage Min Op Tm, IDMT stage Max Op Tm, Reset delay time*.

It is important to note, that:

1. Settings *Reduction factor* and *Maximum earthing Ris* are used to scale the estimated effective earth-fault current value into corresponding touch voltage or earth-potential rise estimate.
2. Setting *UTp multiplier* enables operation based on permissible earth potential rise U_E, by scaling of the permissible time-touch voltage characteristics given in standard EN 50522 with Setting *UTp multiplier*, see table below.

Table 632: Permissible touch voltages U_{Tp} and earth potential rise U_E values as a function of the fault duration t_f according to standard EN50522 with U_{Tp} multiplier as a parameter

Fault duration t_f [sec.]	Permissible touch voltage, U_{Tp}, U_{Tp} multiplier = 1.0 [V]	Permissible earth potential rise, U_E, U_{Tp} multiplier = 2.0 [V]	Permissible earth potential rise, U_E, U_{Tp} multiplier = 4.0 [V]
0.05	716	1432	2864
0.10	654	1308	2616
0.20	537	1074	2148
0.50	220	440	880
1.00	117	234	468
2.00	96	192	384
5.00	86	172	344
10.00	85	170	340

3. Minimum touch voltage or earth potential rise magnitude (considering the effect of *Reduction factor*), which must be exceeded for the function to start, is defined with setting *Touch Vol Str Val*. It is important to set setting *Touch Vol Str Val* according to required protection sensitivity.
4. With *IDMT stage Min Op Tm* setting user can define minimum allowed operate time for IFPTOC i.e. this is the minimum allowed operate time of IFPTOC.
5. With *IDMT stage Max Op Tm* setting user can define maximum allowed operate time for IFPTOC i.e. this is the maximum allowed operate time of IFPTOC although IDMT timer would define slower operate time.

Parameter defining maximum earthing resistance, setting *Maximum earthing Ris* must be always set in case *Operation principle* = “Touch voltage based” and *Operating curve type* = “Inverse time EN50522” is selected. Setting *Maximum earthing Ris* is needed to scale the estimated effective earth-fault current value to corresponding touch voltage or earth potential rise value.

Setting *Reduction factor* considers the fact that only part of the earth-fault current (I_F) will flow back through “remote” earth and introduces earthing and touch voltages.

Minimum practical value for setting *Touch Vol Str Val* is 0.5% of CT primary current multiplied by setting *Maximum earthing Ris*. For example, in case CT primary current is 200 A, and *Maximum earthing Ris* = 10 ohm, then minimum practical value for setting *Touch Vol Str Val* is 0.5%*200 A*10 ohm = 10 V. For CT with 400 A primary current, then minimum practical value for setting *Touch Vol Str Val* is 0.5%*400 A*10 ohm = 20 V. The lower setting *Touch Vol Str Val* is used, the higher sensitivity in terms of fault resistance can be obtained. Sensitivity

in terms of fault resistance depends also on the network parameters (nominal voltage, damping and detuning) as described by *Equation 126*.

$$R_F[ohm] \leq \frac{U_{PE}\cdot\left(\sqrt{I_d^4+2I_d^2\cdot I_v^2-(U_F/R_E)^2\cdot I_v^2+I_v^4}-I_d\cdot(U_F/R_E)\right)}{(I_d^2+I_v^2)\cdot(U_F/R_E)}$$

(Equation 126)

where U_{PE} is the nominal phase-to-earth voltage [V], I_d is the total system damping [A], I_v is the detuning [A], U_F is setting *Touch Vol Str Val* in primary volts and R_E is setting *Maximum earthing Ris* in primary ohms.

When *Operating curve type* = "Inverse time EN50522" is selected, then the protection operate time as a function of estimated touch voltage U_{TF}^{est} (taking account the effect of *Reduction factor*) is according to *Equation 127*:

$$t = 0.29 \times e^{ln\left(-\frac{722.8-\left(\frac{U_{TF}^{est}}{UTp\ multiplier}\right)}{85.3-\left(\frac{U_{TF}^{est}}{UTp\ multiplier}\right)}\right)/2.39} - CB\ delay\ comp\ [s]$$

(Equation 127)

In IFPTOC function, the preferred presentation of operation timer characteristics is by plotting the protection operate time as a function of permissible/estimated touch voltage as illustrated in *Figure 350*, *Figure 351* and *Figure 352*.

Consider next three examples with *Operating curve type* = "Inverse time EN50522":

Example 5a. Inverse time operation of IFPTOC, when *Operation principle* = "Touch voltage based", *Operating curve type* = "Inverse time EN50522" and setting *UTp multiplier* = 1.0 is illustrated in *Figure 350*. Start value for operation is set to be 20 V (setting *Touch Vol Str Val*). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms (settings *IDMT stage Min Op Tm, IDMT stage Max Op Tm*). Maximum earthing resistance value encountered in the protected feeder is set to be 10 ohms (setting *Maximum earthing Ris*) and Reduction factor = 1. For illustrating the operating speed requirement of protection, limits of touch voltage durations defined in standard EN50522 are shown for reference.

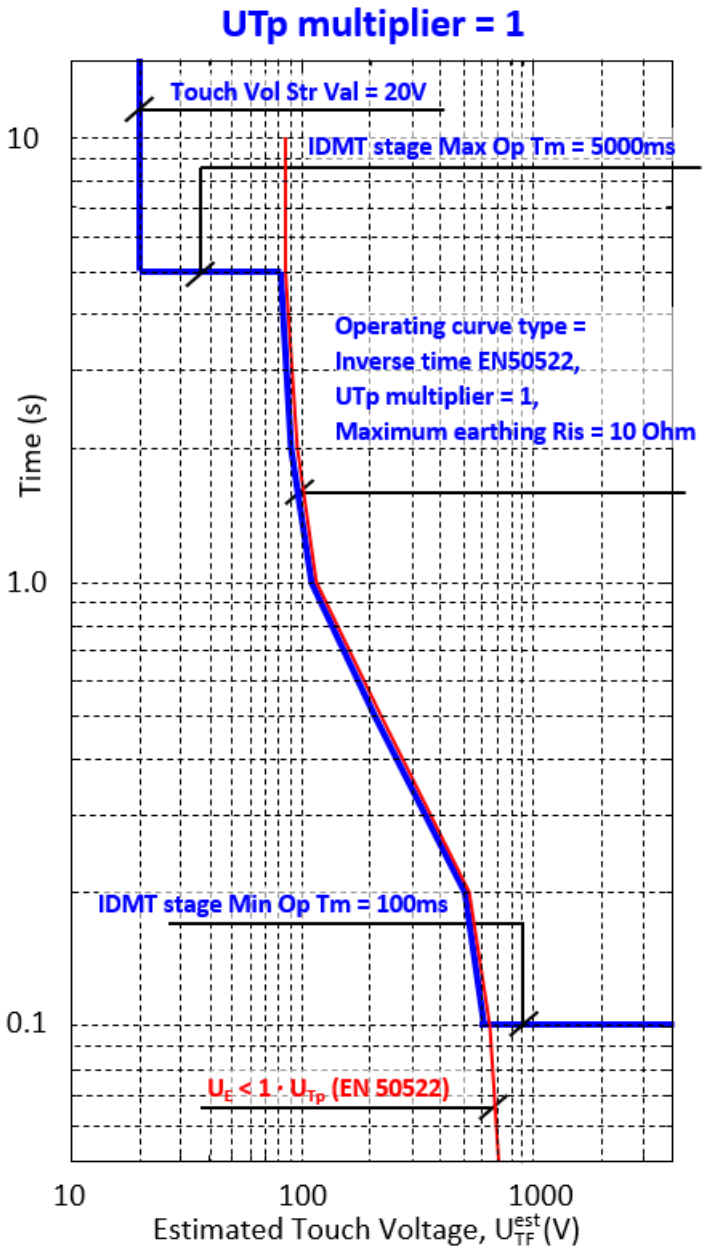

Figure 350: Operation timer characteristic of IFPTOC function when Operation principle = "Touch voltage based", Operating curve type = "Inverse time EN50522" and Operating curve type = 1.0. Characteristics are according to standard EN50522. Maximum earthing Ris = 10 ohm.

Example 5b. Inverse time operation of IFPTOC, when *Operation principle* = "Touch voltage based", *Operating curve type* = "Inverse time EN50522" and setting *UTp multiplier* = 2.0 is illustrated in *Figure 351*. Start value for operation is set to be 40 V (setting *Touch Vol Str Val*). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms (settings *IDMT stage Min Op Tm, IDMT stage Max Op Tm*). Maximum earthing resistance value encountered in the protected feeder is set to be 10 ohms (setting *Maximum earthing Ris*) and *Reduction factor* = 1. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in standard EN50522 are shown for reference.

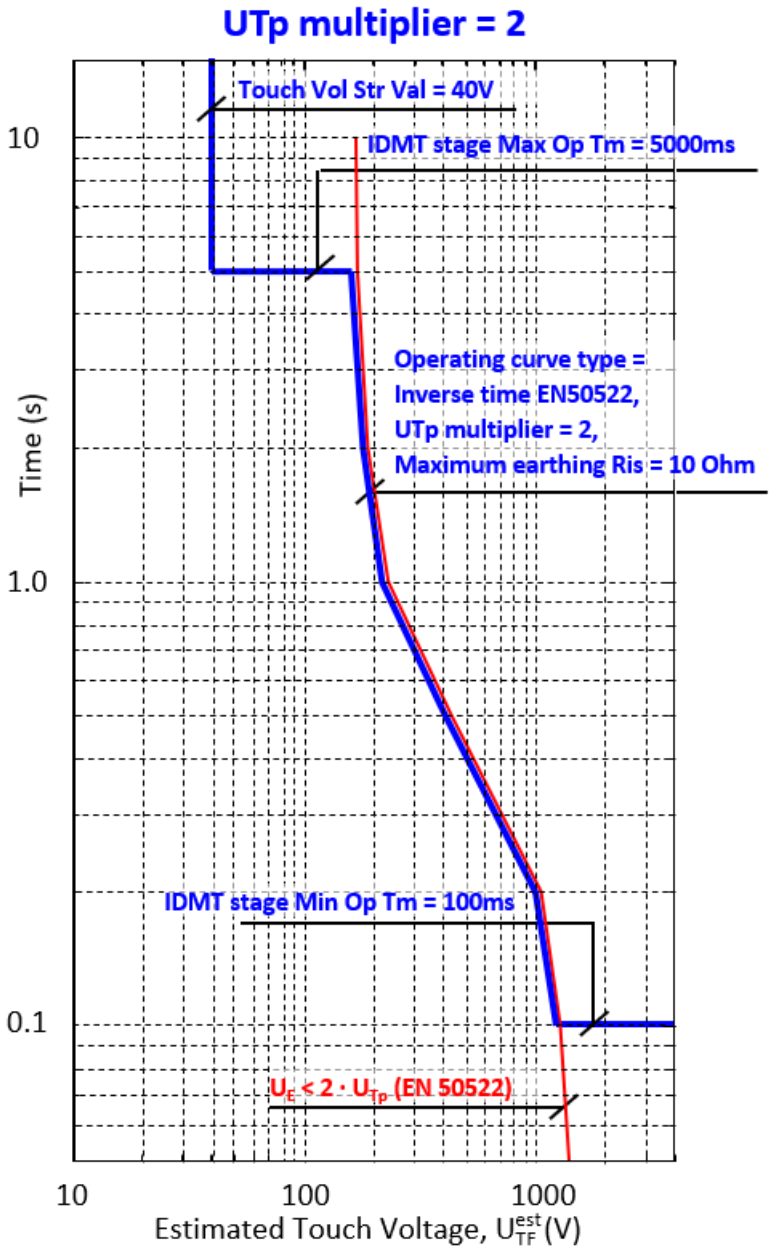

Figure 351: Operation timer characteristic of IFPTOC function when Operation principle = "Touch voltage based", Operating curve type = "Inverse time EN50522" and UTp multiplier = 2.0. Characteristics are according to standard EN50522. Maximum earthing Ris = 10 ohm.

Example 5c. Inverse time operation of IFPTOC, when *Operation principle* = "Touch voltage based", *Operating curve type* = "Inverse time EN50522" and setting *UTp multiplier* = 4.0 is illustrated in *Figure 352*. Start value for operation is set to be 60 V (setting *Touch Vol Str Val*). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms (settings *IDMT stage Min Op Tm, IDMT stage Max Op Tm*). Maximum earthing resistance value encountered in the protected feeder is set to be 10 ohms (setting *Maximum earthing Ris*) and *Reduction factor* = 1. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in standard EN50522 are shown for reference.

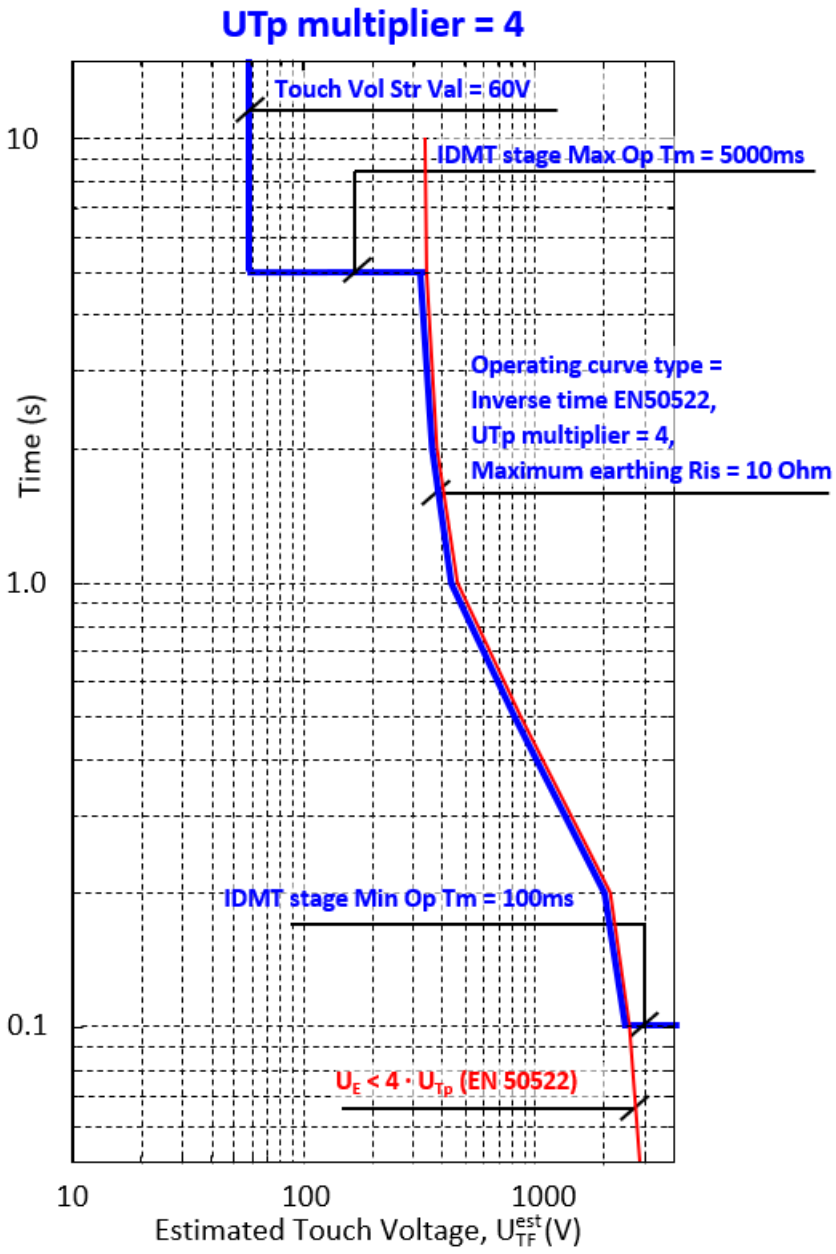

Figure 352: Operation timer characteristic of IFPTOC function when Operation principle = "Touch voltage based", Operating curve type = "Inverse time EN50522" and UTp multiplier = 4.0. Characteristics are according to standard EN50522. Maximum earthing Ris = 10 ohm.

When *Operating curve type* = "Inverse time IEEE80" is selected, then

- Operate time is inverse time according to standard IEEE80:

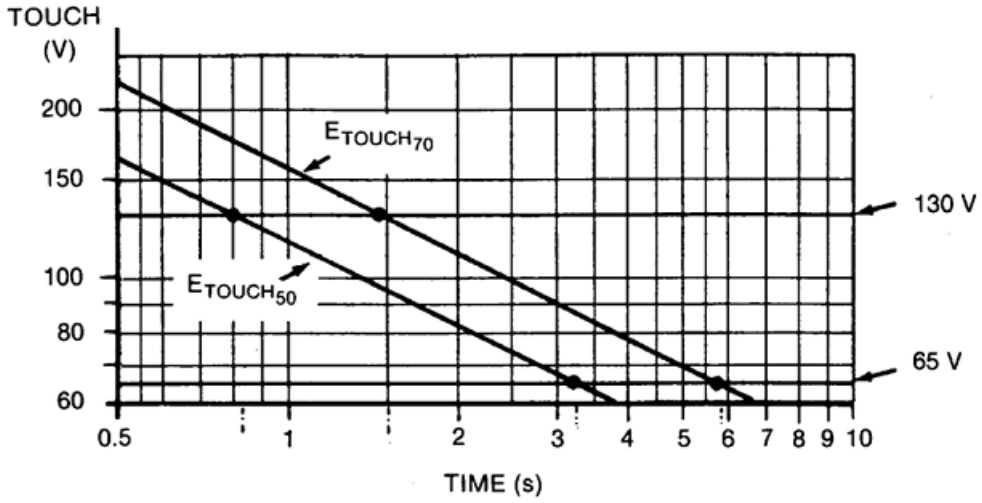

Figure 353: Permissible time-touch voltage characteristics given in standard IEEE80 (metal-to-metal contact).

- This operation mode can be also used when maximum allowed earthing voltage, i.e. earth potential rise, vs. operation speed follows a relationship such as 750V/√*t*[*sec*].
- Time margin for practical circuit-breaker operate time can be applied with setting *CB delay Comp*. Default setting is 0 ms.
- START and ST_EF outputs are activated when estimated touch voltage (considering the effect of settings *Reduction factor* and *Enable harmonics*) exceeds setting *Touch Vol Str Val* and earth fault is detected and earth-fault current estimate is validated. Note that *Ena RF Compensation* = “Enable” does not affect this start condition.
- OPERATE and OP_EF outputs are activated according to time-touch voltage characteristics given in standard IEEE80 i.e. operate time is inversely proportional to the estimated touch voltage.
- Reset timer is started if any of the above conditions for START is not anymore valid. START and ST_EF outputs stay activated until the reset timer expires (setting *Reset delay time*). After OPERATE output activation, START, ST_EF, OPERATE and OP_EF outputs are reset immediately i.e. reset delay time is no longer valid.
- During re-striking/intermittent earth faults, the very high current transient may result to very fast operation times. In case longer operation during re-striking/ intermittent earth faults is preferred and operation should be based preferably on counted number of transients, then setting *Reset delay time* should be set to low value, say 20-40 ms. Dedicated intermittent earth-fault protection functionality based on counted number of transients is described in *Chapter 4.2.10.5.6 Intermittent earth-fault protection*.
- Applicable settings are: *Reduction factor, Maximum earthing Ris, Touch Vol Str Val, CB delay Comp, IEEE multiplier, IDMT stage Min Op Tm, IDMT stage Max Op Tm, Reset delay time*.

According to the standard IEEE80, the values of the permissible touch voltage U_{Tp} as a function of the fault duration t_f are defined as follows:

For body weight of 50 kg:

$$U_{Tp} = (1000 + 1.5 \cdot C_s \cdot \rho_s) \cdot \frac{0.116}{\sqrt{t_s}}$$

(Equation 128)

For body weight of 70 kg:

$$U_{Tp} = (1000 + 1.5 \cdot C_s \cdot \rho_s) \cdot \frac{0.157}{\sqrt{t_s}}$$

(Equation 129)

where

C_s is the surface layer derating factor

ρ_s is the surface material resistivity in Ω·m

ρ is the resistivity of the earth beneath the surface material in Ω·m

If no protective surface layer is used, then C_s =1 and ρ_s = ρ.

The equations of IEEE Std 80-2013 are in IFPTOC function modelled with following simplified equation, with only one parameter *IEEE multiplier*:

$$U_{TF}^{est} = IEEE\ multiplier \cdot \frac{1}{\sqrt{t_s}}$$

(Equation 130)

With setting *IEEE multiplier* operate time as a function of estimated touch voltage magnitude can be adjusted. For body weight of 70 kg, C_s =1, ρ_s = ρ = 0 Ω·m, then *IEEE multiplier* equals 157.0.

In IFPTOC, the protection operate time t as a function of estimated touch voltage U_{TF}^{est} according to standard IEEE80 follows equation below:

$$t = \left(\frac{IEEE\ multiplier}{U_{TF}^{est}}\right)^2 - CB\ delay\ comp\ [s]$$

(Equation 131)

Example numerical values of the permissible touch voltage U_{Tp} as a function of the fault duration t_f according to standard IEEE80 are shown in *Table 633*. Values in *Table 633* assume body weight of 70 kg, C_s =1, ρ_s = ρ = 0 Ω·m, then IEEE multiplier equals 157.0.

Table 633: Numerical example of the values of the permissible touch voltages U_{Tp} as a function of the fault duration t_f according to standard IEEE80 programmed

into IFPTOC. The numerical values assume body weight of 70 kg, C_s =1, ρ_s = ρ = 0 Ω·m, then *IEEE multiplier* equals 157.

Fault duration t_f [sec.]	Permissible touch voltage, U_{Tp} [V]
0.05	702
0.10	496
0.20	351
0.50	222
1.00	157
2.00	111
5.00	70
10.00	50

In some countries, safety during an earth fault is defined in terms of highest allowed earth potential rise (EPR) as a function of fault duration. As an example, in Finnish national Electrical Safety Regulations 89 define highest allowed earth potential rise (EPR) as a function of fault duration as shown in table below.

Table 634: Highest allowed EPR value based on Electrical Safety Regulations 89

Group	Highest allowed EPR [V], when earth-fault is automatically disconnected within time *t* [sec]
a	750V/√*t*
b	2000V/√*t*
c	3000V/√*t*
d	500V/√*t*
e1	750V/√*t*
e2	1000V/√*t*

The regulations of *Table 634* are implemented into IFPTOC. Setting *IEEE multiplier* is set to equal the highest allowed voltage value, for example for group d, *IEEE multiplier* = 500.

It is important to note, that:

1. Minimum effective touch-voltage magnitude (considering the effect of *Reduction factor*), which must be exceeded for the function to start, is defined with setting *Touch Vol Str Val*. It is important to set setting *Touch Vol Str Val* according to required protection sensitivity.
2. With *IDMT stage Min Op Tm* setting user can define minimum allowed operate time for IFPTOC i.e. this is the minimum allowed operate time of IFPTOC.
3. With *IDMT stage Max Op Tm* setting user can define maximum allowed operate time for IFPTOC i.e. this is the maximum allowed operate time of IFPTOC although IDMT timer would define slower operate time.

Parameter defining maximum earthing resistance, setting *Maximum earthing Ris* must be always set in case *Operation principle* = “Touch voltage based” and *Operating curve type* = “Inverse time IEEE80” is selected. Setting *Maximum earthing Ris* is needed to scale the estimated earth-fault current value into corresponding touch voltage or earth potential rise value.

Setting *Reduction factor* considers the fact that only part of the earth-fault current (I_F) will flow back through “remote” earth and introduces earth potential rise and touch voltages.

When *Operating curve type* = “Inverse time IEEE80” is selected, then setting *UTp multiplier* is not effective.

Consider next the following example with Operating curve type = “Inverse time IEEE80”:

Example 6. Inverse time operation of IFPTOC, when *Operation principle* = “Touch voltage based”, *Operating curve type* = “Inverse time IEEE80” and setting *IEEE multiplier* = 500 is illustrated in *Figure 354*. Start value for operation is set to be 20 V (setting *Touch Vol Str Val*). IFPTOC is set to have minimum operate time 100 ms and maximum operate time of 5000 ms (settings *IDMT stage Min Op Tm, IDMT stage Max Op Tm*). Maximum earthing resistance value encountered in the protected feeder is set to be 10 ohms (setting *Maximum earthing Ris*) and *Reduction factor* = 1. For illustrating the operating speed requirement of protection, limits of earth potential rise durations defined in Finnish national Electrical Safety Regulations 89 are shown for reference.

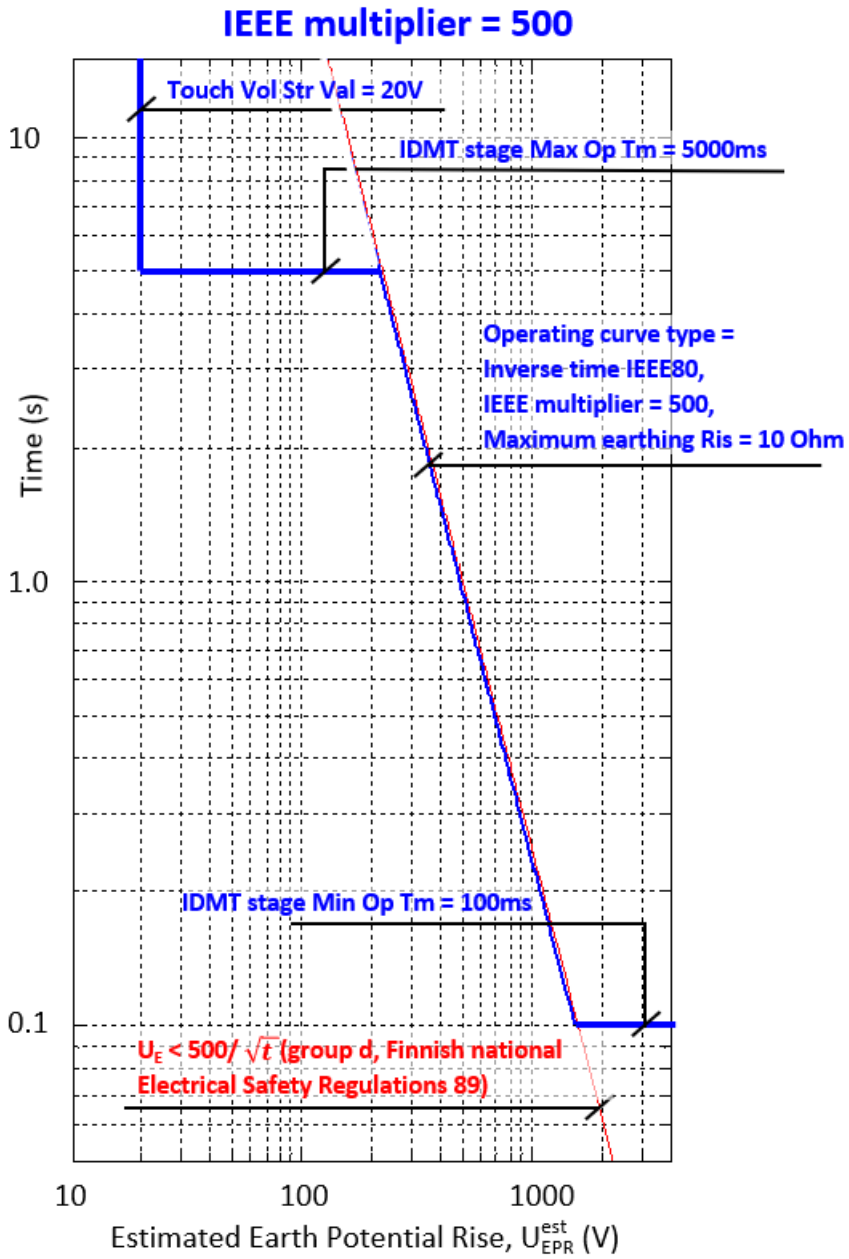

Figure 354: Operation timer characteristic of IFPTOC function when Operation principle = "Touch voltage based", Operating curve type = "Inverse time IEEE80" and IEEE multiplier = 500. Characteristics are according to standard IEEE80. Maximum earthing Ris = 10ohm.

Cross-country fault protection

In high impedance earthed networks, single phase earth fault introduces over-voltages in the healthy phases. Such over-voltages may initiate another single-phase earth fault in another phase and location in a galvanically connected network. Such fault condition is commonly known as cross-country fault, which is a two phase short-circuit through earth with high earth fault current. Cross-country fault must be therefore quickly disconnected in order to limit risk to health and damages to equipment.

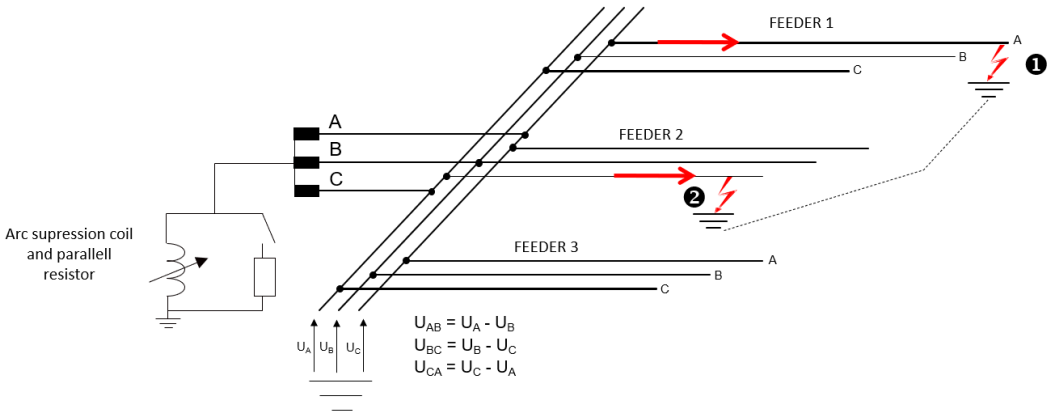

Figure 355: Simplified illustration of a cross-country fault between phases A and C, where two simultaneous single-phase earth faults occur in two different locations and two different phases in the network

IFPTOC has an in-build dedicated functionality for cross-county fault detection and tripping. Detection of cross-country fault is always enabled, but tripping may be enabled or disabled with setting *Enable XC Op mode* = “on” or “off”. In case multiple instances of IFPTOC are applied in the protection configuration, only single instance of IFPTOC requires cross-country fault tripping functionality to be enabled; in other instances, cross-country fault tripping functionality may be disabled. As default *Enable XC Op mode* = “on” i.e. tripping is enabled during cross-country faults.

There are two independent criteria for cross-country fault detection: The 1st criterion requires that residual current exceeds a value which is higher than maximum single-phase earth-fault current of the network, and the 2nd criterion monitors voltage dip in any of the phase-to-phase voltages.

Residual over-current criterion

Monitoring of the magnitude of calculated residual current (I_o) and comparing it to setting *XC stage A Str Val* during a detected earth fault:

$$EF_IND = TRUE, \ \ AND$$
$$I_o \ (calculated) > XC \ stage \ A \ Str \ Val$$

(Equation 132)

Calculated I_o is used to avoid problems in case of possible CBCT saturation during high current cross-country fault.

It should be noted, that setting value *XC stage A Str Val* is given in unit [xIn], where In is phase current nominal value. Typical value for *XC stage A Str Val* in primary amperes is few hundreds of amperes. The setting *XC stage A Str Val* should not be higher than the estimated minimum cross-country fault current (I_{F_XCmin}), and on the other hand it must be checked against the uncompensated earth-fault current of the network (I_{eNet}) and setting of the low-set overcurrent stage (*3I>*):

XC stage A Str Val < I_{F_XCmin} AND
XC stage A Str Val > max(2·I_{eNet}, *3I>*)

(Equation 133)

where

I_{eNet} = Uncompensated earth-fault current of the network taking into account the decentralized compensation.

3I> = Setting of the low-set overcurrent stage of the protected feeder

The magnitude of the minimum expected cross-country fault current can be coarsely estimated based on the knowledge of the maximum earthing resistance values, *Maximum earthing Ris*, of all the feeders in the substation, and using the following equation:

$$I_{F_XCmin} \approx \sqrt{\frac{3 \cdot {U_{PE}}^2 \cdot {Y_{F1}}^2 \cdot {Y_{F2}}^2}{{Y_{F1}}^2 + {Y_{F2}}^2 + 2 \cdot Y_{F1} \cdot Y_{F2} + 4 \cdot {X_k}^2 \cdot {Y_{F1}}^2 \cdot {Y_{F2}}^2 + 4 \cdot {R_k}^2 \cdot {Y_{F1}}^2 \cdot {Y_{F2}}^2 + 4 \cdot R_k \cdot ({Y_{F1}}^2 \cdot Y_{F2} + {Y_{F2}}^2 \cdot Y_{F1})}}$$

(Equation 134)

where

I_{F_XCmin} = Minimum expected cross-country fault current

U_{n_PE} = Nominal phase-to-earth voltage

Y_{F1} = 1 / *Maximum earthing Ris* = Admittance corresponding to the set maximum earthing resistance value of the protected feeder

Y_{F2} = 1 / max(*Maximum earthing Ris_i*) = Admittance corresponding to the maximum of the set earthing resistance values of other feeders in the substation

X_k = Sum of short-circuit reactances of the incoming HV-network and main transformer referred to MV-side

R_k = Sum of short-circuit resistances of the incoming HV-network and main transformer referred to MV-side

Example 1:

- U_{n_PE} = 11.547 kV
- *Maximum earthing Ris* = 15 ohm
- *Maximum earthing Ris_i* = 10 ohm
- X_k = 2.2 ohm
- R_k = 0.2 ohm
- *3I>* = 200 A
- I_{eNet} = 320 A

Using the above parameters I_{F_XCmin} equals 0.8 kA in order of magnitude, which is also higher than the uncompensated earth-fault current of the network and the setting of the low-set overcurrent stage of the protected feeder. So, setting *XC stage A Str Val* can be selected between I_{eNet} = 320 A and I_{F_XCmin} = 800 A.

Assuming phase CT-ratio 400/1 A, the setting *XC stage A Str Val* is selected to be 700 A (1.75*In).

Phase-to-phase under-voltage criterion

Monitoring of the magnitude of any phase-to-phase voltage (U_{AB}, U_{BC} or U_{CA}) and comparing it to setting *XC stage PP V Val* during a detected earth fault:

$$EF_IND = TRUE, \ \ AND$$

$$U_{ph-ph} < XC\ stage\ PP\ V\ Val$$

(Equation 135)

During a single-phase earth fault phase-to-phase voltages are not affected, but during a cross-country fault the phase-to-phase voltages are affected, refer to *Figure 356*. Default setting for *XC stage PP V Val* is 0.9xU_{n_PP}, where U_{n_PP} is the nominal phase-to-phase voltage.

In case all three phase-to-phase voltages (U_{AB}, U_{BC} and U_{CA}) are under setting for *XC stage PP V Val*, such condition is considered as permanent three phase under-voltage condition, not a cross-country fault.

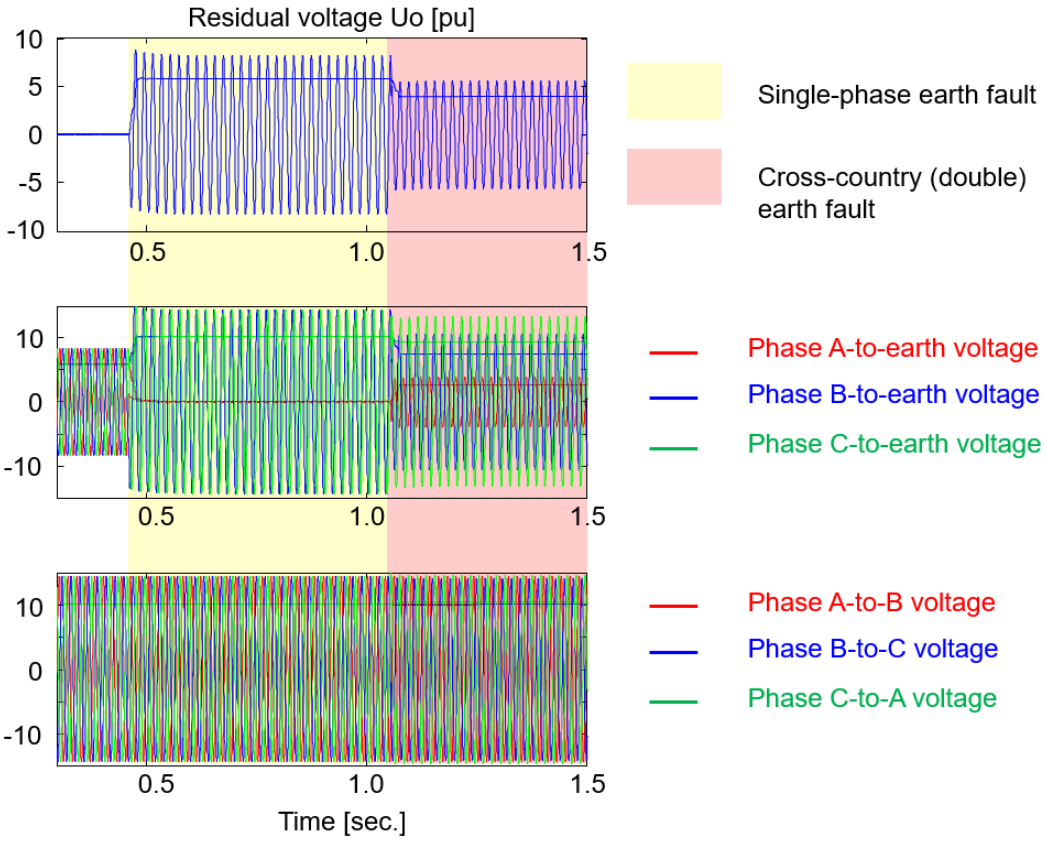

Figure 356: Illustration of behavior of residual, phase-to-earth and phase-to-phase voltages during an evolvement of single-phase earth fault into cross-country fault in a 10 kV compensated network

The magnitude of phase-to-phase voltage between faulted phases during a cross-country fault can be estimated using the following equation:

$$U_{PP_XC} \approx \sqrt{\frac{3 \cdot (Y_{F1}{}^2 + Y_{F2}{}^2 + 2 \cdot Y_{F1} \cdot Y_{F2}) \cdot U_{PE}{}^2}{Y_{F1}{}^2 + Y_{F2}{}^2 + 2 \cdot Y_{F1} \cdot Y_{F2} + 4 \cdot X_k{}^2 \cdot Y_{F1}{}^2 \cdot Y_{F2}{}^2 + 4 \cdot R_k{}^2 \cdot Y_{F1}{}^2 \cdot Y_{F2}{}^2 + 4 \cdot R_k \cdot (Y_{F1}{}^2 \cdot Y_{F2} + Y_{F2}{}^2 \cdot Y_{F1})}}$$

(Equation 136)

where

U_{PP_XC} = Estimate of the highest phase-to-phase voltage during cross-country fault with minimum expected cross-country fault current according to *Equation 136*.

Example 2:

- U_{n_PP} = 20 kV
- *Maximum earthing Ris* = 15 ohm
- *Maximum earthing Ris_i* = 10 ohm
- X_k = 2.2 ohm
- R_k = 0.2 ohm

Using the above parameters U_{PP_XC} equals 19.3 kV in order of magnitude (19.3 kV/20 kV=~0.97xU_{n_PP}). However, taking additionally into account normal variations in supply voltage, the setting *XC stage PP V Val* can be selected 0.9xU_{n_PP} (18.0 kV). In this way unnecessary activations of phase-to-phase undervoltage condition can be prevented.

Figure 357 illustrates fault current magnitude according to *Equation 134* and phase-to-phase voltage magnitude according to *Equation 136*, during a cross-country fault as a function of fault resistance. Note that fault resistance is due to earthing resistances of the fault locations only, and its value equals the average of fault resistances R_{F1} and R_{F2} in both fault locations. U_{n_PP} = 20 kV, X_k = 2.2 ohm, R_k = 0.2 ohm.

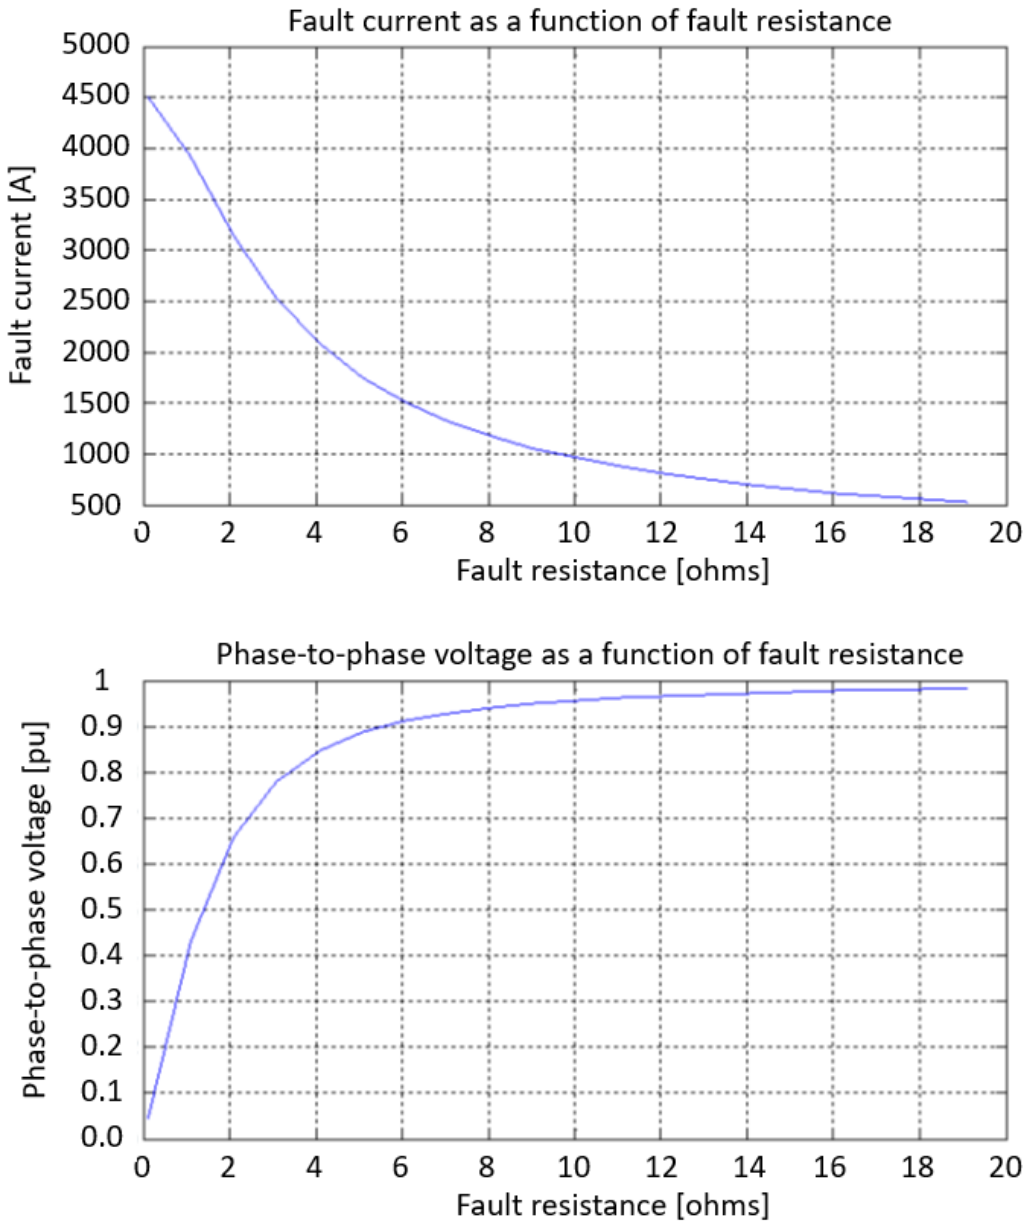

Figure 357: Illustration of fault current magnitude and phase-to-phase voltage magnitude during a cross-country fault as a function of fault resistance. Note that fault resistance equals the average of fault resistances R_{F1} and R_{F2}. U_{n_PP} = 20 kV, X_k = 2.2 ohm, R_k = 0.2 ohm.

Setting value *XC stage PP V Val* is given in per unit format with system nominal phase-to-phase value as reference.

Fulfilment of either *Equation 132* or *Equation 135* declares cross-county fault detection condition in the network. The cross-country fault is indicated by activating the `XC_FLT` output.

During detected cross-country fault, the “EF current based” or “Touch voltage based” operation of IFPTOC is blocked.

In case tripping of cross-country fault is enabled (setting *Enable XC Op mode* = “on”), then operation of IFPTOC requires that simultaneously both the magnitude of calculated residual current (I_o) and estimated earth-fault current (I_F^{est}) exceeds setting *XC stage A Str Val* during a detected earth fault:

$$EF_IND = TRUE, \ \ AND$$
$$I_o\ (calculated) > XC\ stage\ A\ Str\ Val, \ \ AND$$
$$I_F^{est} > XC\ stage\ A\ Str\ Val$$

(Equation 137)

Operate time for cross-country fault operation is given with setting *XC stage Op time*. Typical operate time is 60-100 ms.

The cross-country stage earth fault module always evaluates the true fault current magnitude (considering the effect of setting *Enable harmonics*) i.e. it is not affected by settings *Ena RF Compensation* and *Reduction factor*.

The cross-country fault indication is given in Recorded data as *XC fault detection* or in Output data as XC_FLT.

When start and operate conditions of cross-country earth fault module are fulfilled, this is indicated by activation of START and OPERATE outputs and ST_XC and OP_XC outputs.

In case tripping of cross-country fault is enabled, operate time is given with setting *XC stage Op time*. Reset time is defined with setting *Reset delay time*. Note that setting *CB Delay comp* (circuit breaker delay compensation) is not applicable in definite time operation, but it must be taken into account in setting *XC stage Op time*.

Applicable settings for cross-country earth fault module are: *Enable XC Op mode, XC stage A Str Val, XC stage PP V Val, XC stage Op time and Reset delay time*.

Intermittent earth-fault protection

Operation time requirement of earth-fault protection in safety standards assumes continuous flow of fault current. In case of resonant earthed network, earth faults are often re-striking i.e. fault arc is not continuous, but intermittent. During re-striking/intermittent earth faults, the very high but narrow current transient may result to very fast operation times, if operation time is based on IDMT-operation i.e. *Operation curve type* = Inverse time EN50522 or Inverse time IEEE80. Requirement for operation with IDMT-timer is that timer is not reset between successive current transients i.e. *Reset delay time* should be set long enough. However, in case operation during re-striking/intermittent earth faults is preferably based on number of counted transients, then setting *Reset delay time* should be set to low value, say 20-40 ms, and dedicated intermittent earth-fault protection functionality must be enabled.

Intermittent earth-fault module is enabled with setting *Ena Intermit EF mode* = “on”. Module is enabled by default. In case multiple instances of IFPTOC are applied in the protection configuration, and operation during re-striking/intermittent earth faults is preferably based on number of counted transients, only single instance of IFPTOC requires Intermittent earth-fault module functionality to be enabled; in other instances, Intermittent earth-fault module functionality may be disabled.

The IFPTOC has inbuild directional transient detector module for detecting earth-fault transients. Transient detector module is used to count the number of transients during an earth fault to discriminate intermittent earth fault from continuous earth fault.

Transient detector module counts the number of transients during an earth fault both in faulty and healthy feeders. Detection of transients is indicated with PEAK_IND output.

Internal start of intermittent earth-fault module is obtained when the presence of earth fault is indicated (EF_IND), it's validity is confirmed (VALID_EF) and at least one transient is detected in the protected feeder. Whenever a fault transient is detected, this is indicated with the PEAK_IND output.

When the number of detected transients reaches the *Intr EF counter Lim* setting, INTR_EF output is activated. Activation of INTR_EF output indicates detection of a restriking or intermittent earth fault in the protected feeder.

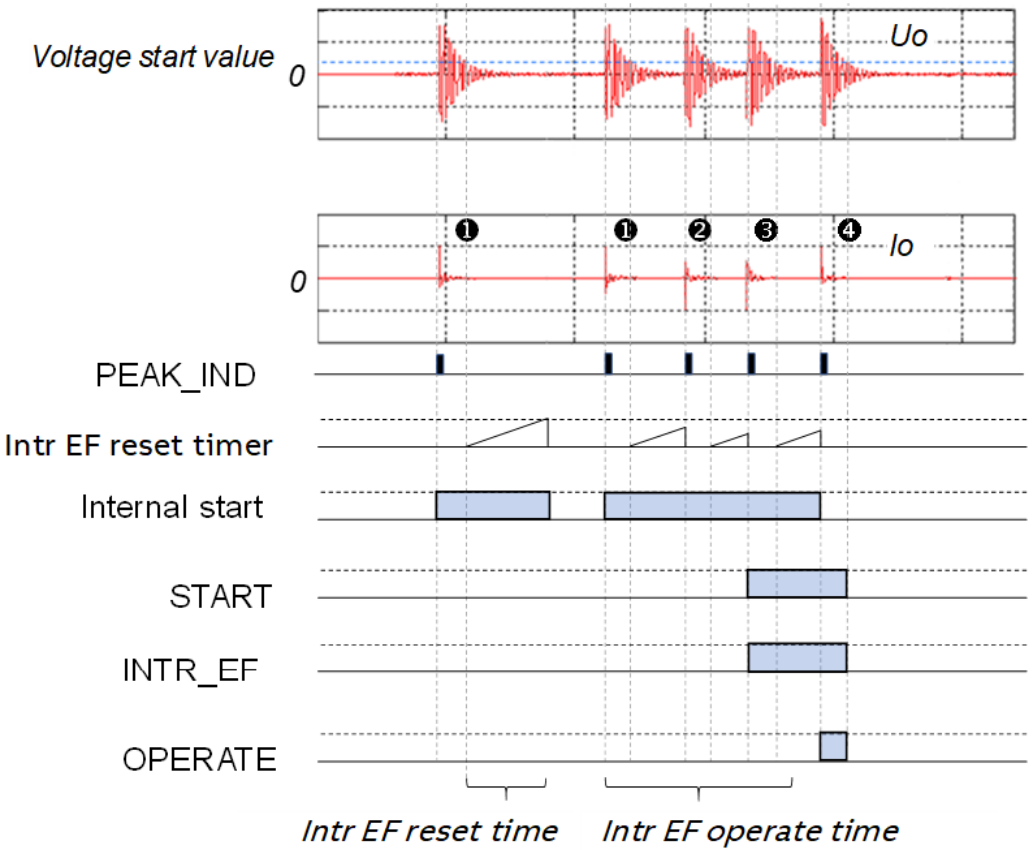

Figure 358: Illustration of operation of intermittent earth-fault module. Setting Intr EF counter Lim = 3

When a required number of intermittent earth-fault transients set with the *Intr EF counter Lim* setting are detected without the function being reset (depends on the drop-off time set with the setting *Intr EF reset time*) and the presence of single-phase earth fault in the protected feeder is confirmed (activation of EF_IND and VALID_EF outputs), the START and ST_INTR_EF outputs are activated. The OPERATE and OP_INTR_EF outputs are activated when operate delay time *Intr EF operate time* has elapsed (from fault beginning), required number of transients exceeds setting *Intr EF counter Lim* (so actually for operation there must be *Intr*

EF counter Lim +1 detected transients). OPERATE output activation occurs always at time of detected transient. OPERATE output signal has fixed length of 100 ms, but OP_INTR_EF signal is activated for only one cycle time i.e. 2. 5m.

Several factors affect the magnitude and frequency of fault transients, such as the fault inception angle on the voltage wave, fault location, fault resistance and the parameters of the feeders and the supplying transformers. If the fault is permanent (non-transient), the initial fault transient in current and voltage can be measured, whereas the intermittent fault creates repetitive transients. The practical sensitivity of transient detection is limited to approximately a few hundreds of ohms of fault resistance. Therefore, the application of transient detection is limited to low-ohmic earth faults.

Setting *Intr EF counter Lim* minimum value is 3 in order to provide secure indication of intermittent/re-striking earth fault. This is due to the fact that sometimes the fault ignition transient is characterized by highly distorted waveform, which may result into multiple transients to be detected at time of fault ignition. By increasing the value of *Intr EF counter Lim* setting, one increases the security of correct fault type identification.

Information about detected intermittent earth fault is also available in *Recorded data* as *Intermittent EF Det* or in Output data as INTR_EF.

During re-striking/intermittent earth faults, the very high current transient may result to very fast operation times in case operation principle is based on earth fault current or touch voltage estimate. In case longer and more deterministic operation during re-striking/ intermittent earth faults is preferred, the operation can be based on counted number of transients instead of IDMT operation. In transient counter-based operation the setting *Reset delay time* should be set to low value, say 20-40 ms. For the Intermittent earth-fault module reset delay time is defined with setting *Intr EF reset time*. During intermittent earth faults, typically longer reset time is needed to prevent unwanted function reset between the current spikes. Recommended setting value for *Intr EF reset time* is between 300-500 ms.

Actual operation time of intermittent earth-fault module cannot pre-determined exactly as the timing of successive transients is not constant.

At time OPERATE output is activated from intermittent earth-fault protection, also output OP_INTR_EF is activated OPERATE output signal has fixed length of 100 ms, but OP_INTR_EF signal is activated for only one cycle time i.e. 2.5 m. If OP_INTR_EF is to be used in e.g. protection logics, it should be prolonged with TOF-function in protection configuration.

Applicable settings for Intermittent earth-fault module are: *Ena Intermit EF mode, Intr EF counter Lim, Intr EF operate time and Intr EF reset time*.

Note that setting *CB Delay Comp* (circuit breaker delay compensation) is not applicable in definite time operation, but it must be taken into account in setting *Intr EF operate time*.

Switch onto fault protection

During switch onto fault condition i.e. when breaker is closed into existing fault, earth-fault current estimate may be disturbed by the inrush currents of energized transformers. Therefore, IFPTOC includes a dedicated switch onto fault (SOTF) logic module. SOTF-functionality provides dedicated fault detection and tripping in case feeder breaker is closed into earth fault.

Switch onto fault protection module is enabled with setting *Enable SOTF mode* = “on”. Module is enabled by default.

In case multiple instances of IFPTOC are applied in the protection configuration, ALL instances of IFPTOC requires SOTF module functionality to be enabled to provide selective operation during an SOTF condition.

SOTF condition is declared, if an earth fault is detected (`EF_IND = TRUE`) within set *SOTF Cond duration* milliseconds from breaker close command (input `CB_CL_CMD` is activated).

Indication of detected SOTF condition is declared by activation of `ST_SOTF` and `START` outputs.

Operate time during switch onto fault condition is given with setting SOTF operate time. `OPERATE` and `OP_SOTF` outputs are activated after operation timer has elapsed.

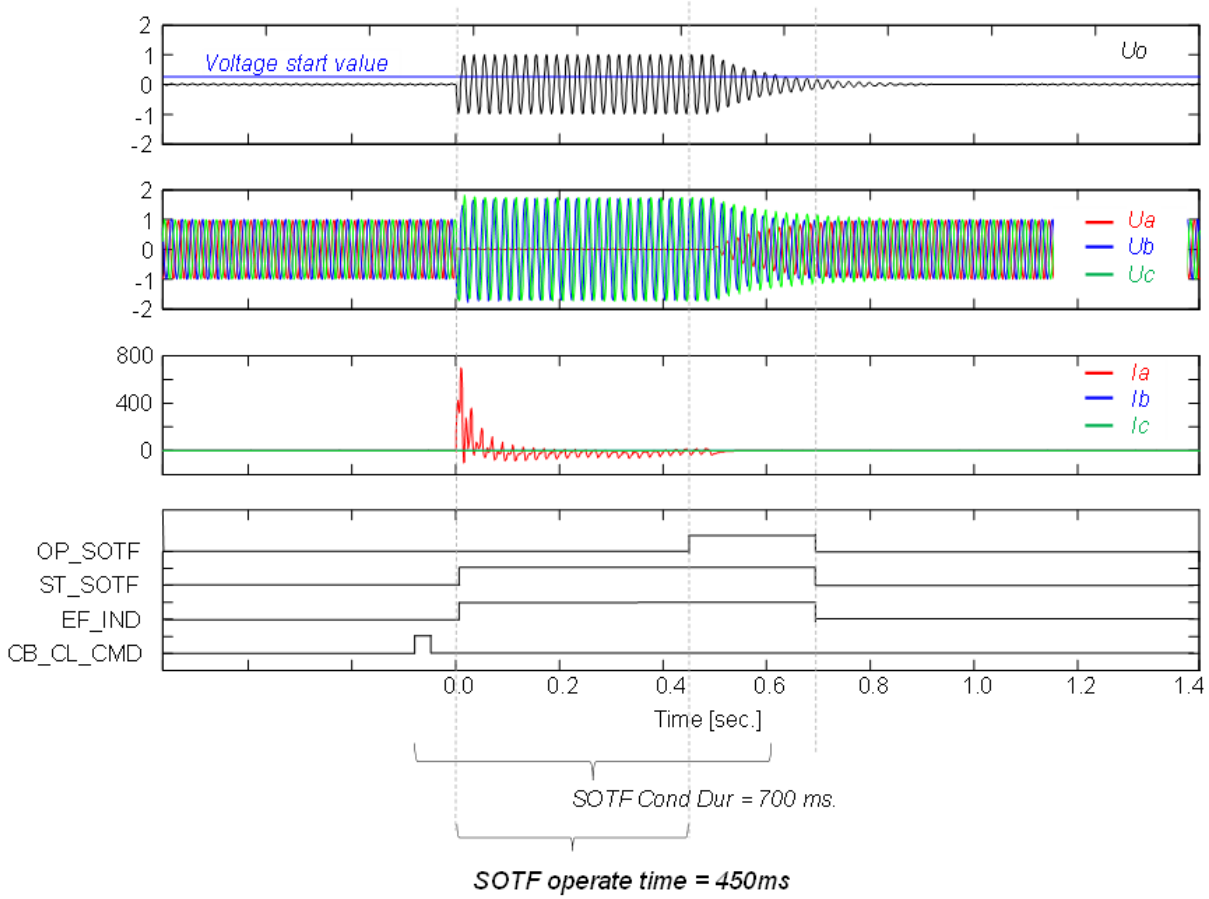

Figure 359: Illustration of switch onto fault condition and operation of SOTF logic in IFPTOC

Switch-onto-fault (SOTF) logic module enabling requires connection of breaker close command into input CB_CL_CMD. Switch-onto-fault (SOTF) logic module can be disabled by not connecting the breaker close command signal to IFPTOC.

In case SOTF condition is detected, then all other functionality of IFPTOC function is blocked.

Setting *SOTF Cond duration* must be set higher than *SOTF operate time* + *SOTF reset time*. SOTF functionality is reset after *SOTF Cond duration* expires or at least when earth-fault detection signal deactivates (EF_IND).

SOTF logic is not activated in case earth fault is detected (EF_IND = TRUE) before breaker close command (input CB_CL_CMD is activated).

For the SOTF module typically longer reset time is needed to prevent unwanted function reset between the current spikes during intermittent earth fault, setting SOTF reset time. Recommended setting value is between 300-500 ms.

Applicable settings for the SOTF-module are: *Enable SOTF mode, SOTF Cond duration, SOTF operate time and SOTF reset time*.

Note that setting *CB Delay comp* (circuit breaker delay compensation) is not applicable in definite time operation, but it must be taken into account in setting *SOTF operate time*.

Faulted phase identification

The faulted phase selection module provides information about the faulted phase (A, B or C) during a single-phase earth fault.

The faulted phase is identified by monitoring the “phase-wise” fault current estimators as follows:

$$I^1_{EF_A} = abs(\Delta\underline{I}^1_A - (\Delta\underline{I}^1_B + \Delta\underline{I}^1_C)/2)$$

(Equation 138)

$$I^1_{EF_B} = abs(\Delta\underline{I}^1_B - (\Delta\underline{I}^1_C + \Delta\underline{I}^1_A)/2)$$

(Equation 139)

$$I^1_{EF_C} = abs(\Delta\underline{I}^1_C - (\Delta\underline{I}^1_A + \Delta\underline{I}^1_B)/2)$$

(Equation 140)

Maximum value indicates the faulted phase. Actual implementation utilizes Cumulative Phasor Summing (CPS) together with admittance calculation.

Faulted phase is available in Recorded data as *Faulted phase*. In Monitored data faulted phase is given in FAULT_PHASE.

Faulted phase information is not given in case of cross-country fault (XC_FLT = TRUE).

Fault resistance estimation

Protection function IFPTOC includes fault resistance (R_F) magnitude estimation based on information on the faulted phase, the faulted phase voltage and estimated earth fault current magnitude (fundamental frequency). Fault resistance magnitude can be estimated with equation:

$$R_F = \frac{U_{ph_faulted}}{I_F^{est1}}$$

(Equation 141)

Where

$U_{ph_faulted}$ = Faulted phase voltage magnitude, fundamental frequency [V]

I_F^{est1} = Estimated earth-fault current magnitude, fundamental frequency [A]

Actual implementation utilizes Cumulative Phasor Summing (CPS).

Magnitude of estimated fault resistance in primary ohms is available in Recorded data: *Fault resistance*. In monitored data this information is given: RF.

Fault resistance estimation is not done in case of cross-country fault (XC_FLT = TRUE).

In case of intermittent earth fault, fault resistance estimation is not accurate.

Trip logic

Protection function IFPTOC supports both tripping and alarming earth-fault handling defined with setting *Operation mode* = “Alarming EF” or “Tripping EF”. With *Operation mode* = “Alarming EF”, OPERATE and corresponding OP_EF/OP_XC/OP_SOTF/OP_INTR outputs are not activated. *Operation mode* = “Alarming EF” is applicable in networks, where due to low touch voltages tripping of earth-fault is not required (requires existence of Global Earthing System, GES). Monitoring of prevailing earth-fault current and/or touch voltage magnitude can be done via Monitored data.

When start conditions of touch voltage protection, earth-fault current protection, cross-country fault protection, intermittent earth-fault protection or switch onto fault protection are fulfilled, this is indicated by activation of START and corresponding ST_EF/ST_XC/ST_SOTF/ST_INTR outputs. When operate conditions are fulfilled and setting *Operation mode* = “Tripping EF”, this is indicated by activation of OPERATE and corresponding OP_EF/OP_XC/OP_SOTF/OP_INTR outputs.

The timer calculates the start duration value, which indicates the percentage elapse of operate timer, 100% means that operate time is completely elapsed and OPERATE output is activated. The value is available in the Recorded data as *Start duration* and in Monitored data as START_DUR.

Estimate for time left to operate is available in in Monitored data as TIME_TO_OPER in real time based on fault current or touch voltage magnitude. In the Recorded data estimate for time left to operate is available as *Time left to operate* with assumption that fault current or touch voltage at the triggering moment (recorded data is triggered with TRIGG_REC input rising edge) will remain the same until the OPERATE and corresponding OP_EF/OP_XC/OP_SOTF/OP_INTR outputs would become activated. Furthermore, if OPERATE and corresponding OP_EF/OP_XC/OP_SOTF/OP_INTR outputs have been activated, the actual operate time of protection is available in the Recorded data as *Operate time* and in Monitored data as OPERATE_TIME.

Information about started and operated timers are available in Recorded data: *Started timers, Operated timers*. This data is binary coded number as illustrated in *Table 635*.

Table 635: Binary to decimal conversion of the *Started timers* and *Operated timers* in Recorded data

Timer notation	Timer1	Timer2	Timer3	Timer4
Timer description	Touch voltage/fault current estimation module	Cross-country earth-fault module	Switch onto fault (SOTF) module	Intermittent earth fault module
Binary (0 or 1) 0=not started/not operated, 1=started/operated	0 or 1	0 or 1	0 or 1	0 or 1

Started/Operated timers (integer): Timer1·2^0+ Timer2·2^1+ Timer3·2^2+ Timer4·2^3

Numerical example. If both Touch voltage/fault current estimation module timer (+1) and intermittent timer (+8) have been started but only Touch voltage estimation module timer have operated, then: *Started timers* 1+8 = 9 and *Operated timers* = 1.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal in protection configuration. The influence of the BLOCK input signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timer” mode, the operation timer is frozen to the prevailing value, but the operate outputs are not deactivated when blocking is activated. In the “Block all” mode, the whole function is blocked, and the timers and pre-fault phasor buffers are reset. In the “Block OPERATE output” mode, only the operate outputs are blocked.

Recorded data

The required information for later fault analysis is recorded when the recording function of IFPTOC function is triggered by activating TRIGG_REC input or writing to the corresponding DO “LD0.IF1RFRC1.RcdTrg.Oper.ctlVal”.

Activation of OPERATE output results to automatic triggering of fault recording.

The recording function of IFPTOC includes recorded data 1 data objects as shown in *Table 636*.

Table 636: Recorded data 1 data objects of the IFPTOC function

Parameter name	Parameter description	Recorded Data DO
Triggering time	Triggering time	(Timestamp) IF1RFRCx.TchV.t.

A total of two sets of recorded data are saved in data banks *Recorded data 1* and *Recorded data 2*. Data bank *Recorded data 1* holds the most recent recorded data and the older data is moved into the data bank *Recorded data 2* when triggering occurs. When all two banks have data and a new triggering occurs, the latest data is placed into bank *Recorded data 1* and the data in bank *Recorded data 2* is overwritten by the data from bank *Recorded data 1*.

It is possible to reset corresponding recorded data by either:

- activating LHMI parameter Clear/Clear/IFPTOCx reset = 1 (“Clear”) or
- writing directly by MMS LD0.IFPTRCx.RcdRs.Oper.ctlVal = 1 (“Clear”)”

4.2.10.6 Signals

IFPTOC Input signals

Table 637: IFPTOC Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
IRES	SIGNAL	-	Residual current
U3P	SIGNAL	-	Three-phase voltages
URES	SIGNAL	-	Residual voltage
EXT_RELEASE	BOOLEAN	0=False	External GFC start signal, alternative for internal GFC module.
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode
CB_CL_CMD	BOOLEAN	0=False	Defines breaker close command. This signal is used in the switch on to fault (SOTF) logic.
TRIGG_REC	BOOLEAN	0=False	External recorded data triggering. There are two recorded data banks available.

IFPTOC Output signals

Table 638: IFPTOC Output signals

Name	Type	Description
OPERATE	BOOLEAN	Operate
START	BOOLEAN	Start
ST_EF	BOOLEAN	Start signal according to estimated fault current or touch voltage according to the standards
ST_XC	BOOLEAN	Start signal according to cross-country stage earth-fault module
ST_SOTF	BOOLEAN	Start signal according to SOTF-module
ST_INTR_EF	BOOLEAN	Start signal according to intermittent earth-fault module
OP_EF	BOOLEAN	Operate signal according to estimated fault current or

Table continues on the next page

Name	Type	Description
		touch voltage according to the standards
OP_XC	BOOLEAN	Operate signal according to cross-country stage earth-fault module
OP_SOTF	BOOLEAN	Operate signal according to SOTF-module
OP_INTR_EF	BOOLEAN	Operate signal according to intermittent earth-fault module
PEAK_IND	BOOLEAN	Current transient detection indication (both in the faulty and healthy feeder)
INTR_EF	BOOLEAN	Intermittent earth fault indication in the faulty feeder
EF_IND	BOOLEAN	Non-directional indication of earth-fault in the network
VALID_EF	BOOLEAN	Validity of earth-fault current estimate is confirmed
XC_FLT	BOOLEAN	Indication of cross-country fault in the network

4.2.10.7 IFPTOC Settings

Table 639: IFPTOC Group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Voltage start value	0.01...1.00	xUn	0.01	0.20	Start value for neutral point voltage Uo. Note that Un means phase to earth nominal voltage.
EF current Str Val	0.005...1.000	xIn	0.001	0.010	Earth-fault current threshold for DT stage or IDMT stage. Note that In means phase nominal current.
Touch Vol Str Val	10.0...2900.0	V	0.1	80.0	Touch voltage start threshold for DT stage or IDMT stage in primary volts
Operating curve type	15=Definite time 18=Inverse time EN50522 19=Inverse time IEEE80			18=Inverse time EN50522	Selection of time delay curve type in touch voltage/fault current estimation module
Ena RF compensation	0=Disable 1=Enable			0=Disable	Enable compensation of fault resistance in the estimated earth-fault current

Table continues on the next page

Parameter	Values (Range)	Unit	Step	Default	Description
DT stage Op time	100...60000	ms	10	500	Operate delay time for Touch voltage/fault current estimation module, DT timer

TR_REACT_COMP	FLOAT32	-6000.0...6000.0	A	Magnitude of transient imaginary part of residual current, in primary amperes (fundamental freq.)
NON_Q_HARMON	INT32	0...127		Non qualified harmonics in binary coded format
START_DUR	FLOAT32	0.00...100.00	%	Ratio of start time / operate time
OPERATE_TIME	FLOAT32	0.000...7200.000	s	Actual operate time
TIME_TO_OPER	FLOAT32	0.000...7200.000	s	Time left to operate

4.2.10.9 Technical data

Table 644: IFPTOC Technical data

Characteristics	Value
Operation accuracy	Depending on the frequency of the measured current f_n ±2 Hz
	Earth-fault current and touch voltage: ±1% of the set value or ±0.005 × I_n for I_F^{est} Accuracy of U_{EPR}^{est} follows I_F^{est} accuracy. Residual voltage: ±1.5% of the set value or ±0.002 × U_n Residual current: ±1.5% of the set value or ±0.002 × I_n (at currents ≤10 x I_n, when Uo is nominal) ±5.0% of the set value (at currents > 10 x I_n)
Start time [1]	Typically 30 ms
Reset time	<30 ms
Reset ratio	Typically 0.96
Retardation time	<50 ms
Operate time accuracy	±1.0% of the set value or ±20 ms (DT) ±3% of the theoretical value or ±40 ms (IDMT)

4.3 Differential protection

4.3.1 Line differential protection with in-zone power transformer LNPLDF (ANSI 87L)

4.3.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Line differential protection with in-zone power transformer	LNPLDF	3Id/I>	87L

[1] Measured with static signal output (SSO)

4.3.1.2 Function block

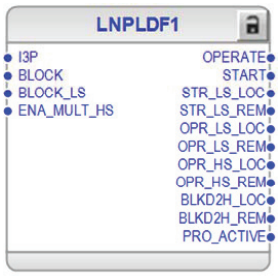

Figure 360: Function block

4.3.1.3 Functionality

The line differential protection with in-zone power transformer LNPLDF is used as feeder differential protection for the distribution network lines and cables. LNPLDF includes low, stabilized and high, non-stabilized stages. The line differential protection can also be used when there is an in-zone transformer in the protected feeder section.

The stabilized low stage provides a fast clearance of faults while remaining stable with high currents passing through the protected zone increasing errors on current measuring. Second harmonic restraint insures that the low stage does not operate due to energizing of a tapped or in-zone transformer. The high stage provides a very fast clearance of severe faults with a high differential current regardless of their harmonics.

The operating time characteristic for the low stage can be selected to be either definite time (DT) or inverse definite time (IDMT). The direct inter-trip ensures both ends are always operated, even without local criteria.

4.3.1.4 Analog channel configuration

LNPLDF has one analog group input which must be properly configured.

Table 645: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”.

The function can also be set into test mode by setting the *Operation* setting to “test/blocked”.

The operation of the line differential protection and related measurements, stabilized and instantaneous stages can be described using a module diagram.

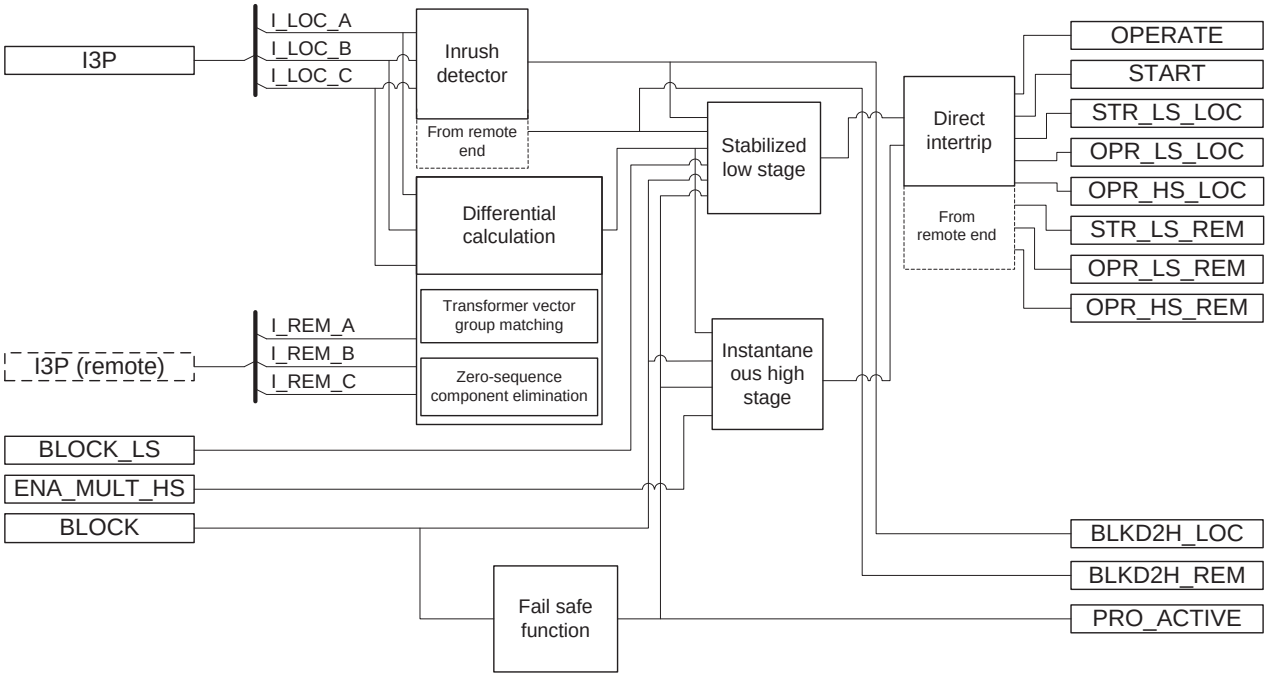

Figure 361: Functional module diagram. I_LOC_x stands for current of the local end and I_REM_x for phase currents of the remote ends.

Stabilized low stage

In the stabilized low stage, the higher the load current is, the higher the differential current required for tripping is. This happens on normal operation or during external faults. When an internal fault occurs, the currents on both sides of the protected object flow towards the fault and cause the stabilizing current to be considerably lower. This makes the operation more sensitive during internal faults. The low stage includes a timer delay functionality.

The characteristic of the low stage taking the apparent differential current into account is influenced by various factors:

- Small tapped loads within the protection zone
- Current transformer errors
- Current transformer saturation
- Small asymmetry of the communication channel go and return paths
- Small steady state line charging current
- In-zone transformer no load current
- Impact of tap changer positions

The timer is activated according to the calculated differential, stabilizing current and the set differential characteristic.

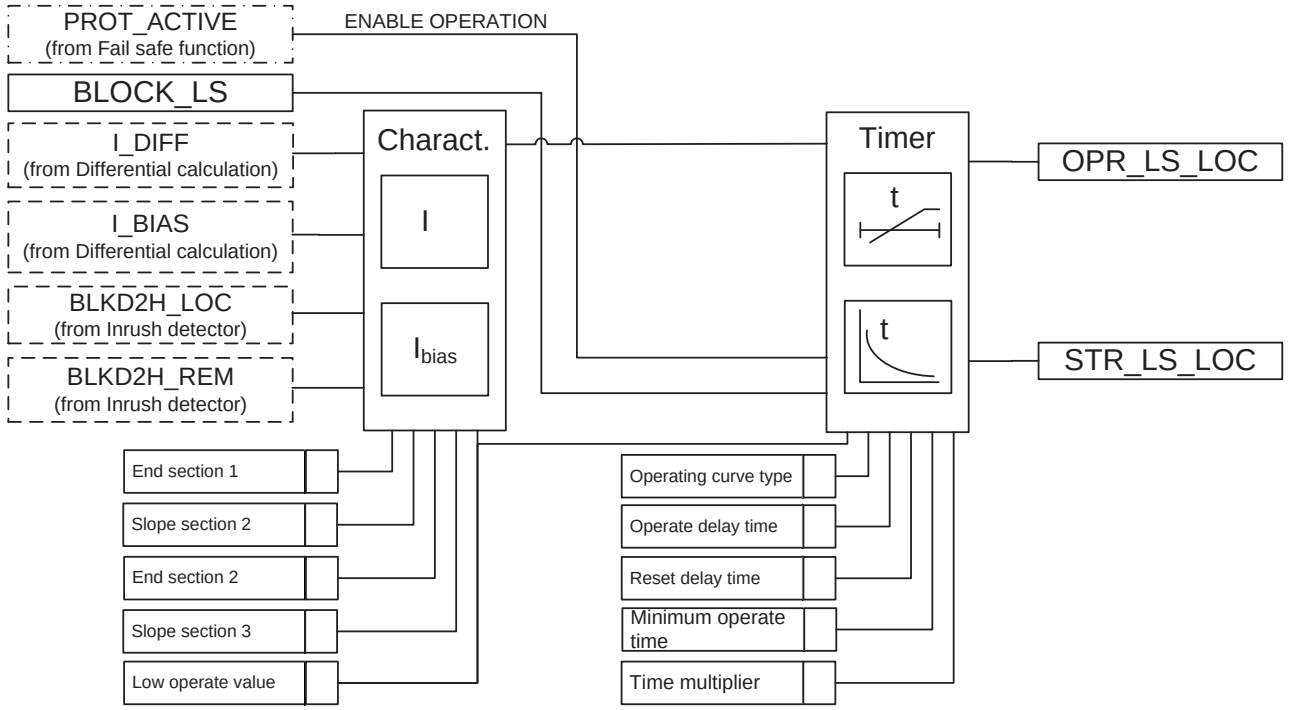

Figure 362: Operation logic of the stabilized low stage

The stabilization affects the operation of the function.

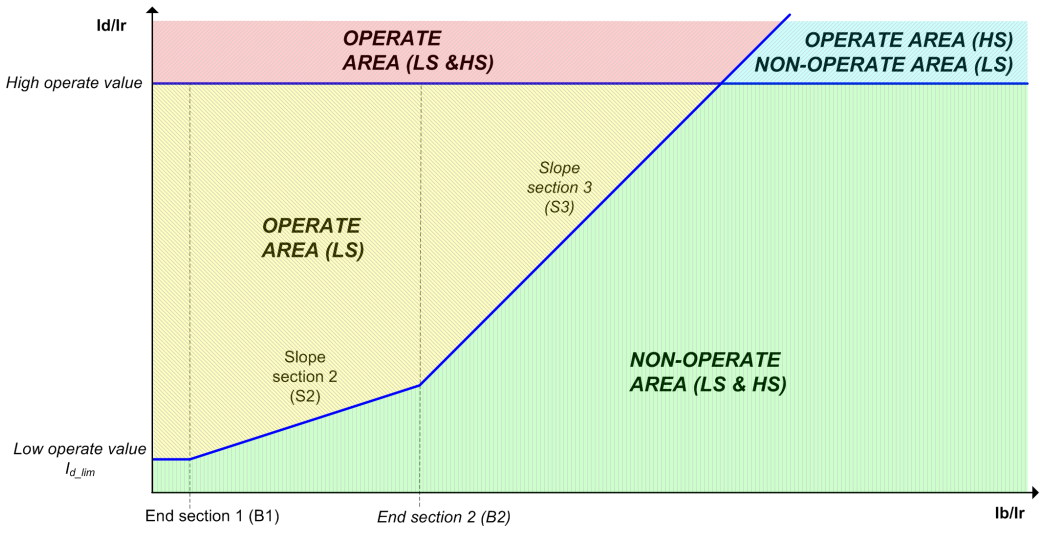

Figure 363: Operating characteristics of the protection. (LS) stands for the low stage and (HS) for the high stage.

The slope of the operating characteristic curve of the differential function varies in the different sections of the range:

- Section 1 where 0.0 < I_b/I_r < *End section 1*. The differential current required for tripping is constant. The value of the differential current is the same as the basic setting (*Low operate value*) selected for the function. The basic setting allows the appearance of the no-load current of the line, the load current of the tapped load and minor inaccuracies of the current transformers. It can also be used to influence the overall level of the operating characteristic.
- Section 2 where *End section 1* < I_b/I_r < *End Section 2*. This is called the influence area of the starting ratio. In this section, the variations in the starting ratio affect the slope of the characteristic, meaning the required change for tripping in the differential current in comparison with the change in the load current. CT errors should be considered in the starting ratio.
- Section 3 where *End section 2* < I_b/I_r. By setting the slope in this section, attention can be paid to prevent unnecessary operation of the protection when there is an external fault, and the differential current is mainly produced by saturated current transformers.

The operation of the differential protection is based on the fundamental frequency components. The operation is accurate and stable and the DC component and the harmonics of the current do not cause unwanted operations.

Inrush detector

The transformer inrush currents cause high degrees of second harmonic to the measured phase currents. The inrush detector detects inrush situations in transformers. The second harmonic based local blocking is selected into use with the *Restraint mode* parameter. The blocking for the low stage on the local end is issued when the second harmonic blocking is selected and the inrush is detected.

The inrush detector calculates the ratio of the second harmonic current `I_2H_LOC_A` and the fundamental frequency current `I_1H_LOC_A`. If the line differential protection is used in normal mode (*Winding selection* is “Not in use”), the calculated value is compared with the parameter value of the *Start value 2.H* setting. If the calculated value exceeds the set value and the fundamental frequency current `I_1H_LOC_A` is more than seven percent of the nominal current, the output signal `BLK2H_A` is activated. The inrush detector handles the other phases the same way.

If the line differential protection is used in the in-zone transformer mode (*Winding selection* is “Winding 1” or “Winding 2”), the weighted average is calculated for the 2 nd harmonic ratios in different phases and the weighted ratio is then compared with the value of the *Start value 2.H* setting. If the calculated weighted ratio value exceeds the set value and the fundamental frequency current `I_1H_LOC_A` is more than seven percent of the nominal current, output signal `BLK2H_A` is activated.

The locally detected transformer inrush is also transferred to the remote end as a binary indication signal independently of the local *Restraint mode* setting parameter value. When the internal blocking of the stabilized low stage is activated, the `RSTD2H_LOC` and `RSTD2H_REM` outputs will also be activated at the same time depending on whether the inrush has been detected on local or remote end or on both ends.

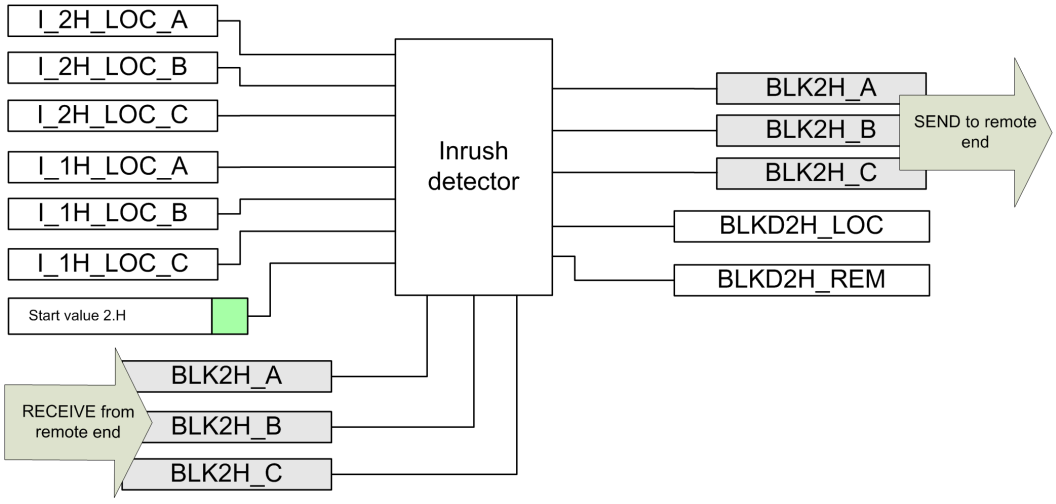

Figure 364: Inrush current detection logic

Differential calculation

The operating principle is to calculate on both ends differential current from currents entering and leaving the protection zone by utilizing the digital communication channels for data exchange. The differential currents are almost zero on normal operation. The differential protection is phase segregated and the differential currents are calculated separately on both ends.

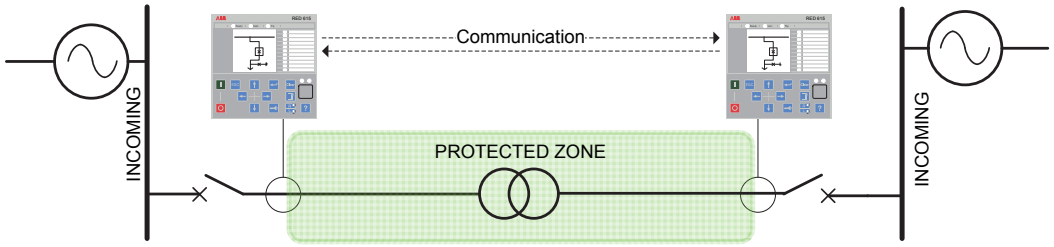

Figure 365: Basic protection principle

The differential current IΔ (I_d) of the protection relay is obtained on both ends with the formula:

$$I_d = \left| \bar{I}_{LOC} + \bar{I}_{REM} \right|$$

(Equation 142)

The stabilizing current I_{bias} (I_b) of the protection relay is obtained on both ends with the formula:

$$I_b = \frac{\left| \bar{I}_{LOC} - \bar{I}_{REM} \right|}{2}$$

(Equation 143)

Depending on the location of the star points of the current transformers, the polarity of the local end remote currents may be different causing malfunction of the calculation algorithms. The CT transformation ratio may be different and this

needs to be compensated to provide a correct differential current calculation result on both ends.

The operation characteristics related settings are given in units as percentage of the current transformer secondary nominal current on each line end protection relay. For the actual primary setting, the corresponding CT ratio on each line end has to be considered. An example of how the *CT ratio correction* parameter values should be selected on both line ends in the example case to compensate the difference in the nominal levels can be presented.

Another example for differential application without in-zone transformer where line rated current is 400 A. The ratio of CTs are 800/1 and 400/1.

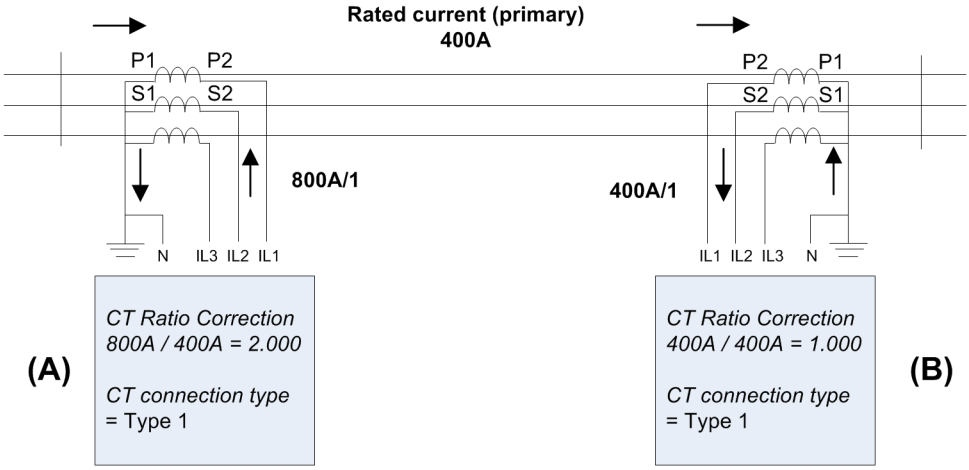

Figure 366: Example of CT ratio correction setting calculation in line differential application

The settings for *CT ratio Corrections* for protection relay A and protection relay (B) are:

CT ratio Correction (A) = 800 A / 400 A = 2.000

CT ratio Correction (B) = 400 A / 400 A = 1.000

The CT secondary current often differs from the rated current at the rated load of the power transformer. The CT transforming ratio can be corrected on both sides of the power transformer with the *CT ratio Correction* setting.

First, the rated load of the power transformer is calculated on both sides when the apparent power and phase-to-phase voltage are known.

$$I_{nT} = \frac{S_n}{\sqrt{3} \times U_n}$$

(Equation 144)

I_{nT}	Rated load of the power transformer
S_n	Rated power of the power transformer
U_n	Rated phase-to-phase voltage

Next, the settings for the CT ratio correction can be calculated with the formula:

$$CT\ ratio\ correction = \frac{I_n}{I_{nT}}$$

(Equation 145)

I_n Nominal primary current of the CT

After the CT ratio correction, the measured currents and corresponding setting values of LNPLDF are expressed in multiples of the rated power transformer current Ir (×Ir) or percentage value of Ir (%Ir).

An example shows how the CT ratio correction settings are calculated; when the rated power of the transformer is 5 MVA, the ratio of CTs on the 20 kV side is 200/1 and that on the 10.5 kV side is 300/1.

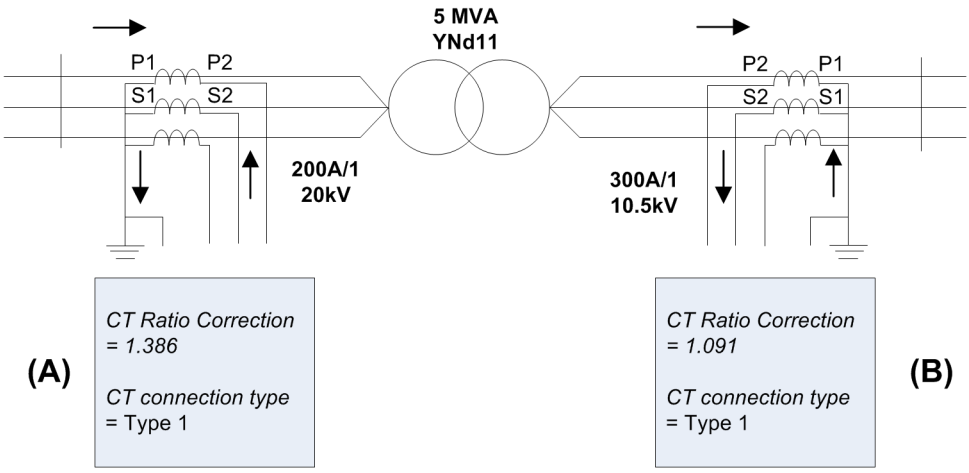

Figure 367: Example of CT ratio correction setting calculation with in-zone transformer

The rated load of the transformer is:

HV side (A): I_{nT_A}= 5 MVA / (1.732 × 20 kV) = 144.3 A

LV side (A): I_{nT_B}= 5 MVA / (1.732 × 10.5 kV) = 274.9 A

So the settings for *CT ratio corrections* at HV (A) and LV (B) side are:

CT ratio correction (A) = 200 A / 144.3 A = 1.386

CT ratio correction (B) = 300 A / 274.9 A = 1.091

CT connections

The connections of the primary current transformers are designated as “Type 1” and “Type 2”.

- If the positive directions of the winding 1 and winding 2 protection relay currents are opposite, the *CT connection type* setting parameter is “Type 1”. The connection examples of “Type 1” are as shown in the *Figure 368* and *Figure 369*.
- If the positive directions of the winding 1 and winding 2 protection relay currents equate, the *CT connection type* setting parameter is “Type 2”. The connection examples of “Type 2” are as shown in the *Figure 370* and *Figure 371*.
- The default value of the *CT connection type* setting is “Type 1”.

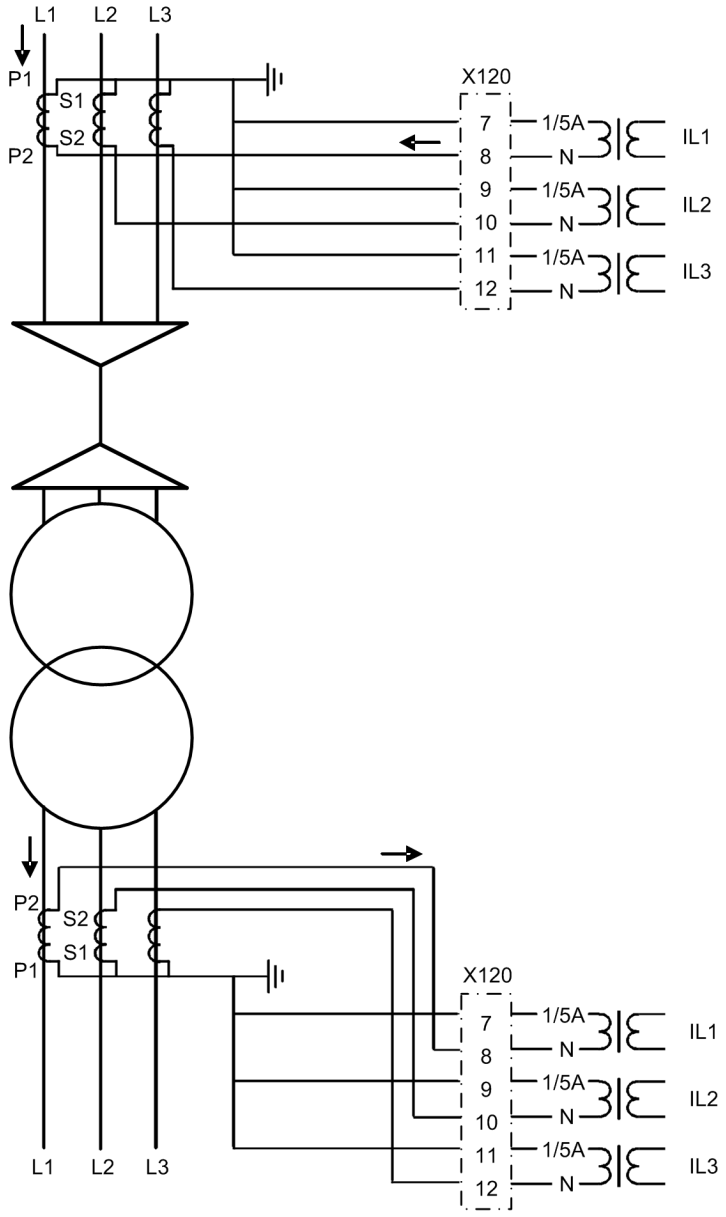

Figure 368: Connection example of current transformers of Type 1

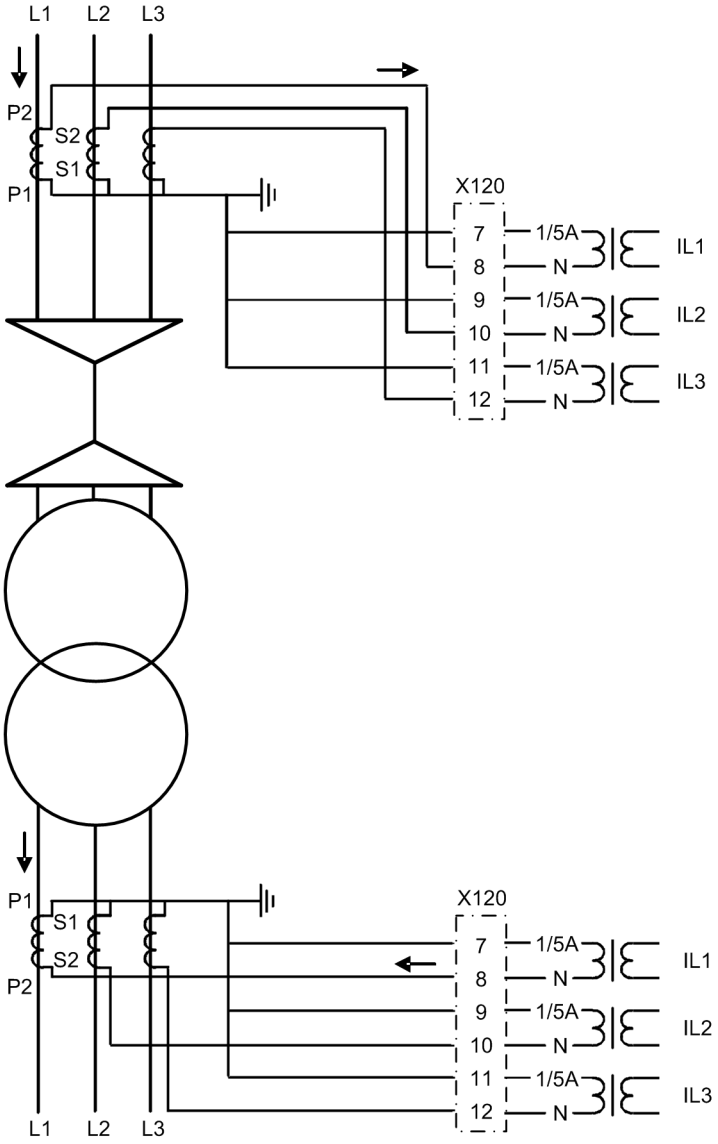

Figure 369: Connection example of current transformers of Type 1

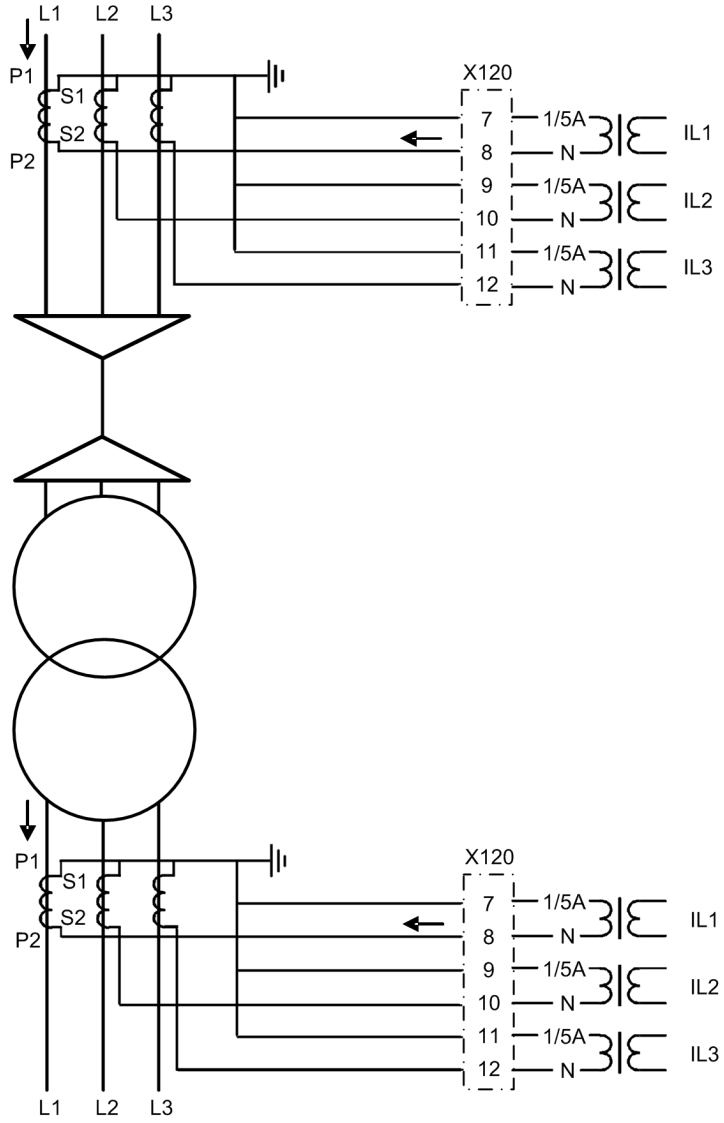

Figure 370: Connection example of current transformers of Type 2

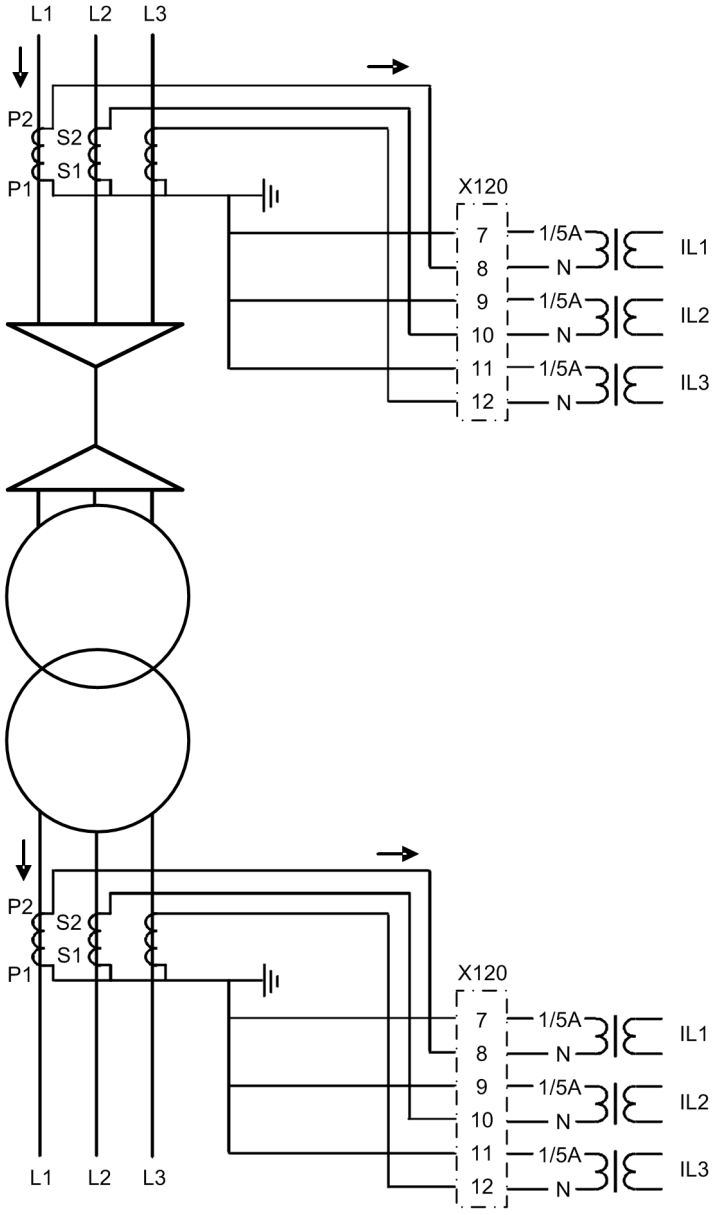

Figure 371: Connection example of current transformers of Type 2

Transformer vector group matching

Before differential and bias currents can be calculated, the phase difference of the currents must be vector group matched based on the transformer connection type. The vector group of the power transformer is numerically matched on the high voltage and low voltage sides by means of the *Winding selection*, *Winding 1 type*, *Winding 2 type* and *Clock number* settings. Thus no interposing CTs are needed if there is only a power transformer inside the protected zone. The matching is based on phase shifting and a numerical delta connection in the protection relay. If the neutral of a star-connected power transformer is earthed, any earth-fault in the network is perceived by the protection relay as a differential current. The elimination of the zero-sequence component can be selected for that winding by setting the Zro A elimination parameter.

Winding selection setting defines the protection relay location respect to the transformer. If the protection relay is situated at the HV side of the transformer, then protection relay location setting is set to “Winding 1” and respectively to “Winding 2” if protection relay is situated at the LV side. If the differential protection relays are used to protect a line without in-zone transformer, then the setting is set to “Not in use”. In this case vector group matching is ignored.

The matching of the phase difference is based on the phase shifting and the numerical delta connection inside the protection relay. The *Winding 1 type* parameter determines the connection on winding 1 (“Y”, “YN”, “D”, “Z”, “ZN”). The vector group matching can be implemented either on both, winding 1 and winding 2, or only on winding 1 or winding 2, at intervals of 30° with the *Clock number* setting. Similarly, the *Winding 2 type* parameter determines the connections of the phase windings on the low voltage side (“y”, “yn”, “d”, “z”, “zn”).

When the vector group matching is Yy0 and the *CT connection type* is according to “Type 2”, the phase angle of the phase currents connected to the protection relay does not change. When the vector group matching is Yy6, the phase currents are on one side turned 180° in the protection relay.

Example 1, vector group matching of an YNd11-connected power transformer on winding 1, *CT connection type* according to type 1. The *Winding 1 type* setting is “YN”, *Winding 2 type* is “d” and *Clock number* is “Clk Num 11”. This is compensated internally by giving winding 1 internal compensation value +30° and winding 2 internal compensation value 0°:

$$\bar{I}_{L1mHV} = \frac{\bar{I}_{L1} - \bar{I}_{L2}}{\sqrt{3}}$$

(Equation 146)

$$\bar{I}_{L2mHV} = \frac{\bar{I}_{L2} - \bar{I}_{L3}}{\sqrt{3}}$$

(Equation 147)

$$\bar{I}_{L3mHV} = \frac{\bar{I}_{L3} - \bar{I}_{L1}}{\sqrt{3}}$$

(Equation 148)

Example 2, if vector group is Yd11 and *CT connection type* is according to type 1, the compensation is a little different. The *Winding 1 type* setting is “Y”, *Winding 2 type* is “d” and *Clock number* is “Clk Num 11”. This is compensated internally by giving winding 1 internal compensation value 0° and winding 2 internal compensation value -30°:

$$\bar{I}_{L1mLV} = \frac{\bar{I}_{L1} - \bar{I}_{L3}}{\sqrt{3}}$$

(Equation 149)

$$\bar{I}_{L2mLV} = \frac{\bar{I}_{L2} - \bar{I}_{L1}}{\sqrt{3}}$$

(Equation 150)

$$\bar{I}_{L3mLV} = \frac{\bar{I}_{L3} - \bar{I}_{L2}}{\sqrt{3}}$$

(Equation 151)

The “Y” side currents stay untouched, while the “d” side currents are compensated to match the currents actually flowing in the windings.

In this example there is no neutral current on either side of the transformer (assuming there are no earthing transformers installed). In the previous example, the matching is done differently to have the winding 1 neutral current compensated at the same time.

Zero-sequence component elimination

If *Clock number* is “Clk Num 2“, “Clk Num 4”, “Clk Num 8” or “Clk Num 10”, the vector group matching is always done on both, winding 1 and winding 2. The combination results in the correct compensation. In this case the zero-sequence component is always removed from both sides automatically. The *Zro A elimination* parameter cannot change this.

If *Clock number* is “Clk Num 1”, “Clk Num 5”, “Clk Num 7” or “Clk Num 11”, the vector group matching is done on one side only. A possible zero-sequence component of the phase currents at earth faults occurring outside the protection area is automatically eliminated in the numerically implemented delta connection before the differential current and the biasing current are calculated. This is why the vector group matching is almost always made on the star connected side of the “Ynd” and “Dyn” connected transformers.

If *Clock number* is “Clk Num 0” or “Clk Num 6”, the zero-sequence component of the phase currents is not eliminated automatically on either side. Therefore, the zero-sequence component on the star connected side that is earthed at its star point has to be eliminated by using the Zro A elimination parameter.

The same parameter has to be used to eliminate the zero-sequence component if there is, for example, an earthing transformer on the delta-connected side of the “Ynd” power transformer in the area to be protected. In this case, the vector group matching is normally made on the side of the star connection. On the side of the delta connection, the elimination of the zero-sequence component has to be eliminated by using the Zro A elimination parameter.

By using the Zro A elimination parameter, the zero-sequence component of the local phase currents is calculated and reduced for each phase current:

$$\bar{I}_{LOC_A} = \bar{I}_{LOC_A} - \frac{1}{3} \times \left(\bar{I}_{LOC_A} + \bar{I}_{LOC_B} + \bar{I}_{LOC_C} \right)$$

(Equation 152)

$$\bar{I}_{LOC_B} = \bar{I}_{LOC_B} - \frac{1}{3} \times \left(\bar{I}_{LOC_A} + \bar{I}_{LOC_B} + \bar{I}_{LOC_C} \right)$$

(Equation 153)

$$\bar{I}_{LOC_C} = \bar{I}_{LOC_C} - \frac{1}{3} \times \left(\bar{I}_{LOC_A} + \bar{I}_{LOC_B} + \bar{I}_{LOC_C} \right)$$

Fail safe function

To prevent malfunction during communication interference, the operation of LNPLDF is blocked when the protection communication supervision detects severe interference in the communication channel. The timer reset stage is activated in case the stabilized stage is started during a communication interruption. The protection communication supervison is connected internally from PCSITPC to LNPLDF (dotted OK line).

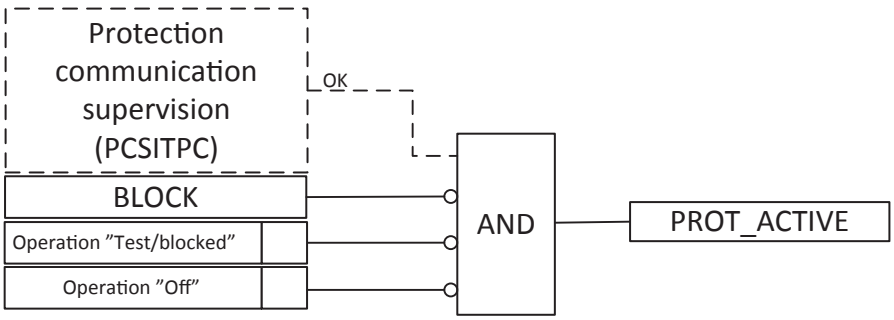

Figure 372: Operation logic of the fail safe function

The function can also be set into “test/blocked” state with the *Operation* setting. This can also be utilized during the commissioning.

The BLOCK input is provided for blocking the function with the logic. When the function is blocked, the monitored data and measured values are still available but the binary outputs are blocked. When the function is blocked, the direct inter-trip is also blocked.

The PRO_ACTIVE output is always active when the protection function is capable of operating. PRO_ACTIVE can be used as a blocking signal for backup protection functions.

Timer

Once activated, the timer activates the STR_LS_LOC output. Depending on the value of the set *Operating curve type*, the timer characteristics are according to DT or IDMT. When the operation timer has reached the value set with the *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPR_LS_LOC output is activated. When the operation mode is according to IDMT, *Low operate value* is used as reference value (Start value) in the IDMT equations presented in the Standard inverse-time characteristics section.

A timer reset state is activated when a drop-off situation happens. The reset is done according to the DT characteristics.

For a detailed description of the timer characteristics, see the *Chapter 11 General function block features* section in this manual.

Instantaneous high stage

In addition to the stabilized low stage, LNPLDF has an instantaneous high stage. The stabilizing is not done with the instantaneous high stage. The instantaneous high stage operates immediately when the differential current amplitude is higher than the set value of the *High operate value* setting. If the ENA_MULT_HS input is active, the *High operate value* setting is internally multiplied by the *High Op value Mult* setting.

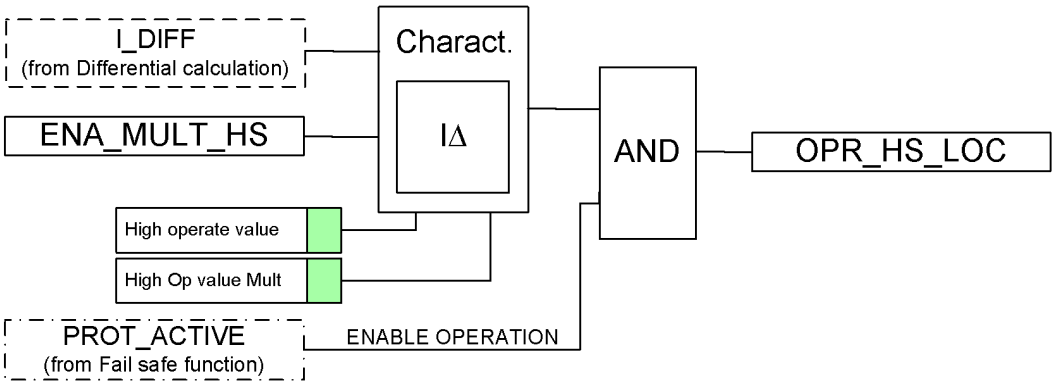

Figure 373: Operation logic of instantaneous high stage

Direct inter-trip

Direct inter-trip is used to ensure the simultaneous opening of the circuit breakers at both ends of the protected line when a fault is detected. Both start and operate signals are sent to the remote end via communication. The direct-intertripping of the line differential protection is included into LNPLDF. The `OPERATE` output combines the operate signals from both stages, local and remote, so that it can be used for the direct inter-trip signal locally.

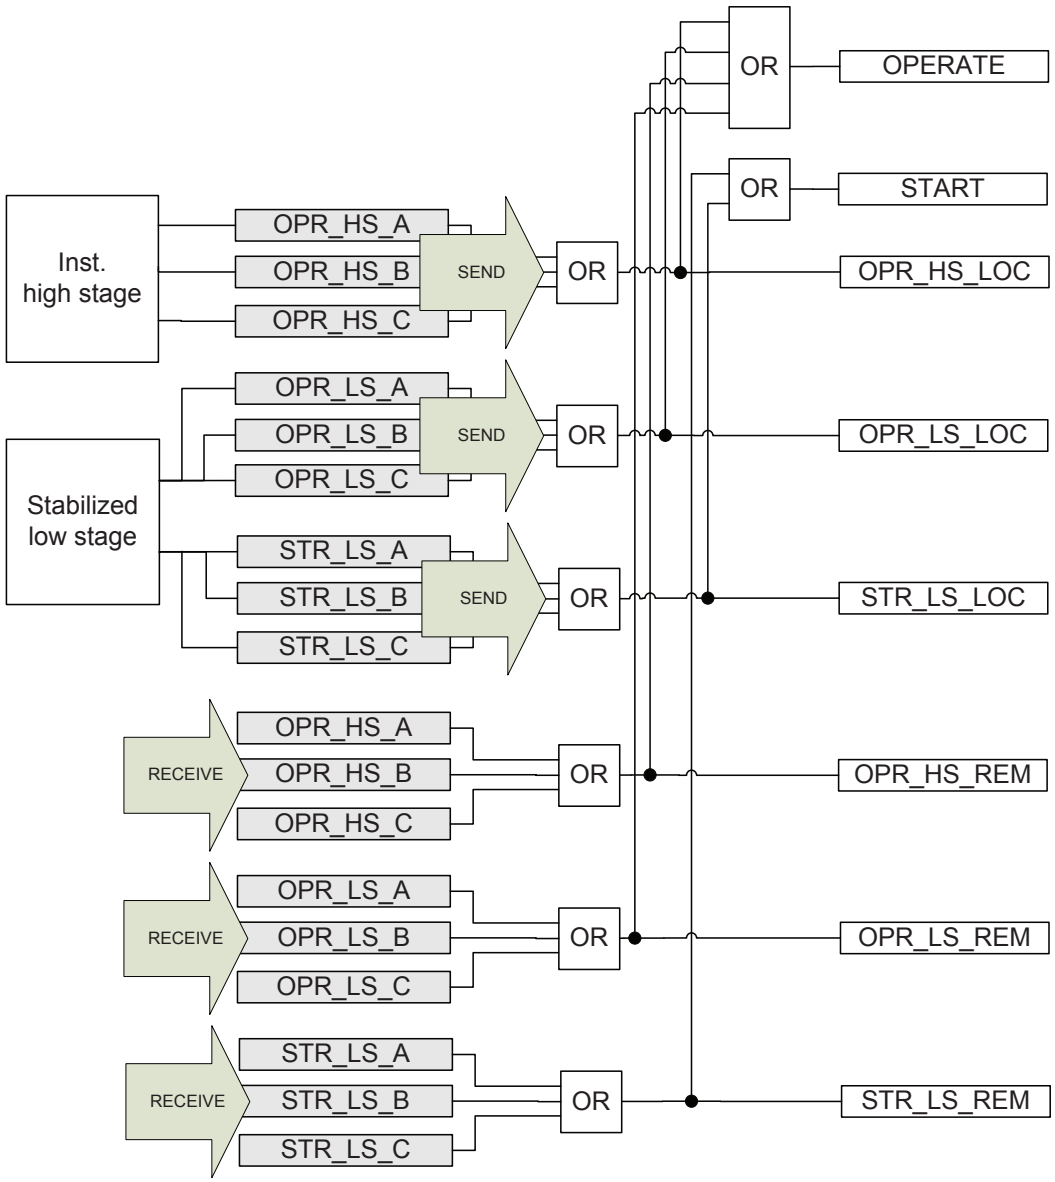

Figure 374: Operation logic of the direct intertrip function

The start and operate signals are provided separately for the low and high stages, and in the local and remote.

Blocking functionality

There are two independent inputs that can be used for blocking the function: `BLOCK` and `BLOCK_LS`. The difference between these inputs is that `BLOCK_LS` (when TRUE) blocks only the stabilized low stage leaving the instantaneous high stage operative. `BLOCK` (when TRUE) blocks both stages and also the `PRO_ACTIVE` output is updated according to the `BLOCK` input status, as described in the Fail safe function chapter.

The `BLOCK` and `BLOCK_LS` input statuses affect only the behavior of the local protection instance. When a line differential protection stage (stabilized low or instantaneous high) is blocked, also the received remote signals related to the corresponding stage are ignored (received direct inter-trip signals from the remote end). The binary signal transfer functionality should therefore be used for

transferring the possible additional blocking information between the local and remote terminals whenever the blocking logic behavior needs to be the same on both line ends.

Test mode

The line differential function in one protection relay can be set to test mode, that is, the *Operation* setting is set to “test/blocked”. This blocks the line differential protection outputs in the protection relay and sets the remote protection relay to a remote test mode, such that the injected currents are echoed back with the shifted phase. It is also possible that both protection relays are simultaneously in the test mode. When the line differential protection function is in the test mode:

- The remote end protection relay echoes locally injected current samples back with the shifted phase. The current samples that are sent to the remote protection relay are scaled with the CT ratio correction setting.
- The operation of both stages (stabilized low or instantaneous high) are blocked, and also the direct inter-trip functionality is blocked (both receive and send) in the protection relay where the test mode is active.
- The remote end line differential protection function that is in the normal mode (On) is not affected by the local end being in the test mode. This means that the remote end function is operative but, at the same time, it ignores the received current samples from the other end protection relay which is in the test mode.
- The PRO_ACTIVE output is false only in the protection relay that is currently in the test mode.

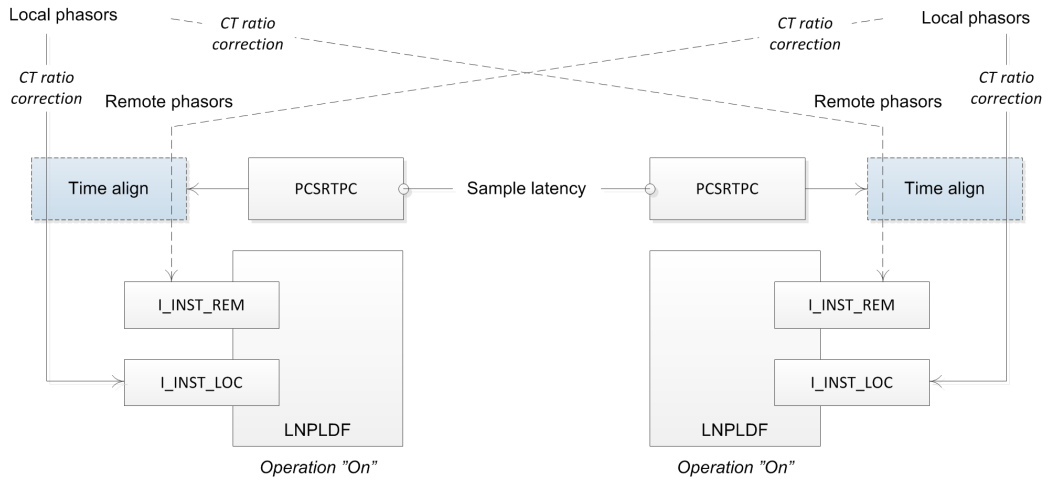

Figure 375: Operation during the normal operation of the line differential protection

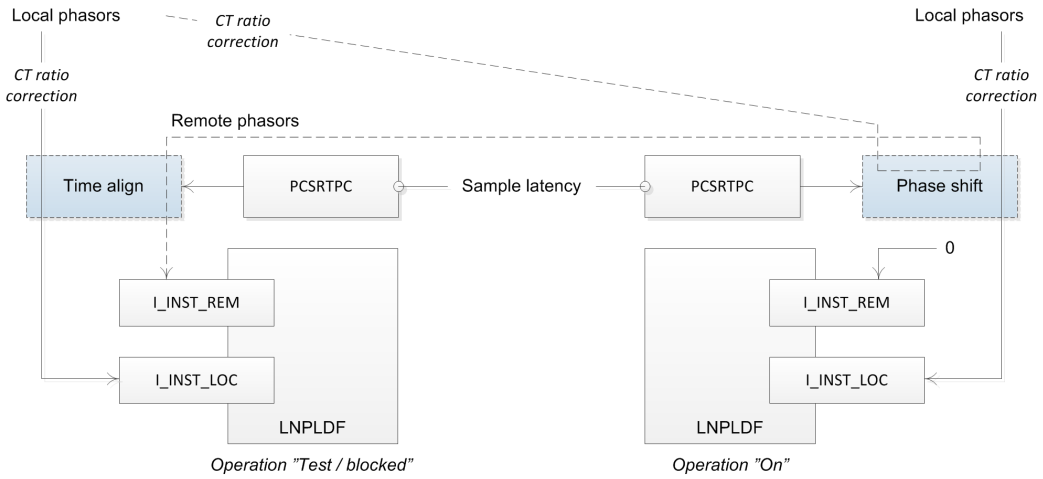

Figure 376: Operation during test operation of the line differential protection

4.3.1.6 Commissioning

The commissioning of the line differential protection scheme would be difficult without any support features in the functionality because of the relatively long distance between the protection relays. This has been taken into consideration in the design of the line differential protection. The communication channel can be used for echoing the locally fed current phasors from the remote end. By using this mode, it is possible to verify that differential calculation is done correctly in each phase. Also, the protection communication operation is taken into account with the differential current calculation when this test mode is used.

Required material for testing the protection relay

- Calculated settings
- Terminal diagram
- Circuit diagrams
- Technical and application manuals of the protection relay
- Single of three-phase secondary current source
- Single of three-phase primary current source
- Timer with start and stop interfaces
- Auxiliary voltage source for the protection relays
- PC with related software, a Web browser for WHMI

The setting and configuration of the protection relay must be completed before testing.

The terminal diagram, available in the technical manual, is a general diagram of the protection relay.

The same diagram is not always applicable to each specific delivery, especially for the configuration of all the binary inputs and outputs. Therefore, before testing, check that the available terminal diagram corresponds to the protection relay.

The circuit diagrams of the application are recommended to be available. These are required for checking the terminal block numbers of the current, trip, alarm and possibly other auxiliary circuits.

The technical and application manuals contain application and functionality summaries, function blocks, logic diagrams, input and output signals, setting parameters and technical data sorted per function.

The minimum requirement for a secondary current injection test device is the ability to work as a one phase current source.

The protection relay should be prepared for the test before testing a particular function. The logic diagram of the tested protection function must be considered while performing the test. All included functions in the protection relay are tested according to the corresponding test instructions in this chapter. The functions can be tested in any order according to user preferences. Therefore, the test instructions are presented in alphabetical order. Only the functions that are in use (*Operation* is set to "On") should be tested.

The response from the test can be viewed in different ways.

- Binary output signals
- Monitored data values in the LHMI (logical signals)
- A PC with a Web browser for WHMI use (logical signals and phasors)

All used setting groups should be tested.

Checking the external optical and electrical connections

The user must check the installation to verify that the protection relay is connected to the other required parts of the protection system. The protection relay and all the connected circuits are to be de-energized during the check-up.

Checking of CT circuits

Check that the wiring is in strict accordance with the supplied connection diagram.

The CTs must be connected in accordance with the terminal diagram provided with the protection relay, both with regards to phases and polarity. The following tests are recommended for every primary CT or CT core connected to the protection relay.

- Primary injection test to verify the current ratio of the CT, the correct wiring up to the protection relay and correct phase sequence connection (that is L1, L2, L3.)
- Polarity check to prove that the predicted direction of the secondary current flow is correct for a given direction of the primary current flow. This is an essential test for the proper operation of the directional function, protection or measurement in the protection relay.
- CT secondary loop resistance measurement to confirm that the current transformer secondary loop DC resistance is within specification and that there are no high resistance joints in the CT winding or wiring.
- CT excitation test to ensure that the correct core in the CT is connected to the protection relay. Normally only a few points along the excitation curve are checked to ensure that there are no wiring errors in the system, for example, due to a mistake in connecting the CT's measurement core to the protection relay.
- CT excitation test to ensure that the CT is of the correct accuracy rating and that there are no short circuited turns in the CT windings. Manufacturer's design curves should be available for the CT to compare the actual results.

- Earthing check of the individual CT secondary circuits to verify that each three-phase set of main CTs is properly connected to the station earth and only at one electrical point.
- Insulation resistance check.
- Phase identification of CT shall be made.

CT and VT connectors are pre-coded, and the CT and VT connector markings are different. For more information, see the installation manual.

De-energize the CT primary side and disconnect the CT secondary circuits from the protection relay while carrying out the CT core excitation curve plotting.

If the CT secondary circuit is opened or its earth connection is missing or removed without the CT primary being de-energized first, dangerous voltages may be produced. This can be lethal and cause damage to the insulation. The re-energizing of the CT primary should be prohibited as long as the CT secondary is open or unearthed.

Checking of the power supply

Check that the auxiliary supply voltage remains within the permissible input voltage range under all operating conditions. Check that the polarity is correct before powering the protection relay.

Checking binary I/O circuits

Always check the binary input circuits from the equipment to the protection relay interface to make sure that all signals are connected correctly. If there is no need to test a particular input, the corresponding wiring can be disconnected from the terminal of the protection relay during testing. Check all the connected signals so that both input voltage level and polarity are in accordance with the protection relay specifications. However, attention must be paid to the electrical safety instructions.

Always check the binary output circuits from the protection relay to the equipment interface to make sure that all signals are connected correctly. If a particular output needs to be tested, the corresponding wiring can be disconnected from the terminal of the protection relay during testing. Check all the connected signals so that both load and polarity are in accordance with the protection relay specifications. However, attention must be paid to the electrical safety instructions.

Checking of optical connections

Check that the Tx and Rx optical connections are correct.

A relay equipped with optical connections requires a minimum depth of 180 mm (7.0866 in) for plastic fiber cables and 275 mm (10.8268 in) for glass fiber cables. Check the allowed minimum bending radius from the optical cable manufacturer.

Applying of required settings for the protection relay

Download all calculated settings and measurement transformer parameters in the protection relay.

Connecting of test equipment to the protection relay

Before testing, connect the test equipment according to the protection relay specific connection diagram.

Pay attention to the correct connection of the input and output current terminals. Check that the input and output logical signals in the logic diagram for the function under test are connected to the corresponding binary inputs and outputs of the protection relay. Select the correct auxiliary voltage source according to the power supply module of the protection relay. Select the correct auxiliary voltage source according to the power supply module of the protection relay.

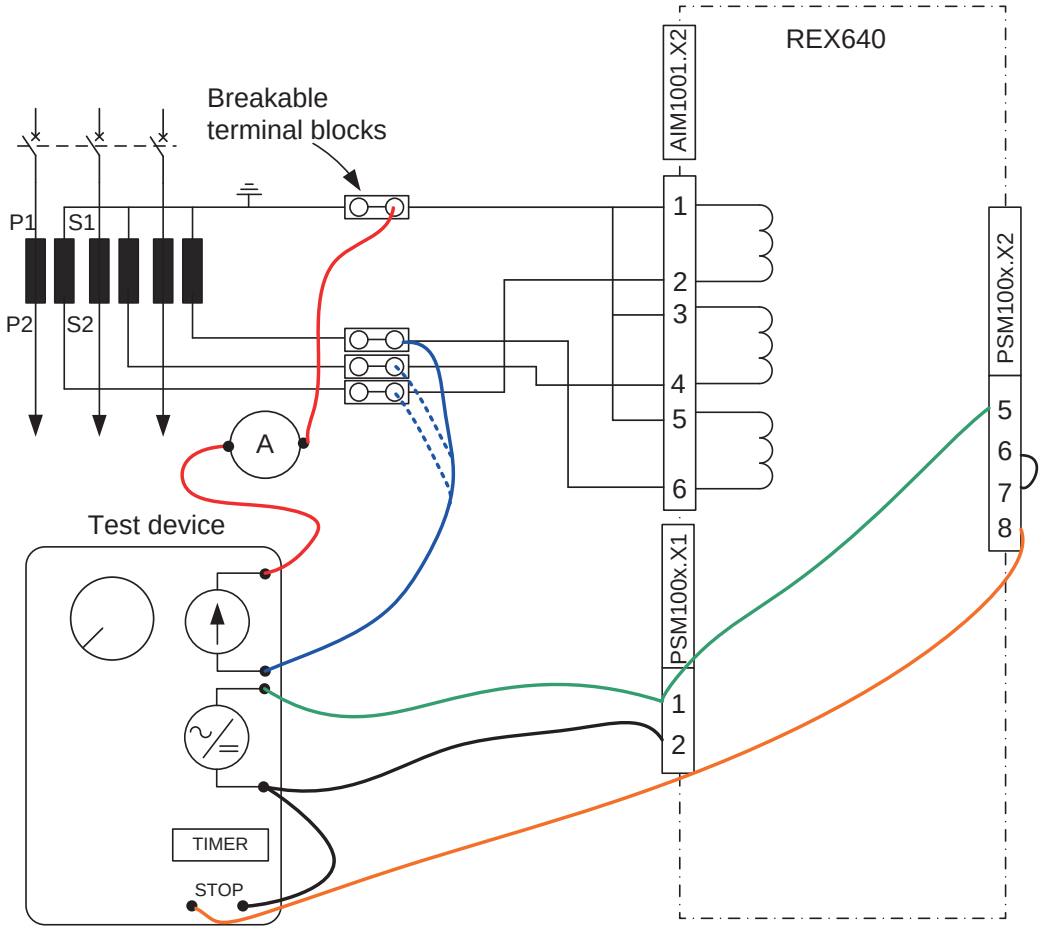

Figure 377: Example of connections to test the line differential protection relay

Secondary current injection

There are two alternative modes to check the operation of a line differential protection relay. These are not exclusive methods for each other and can be used for various test on the protection relay.

Normal mode

In normal mode, that is, the mode when the function is on normal operation, the local end protection relay sends phasors to the remote end protection relay and receives phasors measured by the remote end protection relay. This mode can be

used in testing the operating level and time of the low and high stages of the local end protection relay. This is due to a test situation when the remote end does not measure any current and therefore, all the current fed to the local end current circuit is seen as differential current at both ends.

Testing of the line differential protection is done with both protection relays separated geographically from each other. It is important to note that local actions in one protection relay cause operation also in the remotely located protection relay. When testing the line differential function, actions have to be done in both protection relays.

Before the test, the trip signal to the circuit breaker shall be blocked, for example by breaking the trip circuit by opening the terminal block or by using some other suitable method.

When injecting current to one phase in the local end protection relay, the current is seen as a differential current at both ends. If a current $I_{injected}$ is injected, L1 in phase L1, the differential and stabilizing currents for phase L1 are:

$$ID_A = I_{injected}$$

(Equation 154)

$$IB_A = \frac{I_{injected}}{2}$$

(Equation 155)

The operation is equal for phases L2 and L3.

Verifying the settings

1. Block the unwanted trip signals from the protection relay units involved.
2. Inject a current in phase L1 and increase the current until the function operates for phase L1.

   The injected operate current corresponds to the set *Low operate value*. The monitored values for ID_A should be equal to the injected current.

3. Repeat point 2 by current injection in phases L2 and L3.
4. Measure the operating time by injecting the single-phase current in phase L1.

   The injected current should be four times the operating current. The time measurement is stopped by the trip output from the protection relay unit.

5. Disconnect the test equipment and reconnect the current transformers and all other circuits including the trip circuit.

Phasor echoing method

The line differential function in one protection relay can be set to special test mode, that is, the *Operation* setting is set to “test/blocked”. When this mode is in use, the remote end protection relay echoes locally injected current phasors back with the shifted phase and settable amplitude. Therefore, the local end line differential function is also automatically blocked and the remote end line differential function discards the phasors it receives from the protection relay in the test mode.

When the test mode is active, the *CT connection type* is still used by the line differential protection function as in the normal operation mode. The setting can be used for shifting the phase (0 or 180 degrees).

4.3.1.7 Application

LNPLDF is designed for the differential protection of overhead line and cable feeders in a distribution network. LNPLDF provides absolute selectivity and fast operating times as unit protection also in short lines where distance protection cannot be applied.

LNPLDF provides selective protection for radial, looped and meshed network topologies and can be used in isolated neutral networks, resistance earthed networks, compensated (impedance earthed) networks and solidly earthed networks. In a typical network configuration where the line differential protection scheme is applied, the protected zone, that is, the line or cable, is fed from two directions.

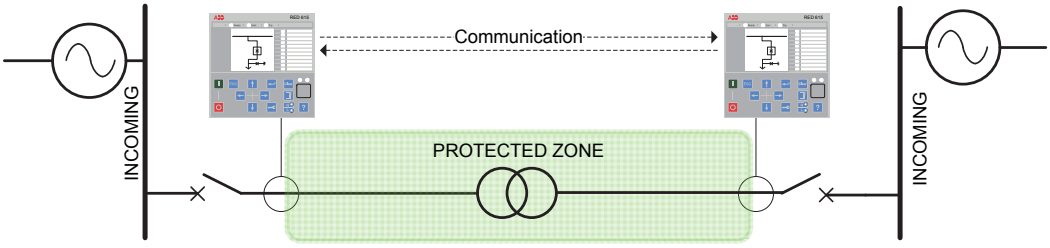

Figure 379: Line protection with phase segregated line differential with in-zone transformer

LNPLDF can be utilized for various types of network configurations or topologies. Case A shows the protection of a ring-type distribution network. The network is also used in the closed ring mode. LNPLDF is used as the main protection for different sections of the feeder. In case B, the interconnection of two substations is done with parallel lines and each line is protected with the line differential protection. In case C, the connection line to mid scale power generation (typical size

around 10...50 MVA) is protected with the line differential function. The protection includes the transformer from the protection field. In case D, the connection between two substations and a small distribution transformer is located at the tapped load. The usage of LNPLDF is not limited to these applications.

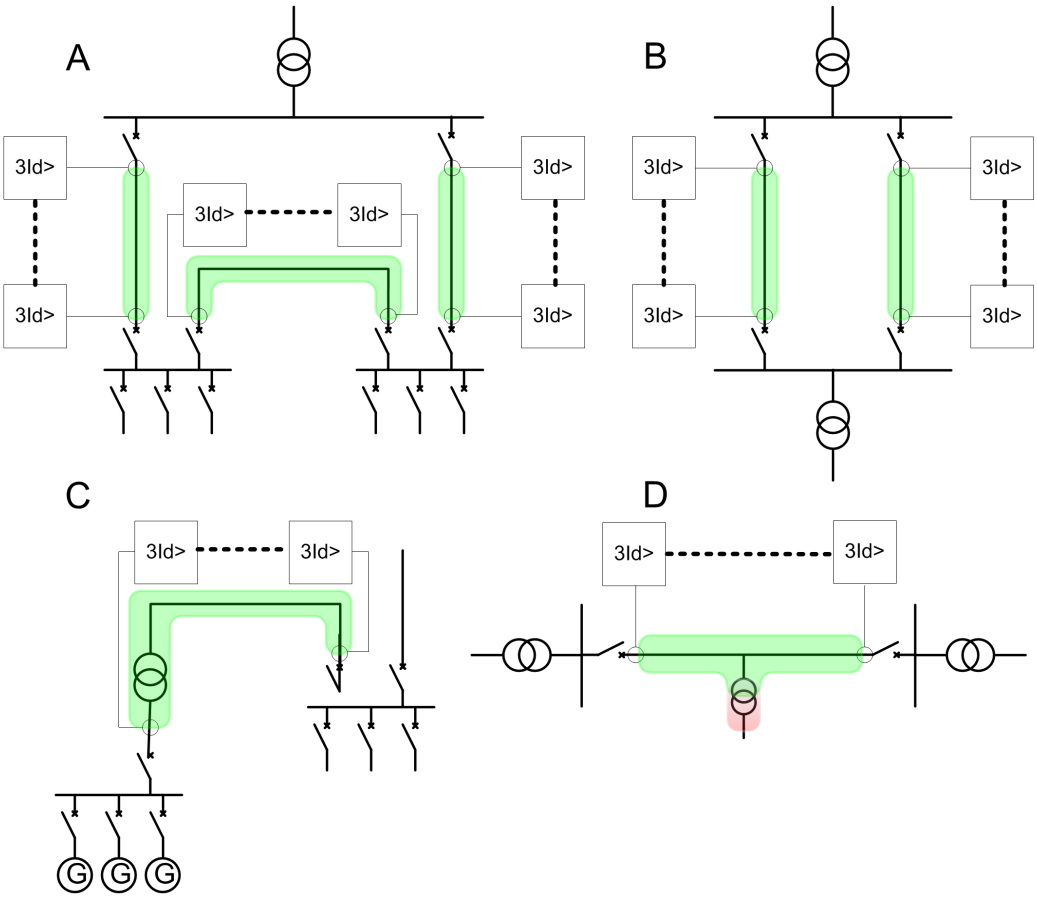

Figure 380: Line differential applications

Communication supervision

A typical line differential protection application includes LNPLDF as the main protection. Backup over current functions is needed if a protection communication failure occurs. When the communication supervision function detects a failure in the communication between the protective units, the safe operation of the line is still guaranteed by blocking the line differential protection and unblocking the over current functions.

When a communication failure is detected, the protection communication supervision function issues block for the LNPLDF line differential protection and unblock for the instantaneous and high stages (instance 2) of the over current protection. These are used to give backup protection for the remote end feeder protection relay. In situations where the selectivity is weaker than usually, the protection should still be available for the system.

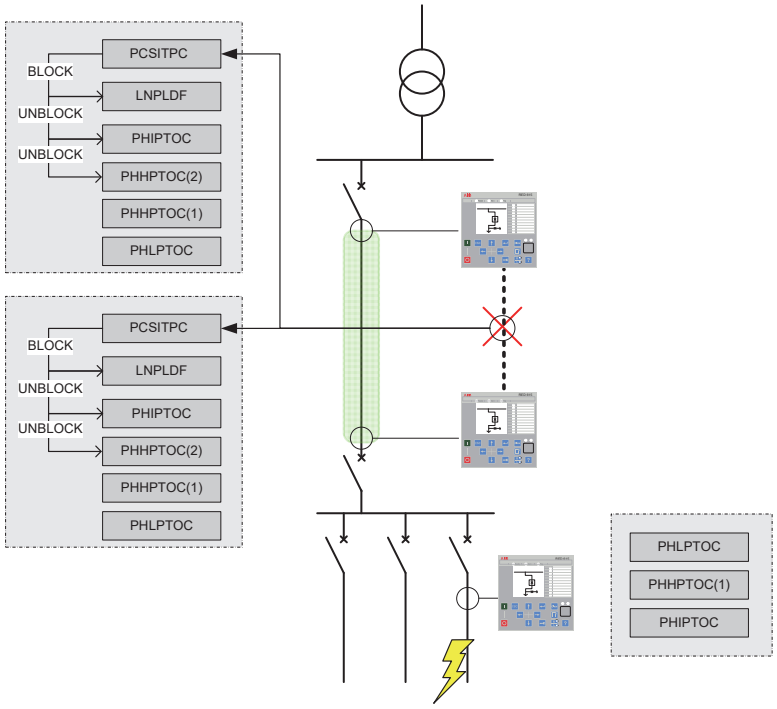

Figure 381: Protection communication supervision detects failures on communication

In-zone transformer

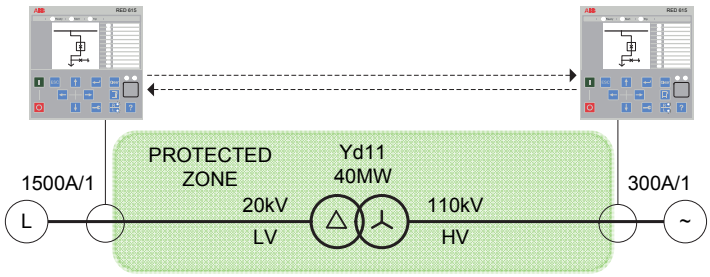

Figure 382: In-zone transformer example about CT ratio correction calculation

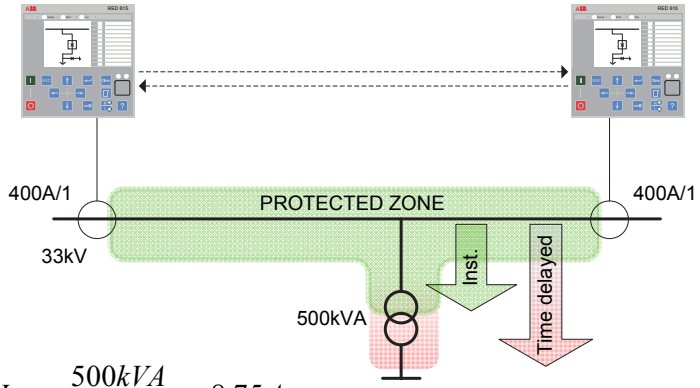
The CT ratio correction calculation starts with the rated load current calculation for HV and LV sides. The rated load current is defined as the rated power of the transformer divided by the square root of three times the nominal phase-to-phase voltage at the HV or LV side.

$$I_{nT} = \frac{S_n}{\sqrt{3} \times U_n}$$

(Equation 156)



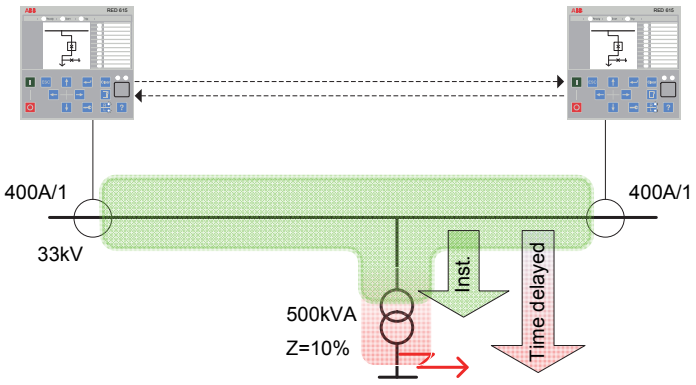
The rated load current of the transformer on the HV side is 209.9 A (40 MW / (√3 × 110 kV)) and the rated load current of the transformer on the LV side is 1154.7 A (40 MW / (√3 × 20 kV)). This means that the CT ratio corrections for the HV and LV sides are:

CT ratio correction (HV) = 1.429 (300 A / 209.9 A)

CT ratio correction (LV) = 1.299 (1500 A / 1154.7 A)

Small power transformers in a tap

With a relatively small power transformer in a line tap, the line differential protection can be applied without the need of current measurement from the tap. In such cases, the line differential function is time delayed for low differential currents below the high set limit and LNPLDF coordinates with the downstream protection relays in the relevant tap. For differential currents above the set limit, the operation is instantaneous. As a consequence, when the load current of the tap is negligible, the low resistive line faults are cleared instantaneously at the same time as maximum sensitivity for the high resistive faults are maintained but with a time delayed operation. The maximum sensitivity for high resistive faults is maintained at the same time, but with a time delayed operation.



$$I_L = \frac{500kVA}{\sqrt{3} \cdot 33kV} \cong 8.75A$$

$$I_\Delta > \left[\frac{8.75A}{400\ A}\right] * 1A = 0.02A = 2\%$$

Figure 383: Influence of the tapped transformer load current to the stabilized low stage setting

The stabilized stage provides both DT and IDMT characteristics that are used for time selective protection against faults which are not covered by the instantaneous stage. The impedance of the line is typically an order of magnitude lower than the transformer impedance providing significantly higher fault currents when the fault is located on the line.

$$I_F = \frac{1.1 \cdot 500kVA}{\sqrt{3} \cdot 33kV \cdot 0.10} \cong 96.23A$$

$$I_\Delta < \left[\frac{96.23A}{400\ A}\right] * 1A = 0.24A = 24\%$$

Figure 384: Influence of the short circuit current at LV side of the tapped transformer to the differential current

Detection of the inrush current during transformer start-up

When the line is energized, the transformer magnetization inrush current is seen as differential current by the line differential protection and may cause malfunction of the protection if not taken into account. The inrush situation may only be detected on one end but the differential current is always seen on both ends. The inrush

current includes high order harmonic components which can be detected and used as the blocking criteria for the stabilized stage. The inrush detection information is changed between two ends so that fast and safe blocking of the stabilized stage can be issued on both ends.

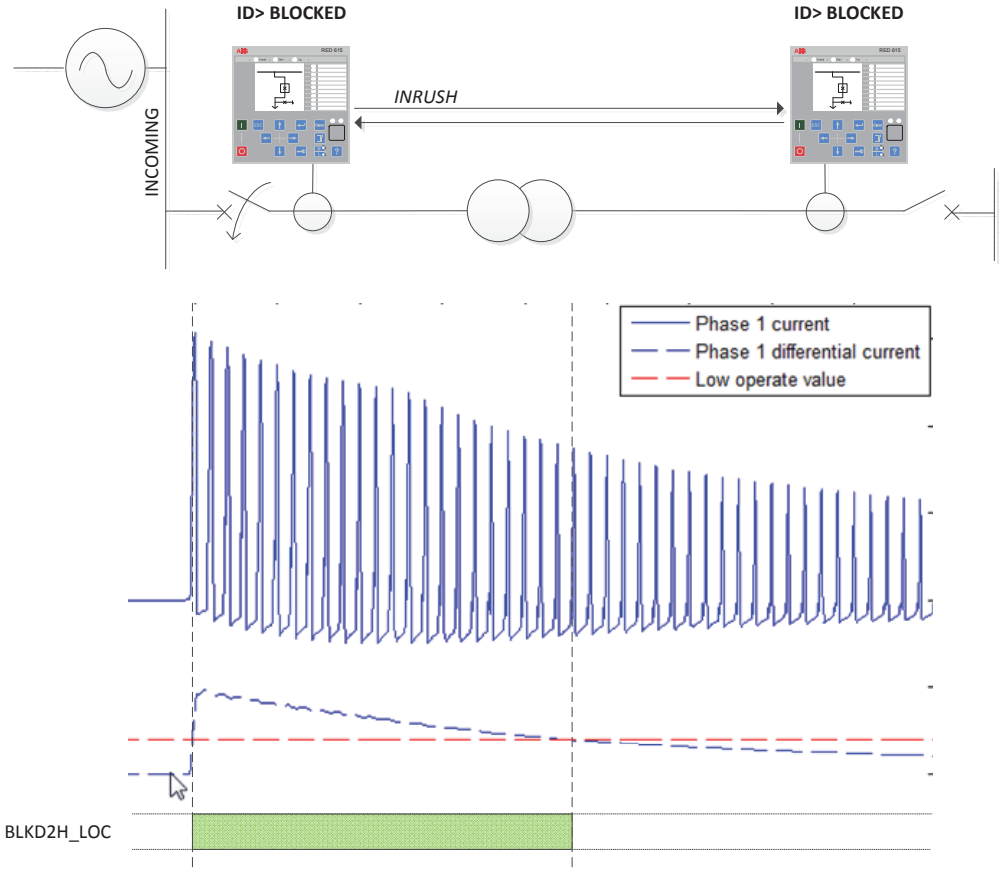


Figure 385: Blocking of line differential functions during detected transformer start-up current

If the protection stage is allowed to start during the inrush situation, the time delay can be selected so that the stabilized stage does not operate in the inrush situation.

4.3.1.8 Signals

LNPLDF Input signals

Table 647: LNPLDF Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
BLOCK	BOOLEAN	0=False	Signal for blocking the function

Table continues on the next page

Name	Type	Default	Description
BLOCK_LS	BOOLEAN	0=False	Signal for blocking the stab. stage
ENA_MULT_HS	BOOLEAN	0=False	Enables the high stage multiplier

LNPLDF Output signals

Table 648: LNPLDF Output signals

Name	Type	Description
OPERATE	BOOLEAN	Operate, local or remote, stabilized or instantaneous stage
START	BOOLEAN	Start, local or remote
STR_LS_LOC	BOOLEAN	Start stabilized stage local
STR_LS_REM	BOOLEAN	Start stabilized stage remote
OPR_LS_LOC	BOOLEAN	Operate stabilized stage local
OPR_LS_REM	BOOLEAN	Operate stabilized stage remote
OPR_HS_LOC	BOOLEAN	Operate instantaneous stage local
OPR_HS_REM	BOOLEAN	Operate instantaneous stage remote
BLKD2H_LOC	BOOLEAN	Restraint due 2nd harmonics detected local
BLKD2H_REM	BOOLEAN	Restraint due 2nd harmonics detected remote
PRO_ACTIVE	BOOLEAN	Status of the protection, true when function is operative

4.3.1.9 LNPLDF Settings

Table 649: LNPLDF Group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Low operate value	10...200	%Ir	1	10	Basic setting for the stabilized stage start
High operate value	200...4000	%Ir	1	2000	Instantaneous stage operate value
Start value 2.H	10...50	%	1	20	The ratio of the 2. harmonic component to fundamental component required for blocking
High Op value Mult	0.5...1.0		0.1	1.0	Multiplier for scaling the high stage operate value

Table continues on the next page

Parameter	Values (Range)	Unit	Step	Default	Description
Time multiplier	0.05...15.00		0.01	1.00	Time multiplier in IDMT curves

Stabilized and instantaneous differential protection for two-winding transformers	TR2PTDF	3dI>T	87T

4.3.2.2 Function block

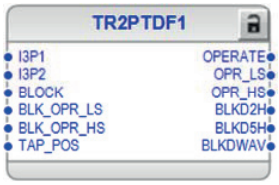

Figure 386: Function block

4.3.2.3 Functionality

The stabilized and instantaneous differential protection for two-winding transformers function TR2PTDF is designed to protect two-winding transformers and generator-transformer blocks. TR2PTDF includes low biased and high instantaneous stages.

The biased low stage provides a fast clearance of faults while remaining stable with high currents passing through the protected zone increasing errors on current measuring. The second harmonic restraint, together with the waveform based algorithms, ensures that the low stage does not operate due to the transformer inrush currents. The fifth harmonic restraint ensures that the low stage does not operate on apparent differential current caused by a harmless transformer over-excitation.

[4] *Low operate value* multiples in the range of 1.5...20

The instantaneous high stage provides a very fast clearance of severe faults with a high differential current regardless of their harmonics.

The setting characteristic can be set more sensitive with the aid of tap changer position compensation. The correction of transformation ratio due to the changes in tap position is done automatically based on the tap changer status information.

4.3.2.4 Analog channel configuration

TR2PTDF has two analog group inputs which must be properly configured.

Table 654: Analog inputs

Input	Description
I3P1	Three-phase currents
I3P2	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of TR2PTDF can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

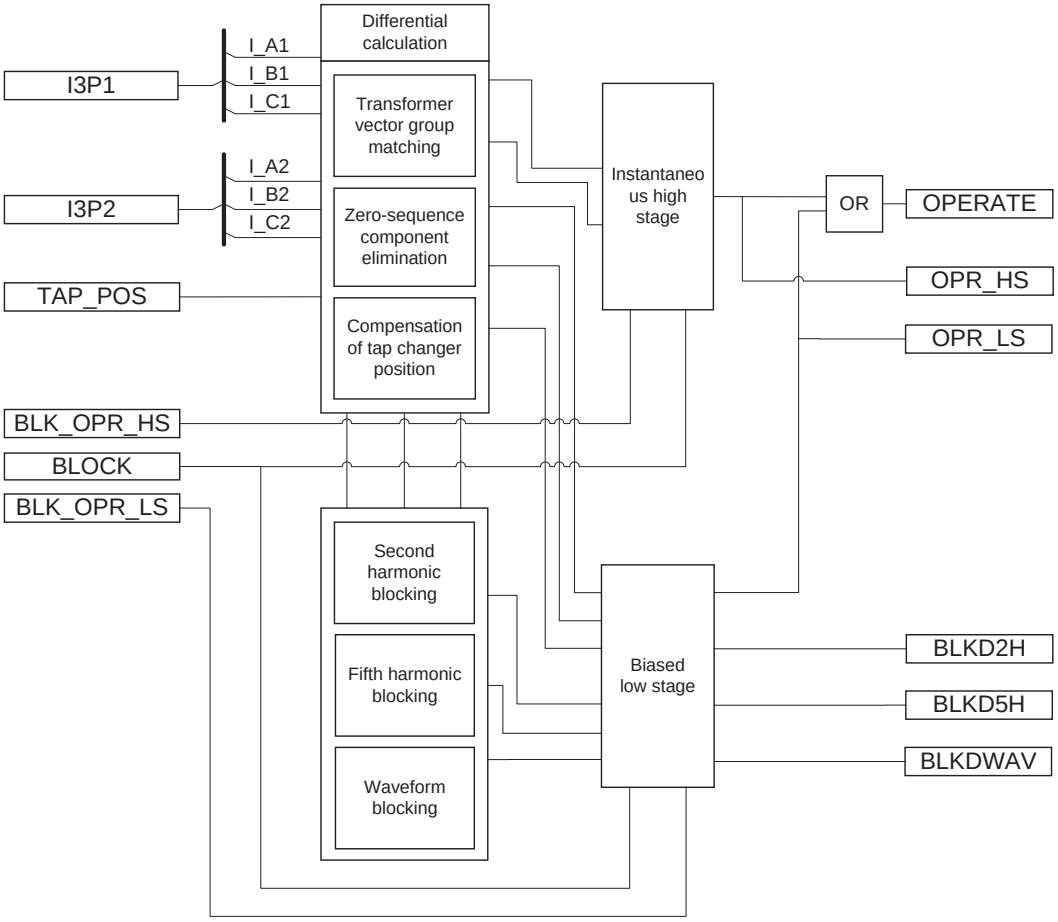

Figure 387: Functional module diagram

Differential calculation

TR2PTDF operates phase-wise on a difference of incoming and outgoing currents. The positive direction of the currents is towards the protected object.

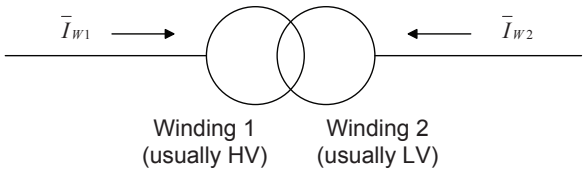

Figure 388: Positive direction of the currents

$$I_d = \left| \bar{I}_{W1} + \bar{I}_{W2} \right|$$

(Equation 157)

In a normal situation, no fault occurs in the area protected by TR2PTDF. Then the currents $\bar{I}_{W1}$ and $\bar{I}_{W2}$ are equal and the differential current I_d is zero. In practice, however, the differential current deviates from zero in normal situations. In the power transformer protection, the differential current is caused by CT

inaccuracies, variations in tap changer position (if not compensated), transformer no-load current and instantaneous transformer inrush currents. An increase in the load current causes the differential current, caused by the CT inaccuracies and the tap changer position, to grow at the same percentage rate.

In a biased differential protection relay in normal operation or during external faults, the higher the load current is the higher is the differential current required for tripping. When an internal fault occurs, the currents on both sides of the protected object are flowing into it. This causes the biasing current to be considerably smaller, which makes the operation more sensitive during internal faults.

$$I_b = \frac{\left|\bar{I}_{W1} - \bar{I}_{W2}\right|}{2}$$

(Equation 158)

If the biasing current is small compared to the differential current or if the phase angle between the winding 1 and winding 2 phase currents is close to zero (in a normal situation, the phase difference is 180 degrees), a fault has most certainly occurred in the area protected by the differential protection relay. Then the operation value set for the instantaneous stage is automatically halved and the internal blocking signals of the biased stage are inhibited.

Transformer vector group matching

The phase difference of the winding 1 and winding 2 currents that is caused by the vector group of the power transformer is numerically compensated. The matching of the phase difference is based on the phase shifting and the numerical delta connection inside the protection relay. The *Winding 1 type* parameter determines the connection on winding 1 (”Y”, ”YN”, ”D”, ”Z”, ”ZN”). The *Winding 2 type* parameter determines the connections of the phase windings on the low voltage side (“y”, ”yn”, ”d”, ”z”, ”zn”).

The vector group matching can be implemented either on both, winding 1 and winding 2, or only on winding 1 or winding 2, at intervals of 30° with the *Clock number* setting.

When the vector group matching is Yy0 and the *CT connection type* is according to "Type 2", the phase angle of the phase currents connected to the protection relay does not change. When the vector group matching is Yy6, the phase currents are turned 180° in the protection relay.

Example 1

Vector group matching of a Ynd11-connected power transformer on winding 1, *CT connection type* according to type 1. The *Winding 1 type* setting is ”YN”, *Winding 2 type* is “d” and *Clock number* is “Clk Num 11”. This is compensated internally by giving winding 1 internal compensation value +30° and winding 2 internal compensation value 0°:

$$\bar{I}_{L1mHV} = \frac{\bar{I}_{L1} - \bar{I}_{L2}}{\sqrt{3}}$$
$$\bar{I}_{L2mHV} = \frac{\bar{I}_{L2} - \bar{I}_{L3}}{\sqrt{3}}$$
$$\bar{I}_{L3mHV} = \frac{\bar{I}_{L3} - \bar{I}_{L1}}{\sqrt{3}}$$

(Equation 159)

Example 2

But if vector group is Yd11 and *CT connection type* is according to type 1, the compensation is a little different. The *Winding 1 type* setting is ”Y”, *Winding 2 type* is “d” and *Clock number* is “Clk Num 11”. This is compensated internally by giving winding 1 internal compensation value 0° and winding 2 internal compensation value -30°;

$$\bar{I}_{L1mLV} = \frac{\bar{I}_{L1} - \bar{I}_{L3}}{\sqrt{3}}$$
$$\bar{I}_{L2mLV} = \frac{\bar{I}_{L2} - \bar{I}_{L1}}{\sqrt{3}}$$
$$\bar{I}_{L3mLV} = \frac{\bar{I}_{L3} - \bar{I}_{L2}}{\sqrt{3}}$$

(Equation 160)

The "Y" side currents stay untouched, while the "d" side currents are compensated to match the currents actually flowing in the windings.

In this example there is no neutral current on either side of the transformer (assuming there are no earthing transformers installed). In the previous example, however, the matching is done differently to have the winding 1 neutral current compensated at the same time.

Zero-sequence component elimination

If *Clock number* is "Clk Num 2", "Clk Num 4", "Clk Num 8" or "Clk Num 10", the vector group matching is always done on both, winding 1 and winding 2. The combination results in the correct compensation. In this case the zero-sequence component is always removed from both sides automatically. The *Zro A elimination* parameter cannot change this.

If *Clock number* is "Clk Num 1", "Clk Num 5", "Clk Num 7" or "Clk Num 11", the vector group matching is done on one side only. A possible zero-sequence component of the phase currents at earth faults occurring outside the protection area is eliminated in the numerically implemented delta connection before the differential current and the biasing current are calculated. This is why the vector group matching is almost always made on the star connected side of the "Ynd" and "Dyn" connected transformers.

If *Clock number* is "Clk Num 0" or "Clk Num 6", the zero-sequence component of the phase currents is not eliminated automatically on either side. Therefore, the

zero-sequence component on the star connected side that is earthed at its star point has to be eliminated by using the *Zro A elimination* parameter.

The same parameter has to be used to eliminate the zero-sequence component if there is, for example, an earthing transformer on the delta-connected side of the "Ynd" power transformer in the area to be protected. In this case, the vector group matching is normally made on the side of the star connection. On the side of the delta connection, the elimination of the zero-sequence component has to be separately selected.

By using the *Zro A elimination* parameter, the zero-sequence component of the phase currents is calculated and reduced for each phase current:

$$\bar{I}_{L1m} = \bar{I}_{L1} - \frac{1}{3} x \left(\bar{I}_{L1} + \bar{I}_{L2} + \bar{I}_{L3} \right)$$

$$\bar{I}_{L2m} = \bar{I}_{L2} - \frac{1}{3} x \left(\bar{I}_{L1} + \bar{I}_{L2} + \bar{I}_{L3} \right)$$

$$\bar{I}_{L3m} = \bar{I}_{L3} - \frac{1}{3} x \left(\bar{I}_{L1} + \bar{I}_{L2} + \bar{I}_{L3} \right)$$

(Equation 161)

In many cases with the earthed neutral of a "wye" winding, it is possible to make the compensation so that a zero-sequence component of the phase currents is automatically eliminated. For example, in a case of a "Ynd" transformer, the compensation is made on the winding 1 side to automatically eliminate the zero-sequence component of the phase currents on that side (and the "d" side does not have them). In those cases, explicit elimination is not needed.

Compensation of tap changer position

The position of the tap changer used for voltage control can be compensated and the position information is provided for the protection function through the tap position indication function TPOSYLTC.

Typically, the tap changer is located within the high voltage winding, that is, winding 1, of the power transformer. The *Tapped winding* parameter specifies whether the tap changer is connected to the high voltage side winding or the low voltage side winding. This parameter is also used to enable and disable the automatic adaptation to the tap changer position. The possible values are "Not in use", "Winding 1" or "Winding 2".

The *Tap nominal* parameter tells the number of the tap, which results in the nominal voltage (and current). When the current tap position deviates from this value, the input current values on the side where the tap changer resides are scaled to match the currents on the other side.

A correct scaling is determined by the number of steps and the direction of the deviation from the nominal tap and the percentage change in voltage resulting from a deviation of one tap step. The percentage value is set using the *Step of tap* parameter.

The operating range of the tap changer is defined by the *Min winding tap* and *Max winding tap* parameters. The *Min winding tap* parameter tells the tap position number resulting in the minimum effective number of winding turns on the side of the transformer where the tap changer is connected. Correspondingly, the *Max*

winding tap parameter tells the tap position number resulting in the maximum effective number of winding turns.

The *Min winding tap* and *Max winding tap* parameters help the tap position compensation algorithm know in which direction the compensation is being made. This ensures also that if the current tap position information is corrupted for some reason, the automatic tap changer position adaptation does not try to adapt to any unrealistic position values.

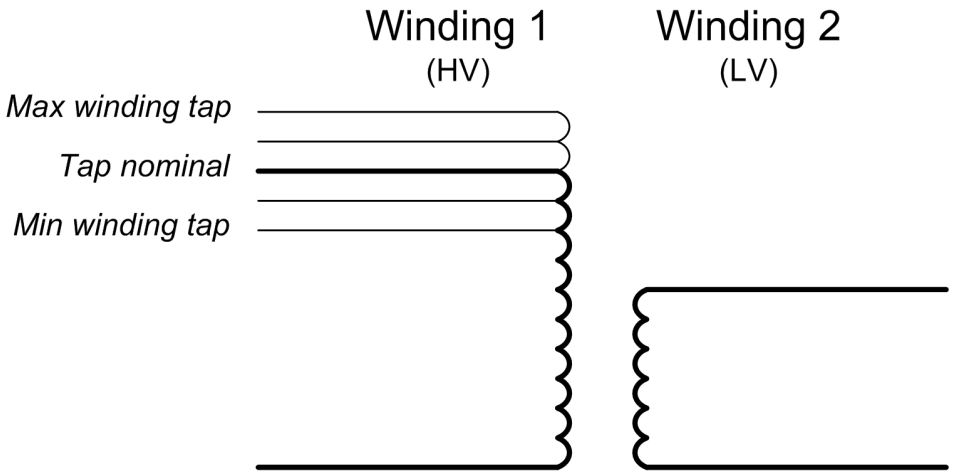

Figure 389: Simplified presentation of the high voltage and medium voltage windings with demonstration of the Max winding tap, Min winding tap and Tap nominal parameters

The position value is available through the Monitored data view on LHMI or through other communication tools in the tap position indication function. When the quality of the TAP_POS value is not good, the position information in TAP_POS is not used but the last value with the good quality information is used instead. In addition, the minimum sensitivity of the biased stage, set by the *Low operate value* setting, is automatically desensitized with the total range of the tap position correction. The new acting low operate value is

$$Desensitized\ Low\ operate\ value = Low\ operate\ value + ABS(Max\ Winding\ tap - Min\ winding\ tap) \times Step\ of\ tap$$

(Equation 162)

Second harmonic blocking

The transformer magnetizing inrush currents occur when energizing the transformer after a period of de-energization. The inrush current can be many times the rated current and the halving time can be up to several seconds. To the differential protection, the inrush current represents a differential current, which would cause the differential protection to operate almost always when the transformer is connected to the network. Typically, the inrush current contains a large amount of second harmonics.

Blocking the operation of the TR2PTDF biased low stage at a magnetizing inrush current is based on the ratio of the amplitudes of the second harmonic digitally filtered from the differential current and the fundamental frequency (Id2f /Id1f).

The blocking also prevents unwanted operation at the recovery and sympathetic magnetizing inrushes. At the recovery inrush, the magnetizing current of the transformer to be protected increases momentarily when the voltage returns to

normal after the clearance of a fault outside the protected area. The sympathetic inrush is caused by the energization of another transformer running in parallel with the protected transformer already connected to the network.

The ratio of the second harmonic to a fundamental component can vary considerably between the phases. Especially when the delta compensation is done for a Ynd1 connected transformer and the two phases of the inrush currents are otherwise equal but opposite in phase angle, the subtraction of the phases in a delta compensation results in a very small second harmonic component.

Some measures have to be taken in order to avoid the false tripping of a phase having too low a ratio of the second harmonic to the fundamental component. One way could be to always block all the phases when the second harmonic blocking conditions are fulfilled in at least one phase. The other way is to calculate the weighted ratios of the second harmonic to the fundamental component for each phase using the original ratios of the phases. The latter option is used here. The second harmonic ratios I_2H_RAT_x are given in Monitored data.

The ratio to be used for second harmonic blocking is, therefore, calculated as a weighted average on the basis of the ratios calculated from the differential currents of the three phases. The ratio of the concerned phase is of most weight compared to the ratios of the other two phases. In this protection relay, if the weighting factors are four, one and one, four is the factor of the phase concerned. The operation of the biased stage on the concerned phase is blocked if the weighted ratio of that phase is above the set blocking limit *Start value 2.H* and if blocking is enabled through the *Restraint mode* parameter.

Using separate blocking for the individual phases and weighted averages calculated for the separate phases provides a blocking scheme that is stable at the connection inrush currents.

If the peak value of the differential current is very high, that is I_r>12×In, the limit for the second harmonic blocking is desensitized (in the phase in question) by increasing it proportionally to the peak value of the differential current.

The connection of the power transformer against a fault inside the protected area does not delay the operation of the tripping, because in such a situation the blocking based on the second harmonic of the differential current is prevented by a separate algorithm based on a different waveform and a different rate of change of the normal inrush current and the inrush current containing the fault current. The algorithm does not eliminate the blocking at inrush currents, unless there is a fault in the protected area.

The feature can also be enabled and disabled with the *Harmonic deblock 2.H* parameter.

Fifth harmonic blocking

The inhibition of TR2PTDF operation in the situations of overexcitation is based on the ratio of the fifth harmonic and the fundamental component of the differential current (Id5f/Id1f) . The ratio is calculated separately for each phase without weighting . If the ratio exceeds the setting value of *Start value 5.H* and if blocking is enabled through the *Restraint mode* parameter, the operation of the biased stage of TR2PTDF in the concerned phase is blocked. The fifth harmonic ratios I_5H_RAT_x are given in Monitored data.

At dangerous levels of overvoltage, which can cause damage to the transformer, the blocking can be automatically eliminated. If the ratio of the fifth harmonic and the fundamental component of the differential current exceeds the *Stop value*

5.H parameter, the blocking removal is enabled. The enabling and disabling of deblocking feature is also done through the *Harmonic deblock 5.H* parameter.

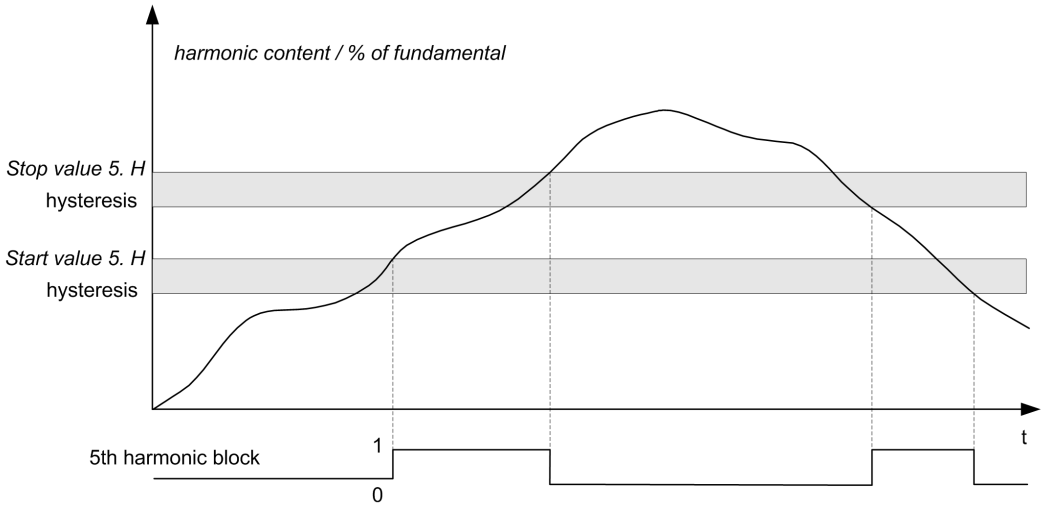

Figure 390: The limits and operation of the fifth harmonic blocking when both blocking and deblocking features are enabled using the Harmonic deblock 5.H control parameter.

The fifth harmonic blocking has a hysteresis to avoid rapid fluctuation between "TRUE" and "FALSE". The blocking also has a counter, which counts the required consecutive fulfillments of the condition. When the condition is not fulfilled, the counter is decreased (if >0).

Also the fifth harmonic deblocking has a hysteresis and a counter which counts the required consecutive fulfillments of the condition. When the condition is not fulfilled, the counter is decreased (if >0).

Waveform blocking

The biased low stage can always be blocked with waveform blocking. The stage can not be disabled with the *Restraint mode* parameter. This algorithm has two parts. The first part is intended for external faults while the second is intended for inrush situations. The algorithm has criteria for a low current period during inrush where also the differential current (not derivative) is checked.

Biased low stage

The current differential protection needs to be biased because the possible appearance of a differential current can be due to something else than an actual fault in the transformer (or generator).

In the case of transformer protection, a false differential current can be caused by:

- CT errors
- Varying tap changer positions (if not automatically compensated)
- Transformer no-load current
- Transformer inrush currents
- Transformer overexcitation in overvoltage
- Underfrequency situations
- CT saturation at high currents passing through the transformer

The differential current caused by CT errors or tap changer positions increases at the same percent ratio as the load current.

In the protection of generators, the false differential current can be caused by various factors.

- CT errors
- CT saturation at high currents passing through the generator

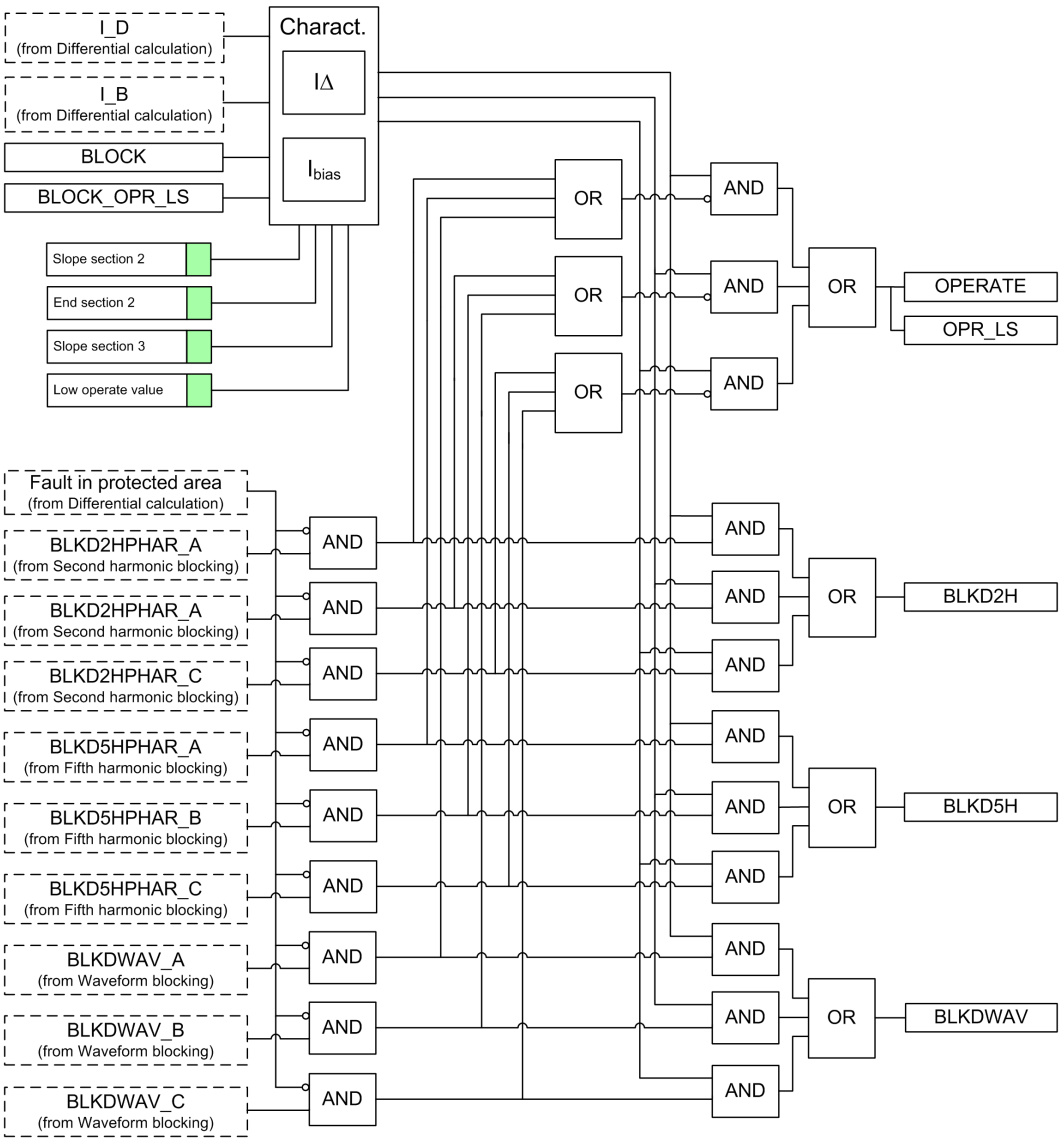

Figure 391: Operation logic of the biased low stage

The high currents passing through a protected object can be caused by the short circuits outside the protected area, the high currents fed by the transformer in motor start-up or the transformer inrush situations. Therefore, the operation of the differential protection is biased in respect to the load current. In biased differential protection, the higher the differential current required for the protection to operate, the higher the load current.

The operating characteristic of the biased low stage is determined by *Low operate value*, *Slope section 2* and the setting of the second turning point of the operating characteristic curve, *End section 2* (the first turning point is fixed). The settings are

the same for all the phases. When the differential current exceeds the operating value determined by the operating characteristic, the differential function awakes. If the differential current stays above the operating value continuously for a suitable period, which is 1.1 times the fundamental cycle, the OPR_LS output is activated. The OPERATE output is always activated when the OPR_LS output is activated .

The stage can be blocked internally by the second or fifth harmonic restraint, or by special algorithms detecting inrush and current transformer saturation at external faults. When the operation of the biased low stage is blocked by the second harmonic blocking functionality, the BLKD2H output is activated.

When operation of the biased low stage is blocked by the fifth harmonic blocking functionality, the BLKD5H output is activated. Correspondingly, when the operation of the biased low stage is blocked by the waveform blocking functionality, the BLKDWAV output is activated according to the phase information.

When required, the operate outputs of the biased low stage can be blocked by the BLK_OPR_LS or BLOCK external control signals.

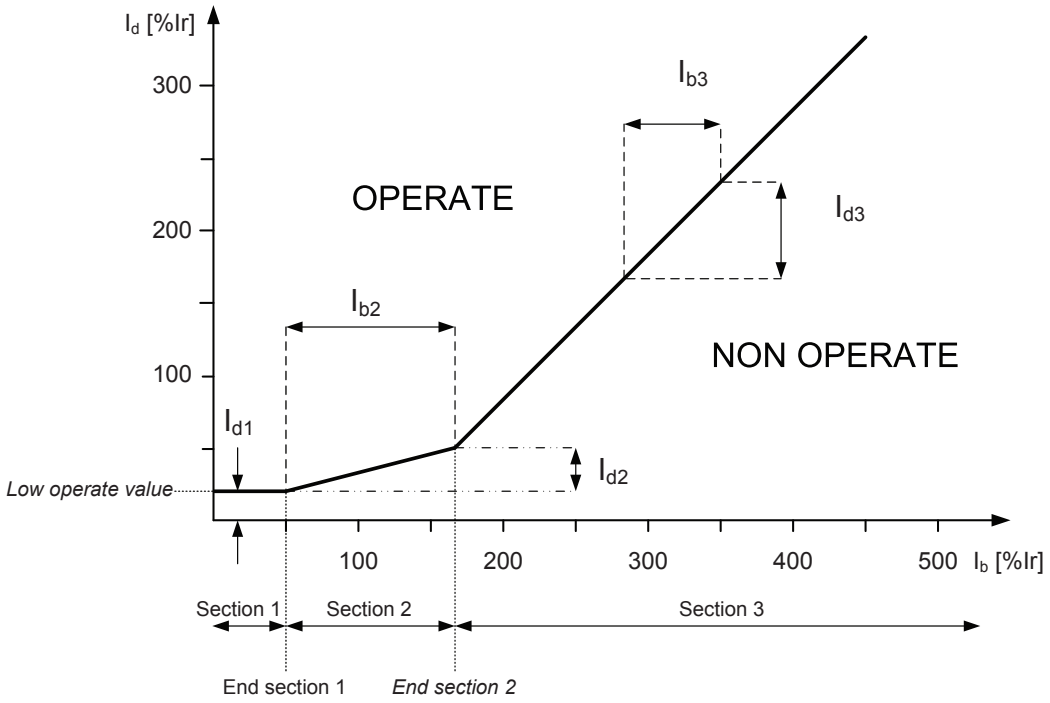

Figure 392: Operation characteristic for biased operation of TR2PTDF

The *Low operate value* of the biased stage of the differential function is determined according to the operation characteristic:

Low operate value = Id1

Slope section 2 and *Slope section 3* are determined correspondingly:

$$Slope\ \ section\,2 = \frac{I_{d2}}{I_{b2}} \cdot 100\%$$

(Equation 163)

$$Slope\ \ section3 = \frac{I_{d3}}{I_{b3}} \cdot 100\%$$

(Equation 164)

The second turning point *End section 2* can be set in the range of 100 percent to 500 percent.

The slope of the differential function's operating characteristic curve varies in the different sections of the range.

- In section 1, where 0 percent Ir < Ib < End section 1, End section 1 being fixed to 50 percent Ir, the differential current required for tripping is constant. The value of the differential current is the same as the *Low operate value* selected for the function. *Low operate value* basically allows the no-load current of the power transformer and small inaccuracies of the current transformers, but it can also be used to influence the overall level of the operating characteristic. At the rated current, the no-load losses of the power transformer are about 0.2 percent. If the supply voltage of the power transformer suddenly increases due to operational disturbances, the magnetizing current of the transformer increases as well. In general the magnetic flux density of the transformer is rather high at rated voltage and a rise in voltage by a few percent causes the magnetizing current to increase by tens of percent. This should be considered in *Low operate value*
- In section 2, where End section 1 < Ib/In < *End section 2*, is called the influence area of *Slope section 2*. In this section, variations in the starting ratio affect the slope of the characteristic, that is, how big a change in the differential current is required for tripping in comparison with the change in the load current. The starting ratio should consider CT errors and variations in the transformer tap changer position (if not compensated). Too high a starting ratio should be avoided, because the sensitivity of the protection for detecting inter-turn faults depends basically on the starting ratio.
- In section 3, where Ib/In > *End section 2*, the slope of the characteristic can be set by *Slope section 3* that defines the increase in the differential current to the corresponding increase in the biasing current.

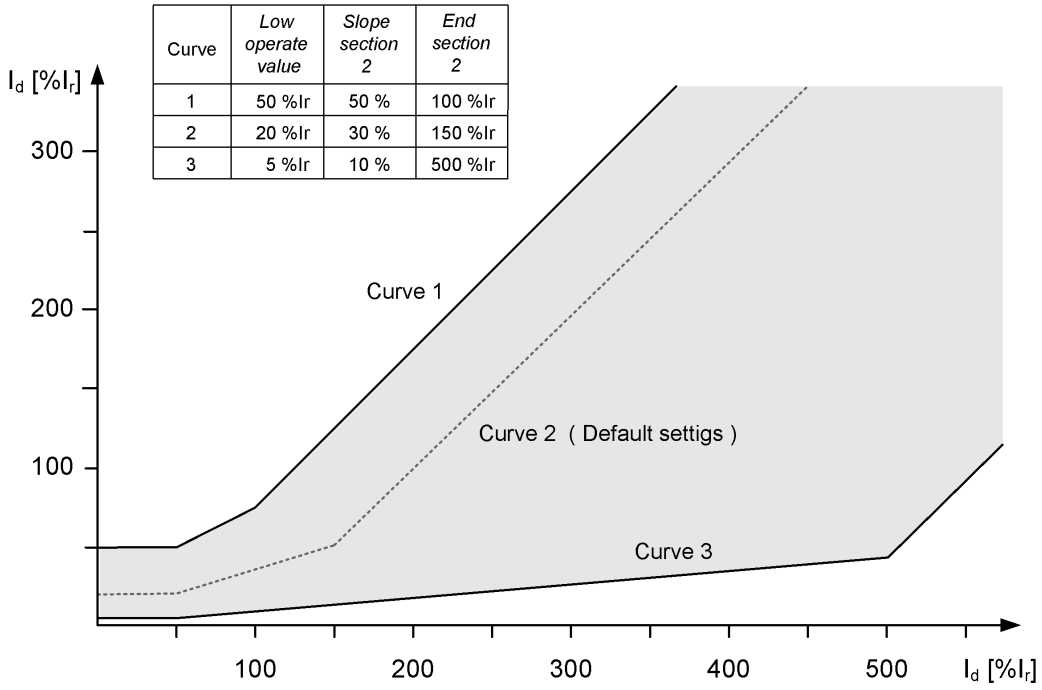

Figure 393: Setting range for biased low stage

If the biasing current is small compared to the differential current of the phase angle between the winding 1 and winding 2 phase currents is close to zero (in a normal situation, the phase difference is 180 degrees), a fault has most likely occurred in the area protected by TR2PTDF. Then the internal blocking signals of the biased stage are inhibited.

Instantaneous high stage

The instantaneous high stage operation can be enabled and disabled with the *Enable high set* setting. The corresponding parameter values are "TRUE" and "FALSE."

The operation of the instantaneous high stage is not biased. The instantaneous stage operates and the output `OPR_HS` is activated when the amplitude of the fundamental frequency component of the differential current exceeds the set *High operate value* or when the instantaneous value of the differential current exceeds 2.5 times the value of *High operate value*. The factor 2.5 (=1.8 × √2) is due to the maximum asymmetric short circuit current.

If the biasing current is small compared to the differential current or the phase angle between the winding 1 and winding 2 phase currents is close to zero (in a normal situation, the phase difference is 180 degrees), a fault has occurred in the area protected by TR2PTDF. Then the operation value set for the instantaneous stage is automatically halved and the internal blocking signals of the biased stage are inhibited.

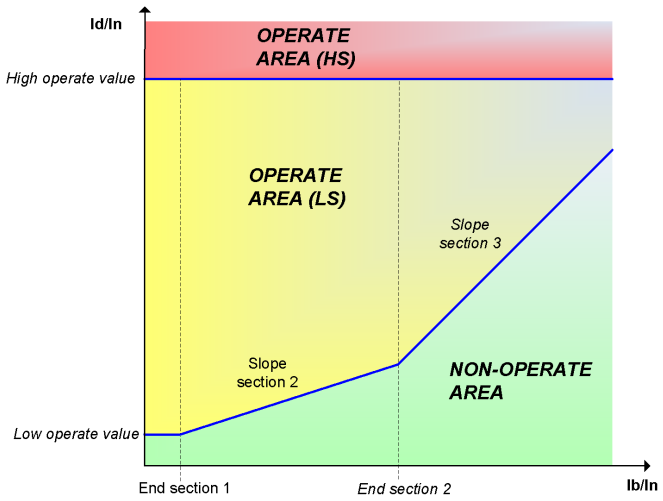

Figure 394: Operating characteristics of the protection. (LS) stands for the biased low stage and (HS) for the instantaneous high stage

The OPERATE output is activated always when the OPR_HS output activates .

The internal blocking signals of the differential function do not prevent the operate signal of the instantaneous differential current stage. When required, the operate outputs of the instantaneous high stage can be blocked by the BLK_OPR_HS and BLOCK external control signals.

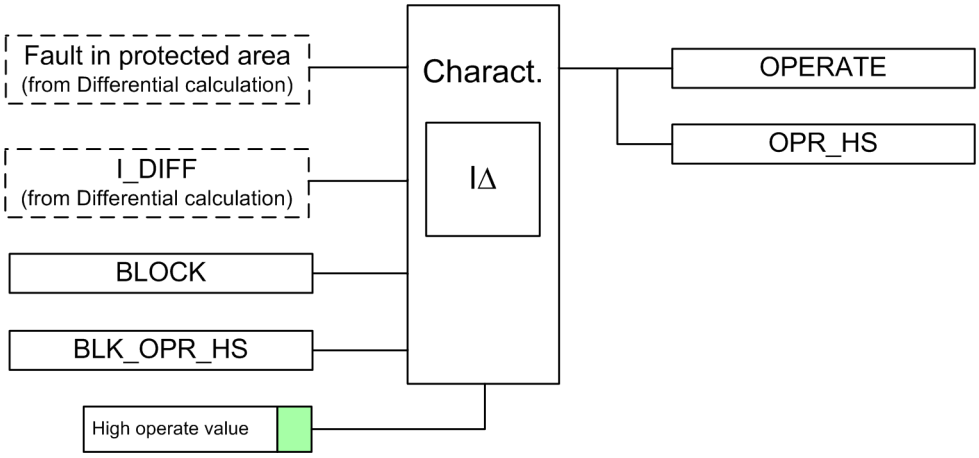

Figure 395: Operation logic of instantaneous high stage

Reset of the blocking signals (de-block)

All three blocking signals, that is, waveform and second and fifth harmonic, have a counter, which holds the blocking on for a certain time after the blocking conditions have ceased to be fulfilled. The deblocking takes place when those counters have elapsed. This is a normal case of deblocking.

The blocking signals can be reset immediately if a very high differential current is measured or if the phase difference of the compared currents (the angle between the compared currents) is close to zero after the automatic vector group matching has been made (in a normal situation, the phase difference is 180 degrees). This

does not, however, reset the counters holding the blockings, so the blocking signals may return when these conditions are not valid anymore.

External blocking functionality

TR2PTDF has three inputs for blocking.

- When the BLOCK input is active ("TRUE"), the operation of the function is blocked but measurement output signals are still updated.
- When the BLK_OPR_LS input is active ("TRUE"), TR2PTDF operates normally except that the OPR_LS output is not active or activated in any circumstance. Additionally, the OPERATE output can be activated only by the instantaneous high stage (if not blocked as well).
- When the BLK_OPR_HS input is active ("TRUE"), TR2PTDF operates normally except that the OPR_HS output is not active or activated in any circumstance. Additionally, the OPERATE output can be activated only by the biased low stage (if not blocked as well).

4.3.2.6 Application

TR2PTDF is a unit protection function serving as the main protection for transformers in case of winding failure. The protective zone of a differential protection includes the transformer, the bus-work or the cables between the current transformer and the power transformer. When bushing current transformers are used for the differential protection relay, the protective zone does not include the bus work or cables between the circuit breaker and the power transformer.

In some substations, there is a current differential protection for the busbar. The busbar protection includes bus work or cables between the circuit breaker and the power transformer. Internal electrical faults are very serious and cause immediate damage. Short circuits and earth faults in windings and terminals are normally detected by the differential protection. If enough turns are short-circuited, the interturn faults, which are flashovers between the conductors within the same physical winding, are also detected. The interturn faults are the most difficult transformer-winding faults to detect with electrical protections. A small interturn fault including a few turns results in an undetectable amount of current until the fault develops into an earth fault. Therefore, it is important that the differential protection has a high level of sensitivity and that it is possible to use a sensitive setting without causing unwanted operations for external faults.

It is important that the faulty transformer is disconnected as fast as possible. As TR2PTDF is a unit protection function, it can be designed for fast tripping, thus providing a selective disconnection of the faulty transformer. TR2PTDF should never operate to faults outside the protective zone.

TR2PTDF compares the current flowing into the transformer to the current leaving the transformer. A correct analysis of fault conditions by TR2PTDF must consider the changes to voltages, currents and phase angles. The traditional transformer differential protection functions required auxiliary transformers for the correction of the phase shift and turns ratio. The numerical microprocessor based differential algorithm implemented in TR2PTDF compensates for both the turns ratio and the phase shift internally in the software.

The differential current should theoretically be zero during normal load or external faults if the turns ratio and the phase shift are correctly compensated. However, there are several different phenomena other than internal faults that cause

unwanted and false differential currents. The main reasons for unwanted differential currents are:

- Mismatch due to varying tap changer positions
- Different characteristics, loads and operating conditions of the current transformers
- Zero sequence currents that only flow on one side of the power transformer
- Normal magnetizing currents
- Magnetizing inrush currents
- Overexcitation magnetizing currents.

TR2PTDF is designed mainly for the protection of two-winding transformers. TR2PTDF can also be utilized for the protection of generator-transformer blocks as well as short cables and overhead lines. If the distance between the measuring points is relatively long in line protection, interposing CTs can be required to reduce the burden of the CTs.

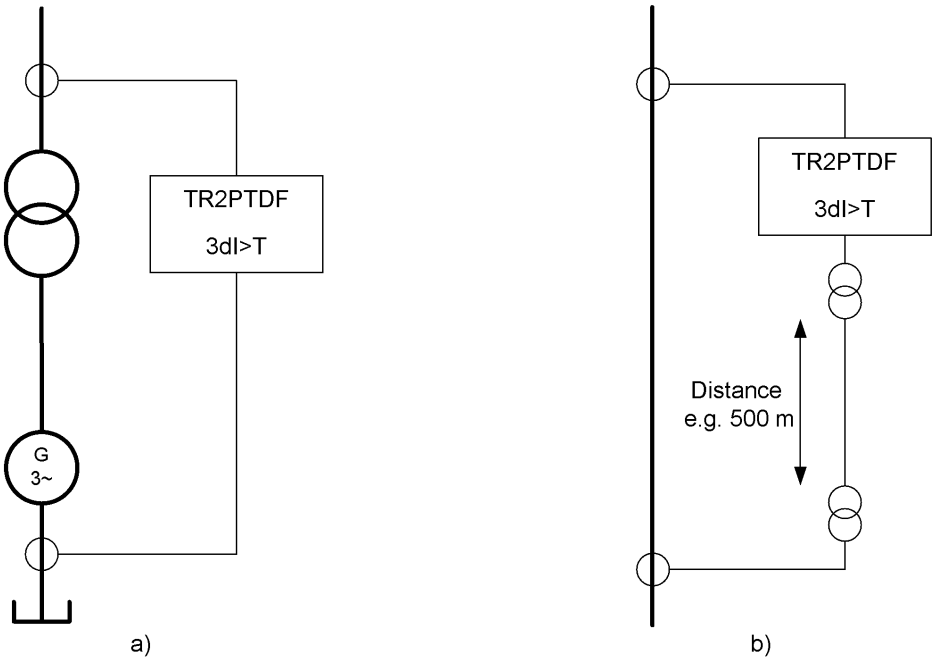

Figure 396: Differential protection of a generator-transformer block and short cable/line

TR2PTDF can also be used in three-winding transformer applications or two-winding transformer applications with two output feeders.

On the double-feeder side of the power transformer, the current of the two CTs per phase must be summed by connecting the two CTs of each phase in parallel. Generally this requires the interposing CTs to handle the vector group and/or ratio mismatch between the two windings/feeders.

The accuracy limit factor for the interposing CT must fulfill the same requirements as the main CTs. Please note that the interposing CT imposes an additional burden to the main CTs.

The most important rule in these applications is that at least 75 percent of the short-circuit power has to be fed on the side of the power transformer with only one connection to the protection relay.

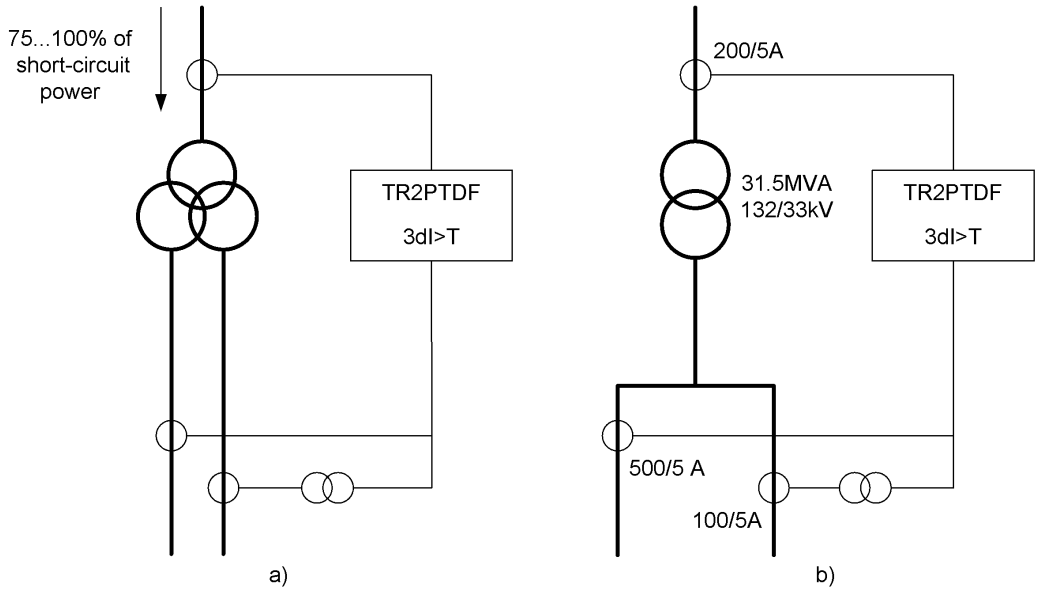

Figure 397: Differential protection of a three-winding transformer and a transformer with two output feeders

TR2PTDF can also be used for the protection of the power transformer feeding the frequency converter. An interposing CT is required for matching the three-winding transformer currents to a two-winding protection relay.

The fundamental frequency component is numerically filtered with a Fourier filter, DFT. The filter suppresses frequencies other than the set fundamental frequency, and therefore the protection relay is not adapted for measuring the output of the frequency converter, that is, TR2PTDF is not suited for protecting of a power transformer or motor fed by a frequency converter

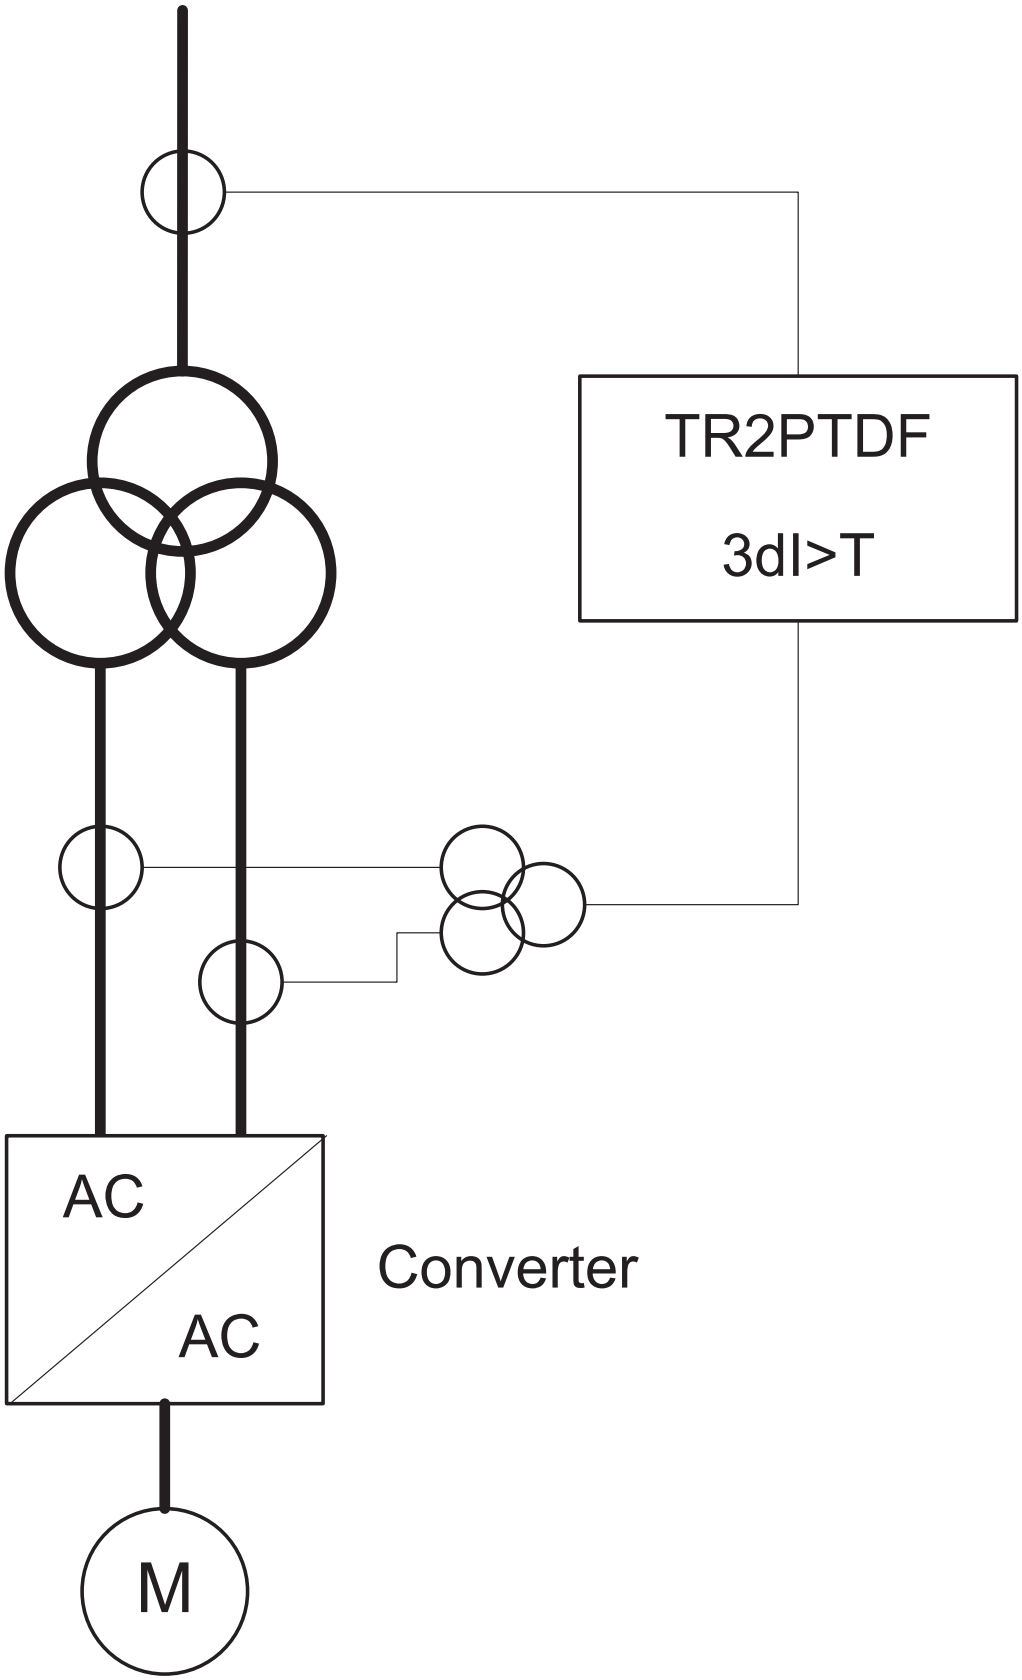

Figure 398: Protection of the power transformer feeding the frequency converter

Transforming ratio correction of CTs

The CT secondary currents often differ from the rated current at the rated load of the power transformer. The CT transforming ratios can be corrected on both sides of the power transformer with the *CT ratio Cor Wnd 1* and *CT ration Cor Wnd 2* settings.

First, the rated load of the power transformer must be calculated on both sides when the apparent power and phase-to-phase voltage are known.

$$I_{nT} = \frac{S_n}{\sqrt{3} \times U_n}$$

(Equation 165)

I_{nT} rated load of the power transformer
S_n rated power of the power transformer
U_n rated phase-to-phase voltage

Next, the settings for the CT ratio correction can be calculated.

$$CT\ ratio\ correction = \frac{I_{1n}}{I_{nT}}$$

(Equation 166)

I_{1n} nominal primary current of the CT

After the CT ratio correction, the measured currents and corresponding setting values of TR2PTDF are expressed in multiples of the rated power transformer current I_r (xI_r) or percentage value of I_r ($\%I_r$).

The rated input current (1A or 5A) of the relay does not have to be same for the HV and the LV side. For example, the rated secondary current of 5 A can be used on the HV side, while 1A is used on the LV side or vice versa.

Example

The rated power of the transformer is 25 MVA, the ratio of the CTs on the 110 kV side is 300/1 and that on the 21 kV side is 1000/1

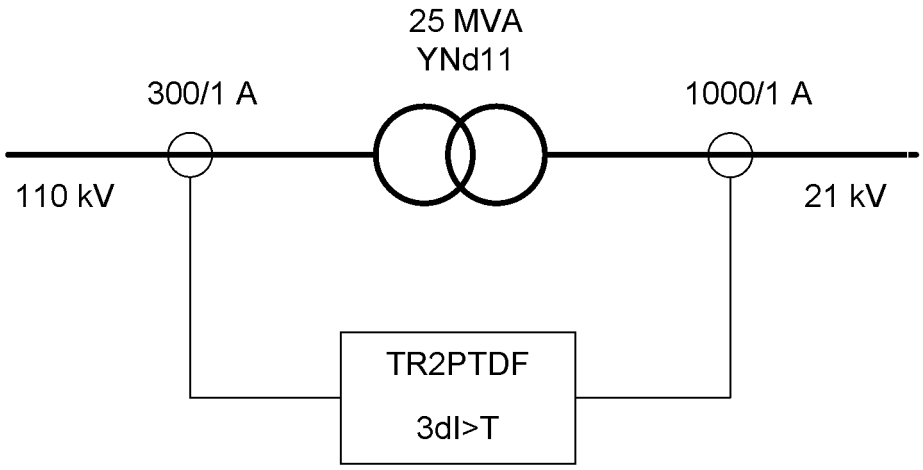

Figure 399: Example of two-winding power transformer differential protection

The rated load of the transformer is calculated:

HV side: I_{nT_Wnd1} = 25 MVA / (1.732 x 110 kV) = 131.2 A

LV side: I_{nT_Wnd2} = 25 MVA / (1.732 x 21 kV) = 687.3 A

Settings:

CT ratio Cor Wnd 1= 300 A / 131.2 A = “2.29”

CT ratio Cor Wnd 2= 1000 A / 687.3 A = “1.45”

Vector group matching and elimination of the zero-sequence component

The vector group of the power transformer is numerically matched on the high voltage and low voltage sides by means of the *Winding 1 type*, *Winding 2 type* and *Clock number* settings. Thus no interposing CTs are needed if there is only a power transformer inside the protected zone. The matching is based on phase shifting and a numerical delta connection in the protection relay. If the neutral of a star-connected power transformer is earthed, any earth fault in the network is perceived by the protection relay as a differential current. The elimination of the zero-sequence component can be selected for that winding by setting the *Zro A elimination* parameter.

Table 655: TR2PTDF settings corresponding to the power transformer vector groups and zero-sequence elimination

Commissioning

The correct settings, which are *CT connection type*, *Winding 1 type*, *Winding 2 type* and *Clock number*, for the connection group compensation can be verified by monitoring the angle values `I_ANGL_A1_B1`, `I_ANGL_B1_C1`, `I_ANGL_C1_A1`, `I_ANGL_A2_B2`, `I_ANGL_B2_C2`, `I_ANGL_C2_A2`, `I_ANGL_A1_A2`, `I_ANGL_B1_B2` and `I_ANGL_C1_C2` while injecting the current into the transformer. These angle values are calculated from the compensated currents. See signal description from Monitored data table.

When a station service transformer is available, it can be used to provide current to the high voltage side windings while the low voltage side windings are short-circuited. This way the current can flow in both the high voltage and low voltage windings. The commissioning signals can be provided by other means as well. The minimum current to allow for phase current and angle monitoring is 0.015 I_r.

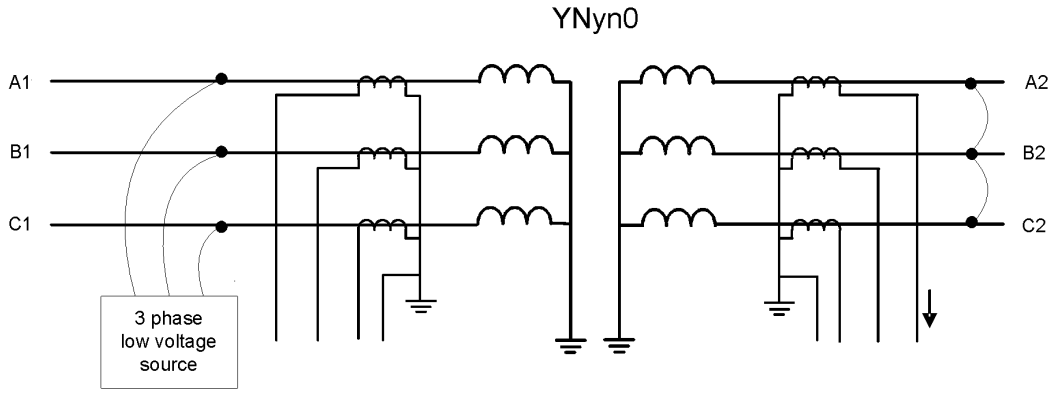

Figure 400: Low voltage test arrangement. The three-phase low voltage source can be the station service transformer.

The *Tapped winding* control setting parameter has to be set to “Not in use” to make sure that the monitored current values are not scaled by the automatic adaptation to the tap changer position. When only the angle values are required, the setting of *Tapped winding* is not needed since angle values are not affected by the tap changer position adaptation.

When injecting the currents in the high voltage winding, the angle values I_ANGL_A1_B1, I_ANGL_B1_C1, I_ANGL_C1_A1, I_ANGL_A2_B2, I_ANGL_B2_C2 and I_ANGL_C2_A2 have to show +120 deg. Otherwise the phase order can be wrong or the polarity of a current transformer differs from the polarities of the other current transformers on the same side.

If the angle values I_ANGL_A1_B1, I_ANGL_B1_C1 and I_ANGL_C1_A1 show -120 deg, the phase order is wrong on the high voltage side. If the angle values I_ANGL_A2_B2, I_ANGL_B2_C2 and I_ANGL_C2_A2 show -120 deg, the phase order is wrong on the low voltage side. If the angle values I_ANGL_A1_B1, I_ANGL_B1_C1 and I_ANGL_C1_A1 do not show the same value of +120, the polarity of one current transformer can be wrong. For instance, if the polarity of the current transformer measuring IL2 is wrong, I_ANGL_A1_B1 shows -60 deg, I_ANGL_B1_C1 shows -60 deg and I_ANGL_C1_A1 shows +120 deg.

When the phase order and the angle values are correct, the angle values I_ANGL_A1_A2, I_ANGL_B1_B2 and I_ANGL_C1_C2 usually show ±180 deg. There can be several reasons if the angle values are not ±180 deg. If the values are 0 deg, the value given for *CT connection type* is probably wrong. If the angle values are something else, the value for *Clock number* can be wrong. Another reason is that the combination of *Winding 1 type* and *Winding 2 type* does not match *Clock number*. This means that the resulting connection group is not supported.

Example

If *Winding 1 type* is set to "Y", *Winding 2 type* is set to "y" and *Clock number* is set to "Clk num 1", the resulting connection group "Yy1" is not a supported combination. Similarly if *Winding 1 type* is set to "Y", *Winding 2 type* is set to "d" and *Clock number* is set to "Clk num 0", the resulting connection group "Yd0" is not a supported combination. All the non-supported combinations of *Winding 1 type*, *Winding 2 type* and *Clock number* settings result in the default connection group compensation that is "Yy0".

4.3.2.7 CT connections and transformation ratio correction

The connections of the primary current transformers are designated as "Type 1" and "Type 2".

- If the positive directions of the winding 1 and winding 2 protection relay currents are opposite, the *CT connection type* setting parameter is "Type 1". The connection examples of "Type 1" are as shown in *Figure 401* and *Figure 402*.
- If the positive directions of the winding 1 and winding 2 protection relay currents equate, the *CT connection type* setting parameter is "Type 2". The connection examples of "Type 2" are as shown in *Figure 403* and *Figure 404*.
- The default value of the *CT connection type* setting is "Type 1".

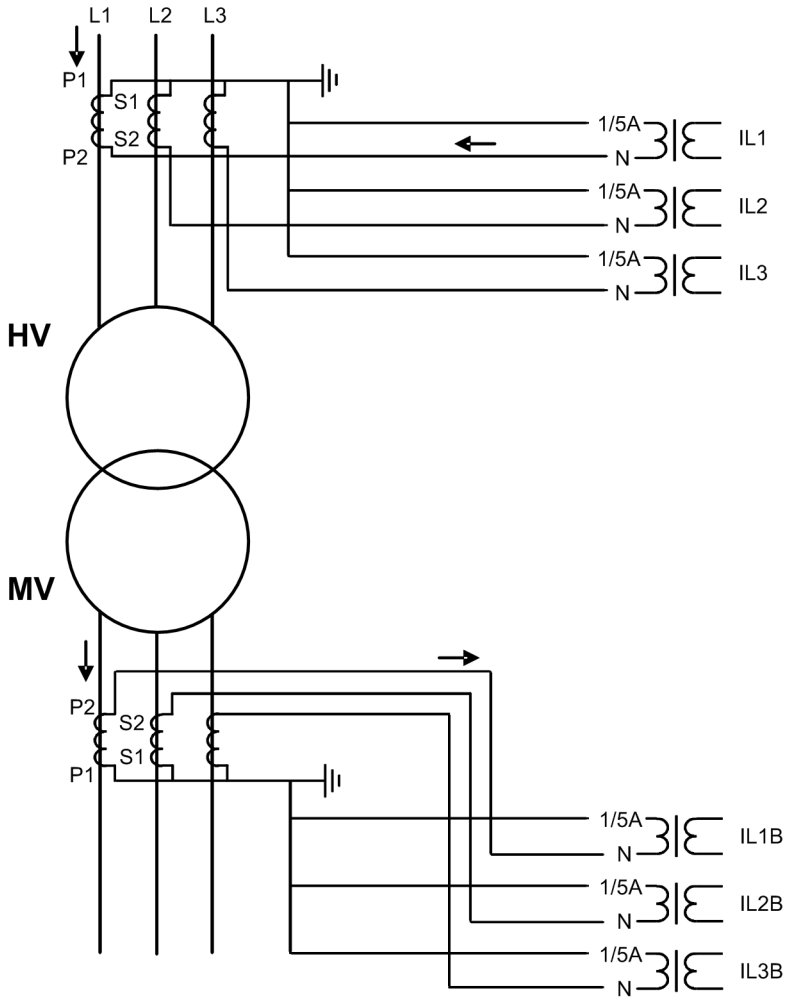

Figure 401: Connection example of current transformers of Type 1

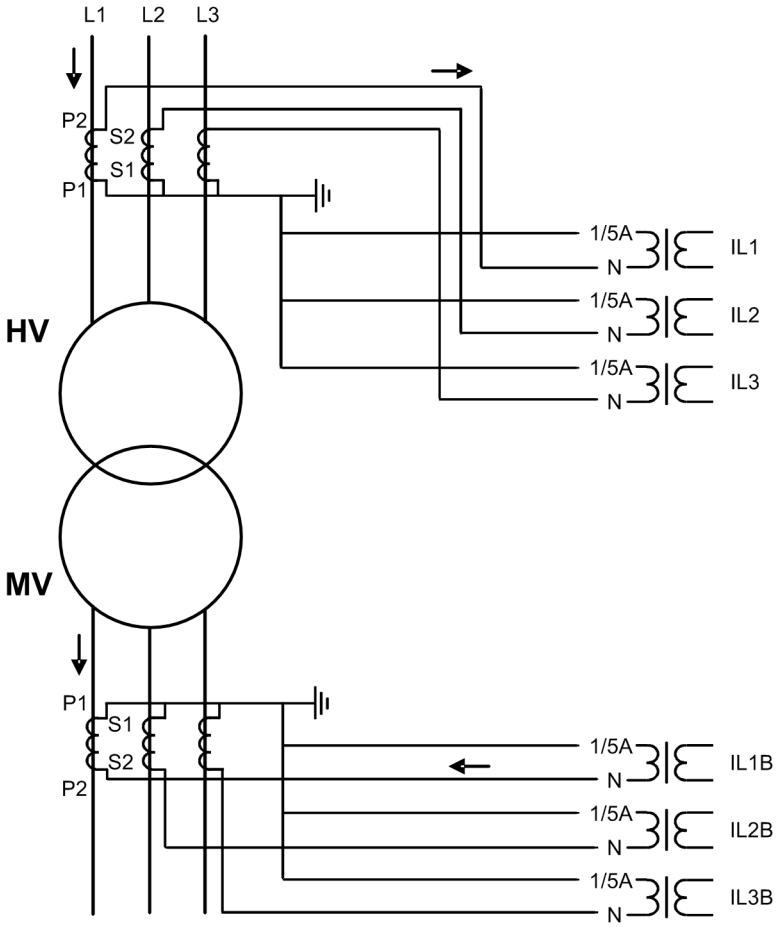

Figure 402: Alternative connection example of current transformers of Type 1

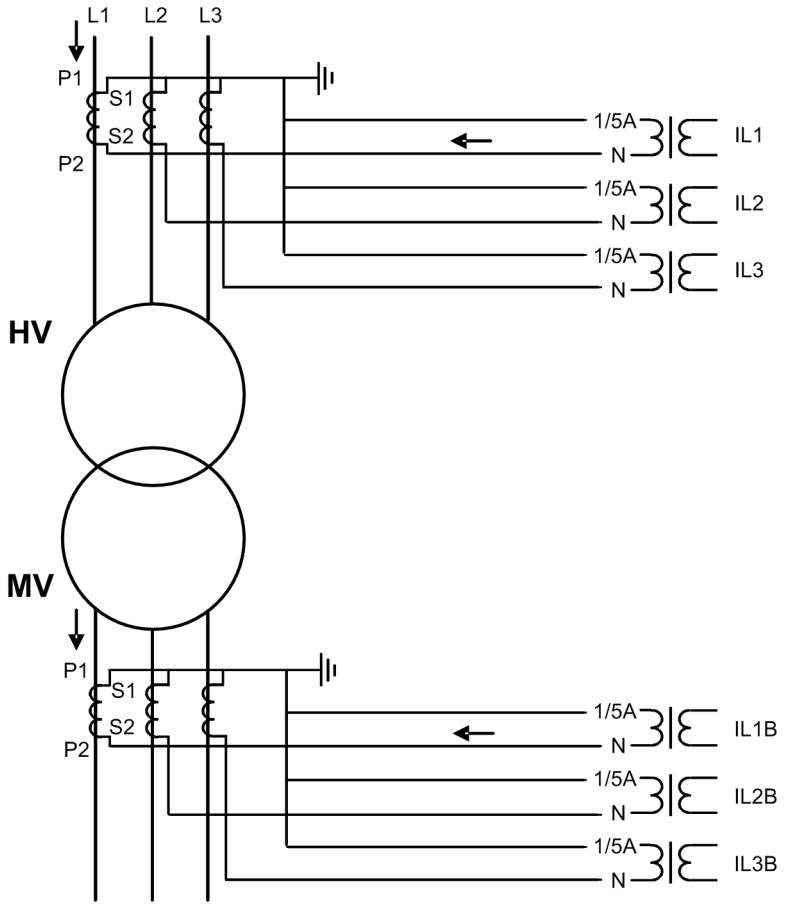

Figure 403: Connection of current transformers of Type 2 and example of the currents during an external fault

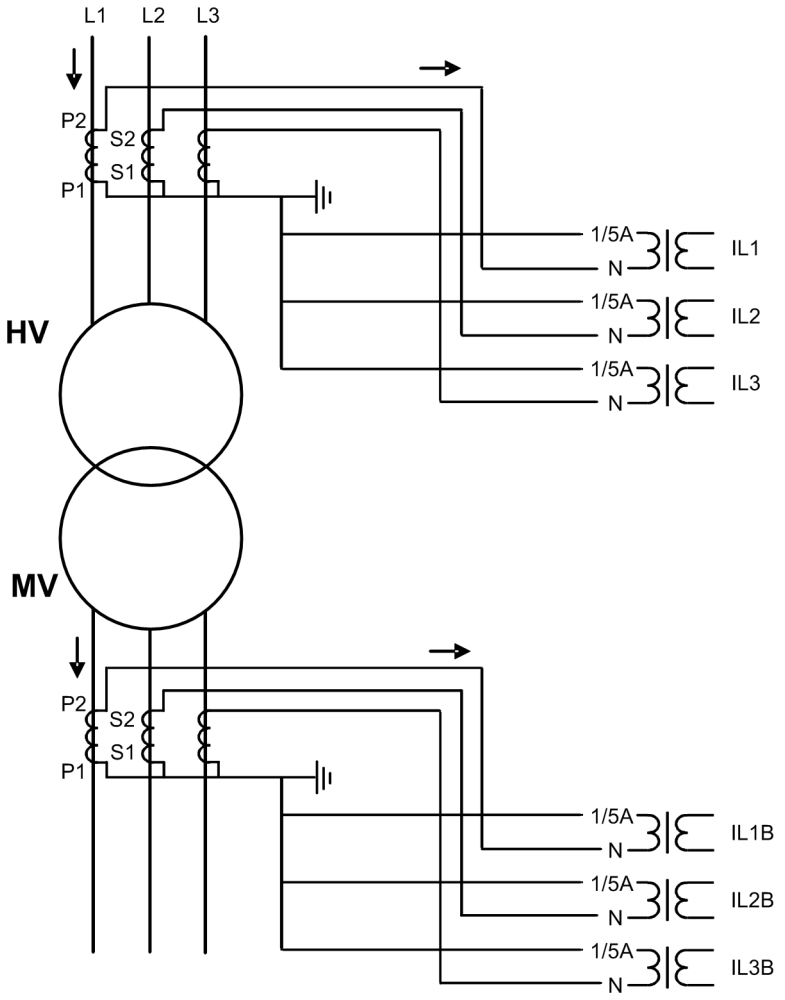

Figure 404: Alternative connection example of current transformers of Type 2

The CT secondary currents often differ from the rated current at the rated load of the power transformer. The CT transforming ratios can be corrected on both sides of the power transformer with the *CT ratio Cor Wnd 1* and *CT ratio Cor Wnd 2* settings.

4.3.2.8 Signals

TR2PTDF Input signals

Table 656: TR2PTDF Input signals

Name	Type	Default	Description
I3P1	SIGNAL	-	Three-phase currents 1
I3P2	SIGNAL	-	Three-phase currents 2
BLOCK	BOOLEAN	0=False	Block

Stabilized and instantaneous differential protection for two- or three-winding transformers	TR3PTDF	3dI>3W	87T3

4.3.3.2 Function block

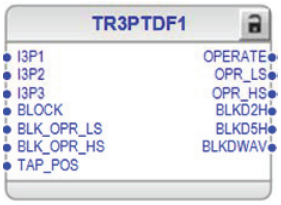

Figure 405: Function block

4.3.3.3 Functionality

The stabilized and instantaneous differential protection for two- or three-winding transformers function TR3PTDF provides up to three three-phase current sets or restraints designed for the protection of two-winding or three-winding transformers and generator-transformer blocks. It is possible to have two three-

[1] Current before fault = 0.0 × I_n, f_n = 50 Hz. Injected differential current = 2.0 × set operation value
[2] Measured with static power output f_n = 50 Hz.

phase current sets either on the winding 1 or winding 2 side in case of two-winding transformer protection. The function includes a biased low stage and an instantaneous high stage.

The biased low stage provides fast fault clearing while remaining stable with the high currents passing through the protected zone, which increase the errors in current measuring. The second harmonic restraint, together with waveform-based algorithms, ensures that the low stage does not operate due to the transformer inrush currents. The fifth harmonic restraint ensures that the low stage does not operate on apparent differential current caused by a harmless transformer overexcitation.

The instantaneous high stage provides very fast clearing of severe faults with a high differential current regardless of their harmonics.

The setting characteristic can be set more sensitive with tap changer position compensation. The correction of the transformation ratio due to changes in tap position is done automatically based on the tap changer status information provided to the function through input.

4.3.3.4 Analog channel configuration

TR3PTDF has three analog group inputs which must be properly configured.

Table 664: Analog inputs

Input	Description
I3P1	Three-phase currents
I3P2	Three-phase currents
I3P3 [1]	Three-phase currents Necessary when *Current group 3 type* is other than "Not in use"

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of TR3PTDF can be described with a module diagram. All the modules in the diagram are explained in the next sections.

[1] Can be connected to GRPOFF if *Current group 3 type* is set to "Not in use"

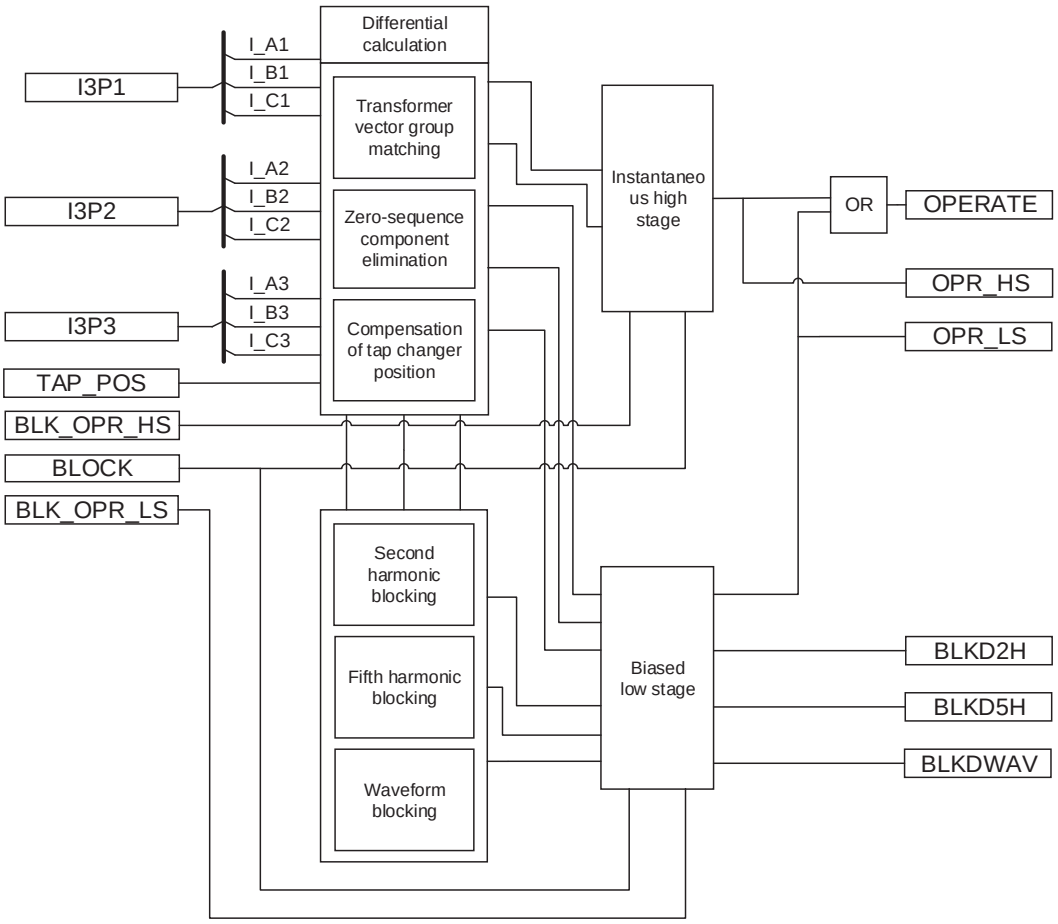

Figure 406: Functional module diagram

Differential calculation

TR3PTDF operates phasewise on the difference of incoming and outgoing currents. The positive direction of the currents is towards the protected object.

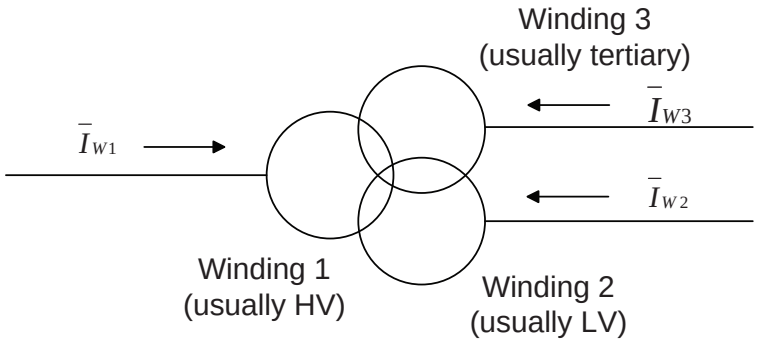

Figure 407: Single-line diagram of the positive direction of the currents in a threewinding transformer

The normalized amplitude of the differential current per phase Id is obtained using the equation:

$$I_d = \left|\bar{I}_{W1} + \bar{I}_{W2} + \bar{I}_{W3}\right|$$

(Equation 167)

In a normal situation, no fault occurs in the area protected by TR3PTDF. Then the currents I_{W1}, I_{W2} and I_{W3} cancel each other and the differential current I_d is zero. In practice, however, the differential current deviates from zero in normal situations. In the power transformer protection, the differential current is caused by CT inaccuracies, variations in tap changer position (if not compensated), transformer no-load current and instantaneous transformer inrush currents. An increase in the load current makes the differential current, caused by the CT inaccuracies and the tap changer position, grow at the same percentage rate.

In a biased differential protection relay in normal operation or during external faults, the higher the load current is, the higher the differential current required for tripping. When an internal fault occurs, the currents on both sides of the protected object are flowing into it. This causes the bias current to be considerably smaller, which makes the operation more sensitive during internal faults.

$$I_b = \frac{\left|\bar{I}_X - \bar{I}_Y - \bar{I}_Z\right|}{2}$$

(Equation 168)

I_X	One of the normalized currents I_{W1}, I_{W2} and I_{W3} determined by the angle differences between the currents and their amplitudes
I_Y and I_Z	Remaining two currents

I_X is selected based on one of the criteria below.

- The angle between I_X and I_Y and also between I_X and I_Z is over 120 degrees while the amplitude of I_X is not less than

  $0.9 \cdot MAX(|I_X|, |I_Y|, |I_Z|)$
- The one with the highest amplitude ($I_X = MAX(|I_X|, |I_Y|, |I_Z|)$)

In case of a two-winding transformer having additional restraint (additional three-phase current set) either on the winding 1 or winding 2 side, currents are connected to the third winding current inputs. This ensures that if the currents of the opposite direction are measured in the restraints (through current), meaning the current is passing through the protected zone, this current affects the bias current of the differential protection.

If the bias current is small compared to the differential current or if the phase angle between the currents of two windings with the highest phase current (in case of three-winding transformer) or the phase angle between the compared phase currents (in case of two-winding transformer) is close to zero, a fault has most certainly occurred in the area protected by the differential protection relay. The operating value set for the instantaneous stage is automatically halved and the internal blocking signals of the biased stage are inhibited.

Transformer vector group matching

The phase differences of the winding 1 and winding 2 currents (winding 1 and winding 3 in case of a three-winding transformer) that are caused by the vector groups of the power transformer are numerically compensated in the function.

Phase difference matching is based on the ABB-patented generalized transform method. Settings *Phase shift Wnd 1-2* and *Phase shift Wnd 1-3* determine the current phase angle difference between windings 1 and 2 and between 1 and 3, respectively.

Normally, the transformer vector group designation includes the winding configurations and the phase angle difference between given with a clock number. For example, YNd1 has clock number 1. Settings *Phase shift Wnd 1-2* and *Phase shift Wnd 1-3* are calculated as clock number · 30 deg.

Table 665: Examples of Phase shift Wnd 1-2 (and Phase shift Wnd 1-3) settings for some common vector groups

Vector group between windings 1 and 2 (or windings 1 and 3)	Phase angle
YNd1, Yd1, Dyn1, Dy1	30°
YNd5, Yd5, Dyn5, Dy5	150°
YNd7, Yd7, Dyn7, Dy7	210°
YNd11, Yd11, Dyn11, Dy11	330°

The vector group matching can be set in the resolution of 0.1 degrees, which allows for cycloconverter applications with a phase angle difference of, for example, 7.5 degrees between windings.

The *Phase Ref winding* setting is used to define which of the windings is the reference. The phase reference can be selected from *Phase Ref winding* as "Winding 1", "Winding 2" or "Winding 3". The currents in the winding selected as the phase reference are not modified (except the removal of the zero-sequence current if set active) when the currents in other windings are matched with the reference winding (if the set phase shift between the windings is not zero).

The *Phase Ref winding* setting does not affect settings *Phase shift Wnd 1-2* and *Phase shift Wnd 1-3*.

Zero-sequence component elimination

If a wye-connected power transformer neutral is earthed, or if there is a separate earthing transformer inside the differential protection zone, any out-of-zone earth fault in the network is seen as differential current unless the zero-sequence component is correctly eliminated.

The zero-sequence elimination is done with the *Zro A elimination* setting. The recommended rules for this setting are:

- For power transformer wye-connected windings with earthed neutral point, *Zro A elimination* must be activated.
- For power transformer wye-connected windings with isolated neutral, and for delta-connected windings, *Zro A elimination* is not activated unless there is a separate earthing transformer inside the protected zone (that is, between the power transformer winding and CTs).
- It does no harm to activate *Zro A elimination* even if it is not needed.

Compensation of tap changer position

The position of the tap changer used for voltage control can be compensated according to the actual tap changer position. The position information is provided

to the protection function through the tap changer position indication function TPOSYLTC.

Typically, the tap changer is located within the HV winding, that is, winding 1 of the power transformer. The *Tapped winding* setting parameter specifies whether the tap changer is connected to winding 1, winding 2 or winding 3. The *Tapped winding* setting parameter is also used to enable or disable the automatic adaptation to the tap changer position. The possible values are "Not in use", "Winding 1", "Winding 2", "Winding 3".

There can be only one tap changer in the transformer, that is, the function can take into account and compensate only for one tap changer.

The *Tap nominal* setting parameter provides the number of the tap which results in the nominal voltage and current. When the current tap position deviates from this value, the input current values where the tap changer resides are scaled to match the currents on the other side.

A correct scaling is determined by the number of steps, the direction of the deviation from the nominal tap and the percentage change in the voltage resulting from a deviation of one tap step. The percentage value is set via the *Step of tap* setting.

The operating range of the tap changer is defined by the *Min winding tap* and *Max winding tap* settings. The *Min winding tap* setting gives the tap position number resulting from the minimum effective number of winding turns on the side of the transformer where the tap changer is connected. Correspondingly, the *Max winding tap* setting gives the tap position number resulting from the maximum effective number of winding turns.

The *Min winding tap* and *Max winding tap* settings help the tap position compensation algorithm find the direction of the compensation. This also ensures that if the current tap position information is corrupted, the automatic tap changer position adaptation does not try to adapt to any unrealistic position values.

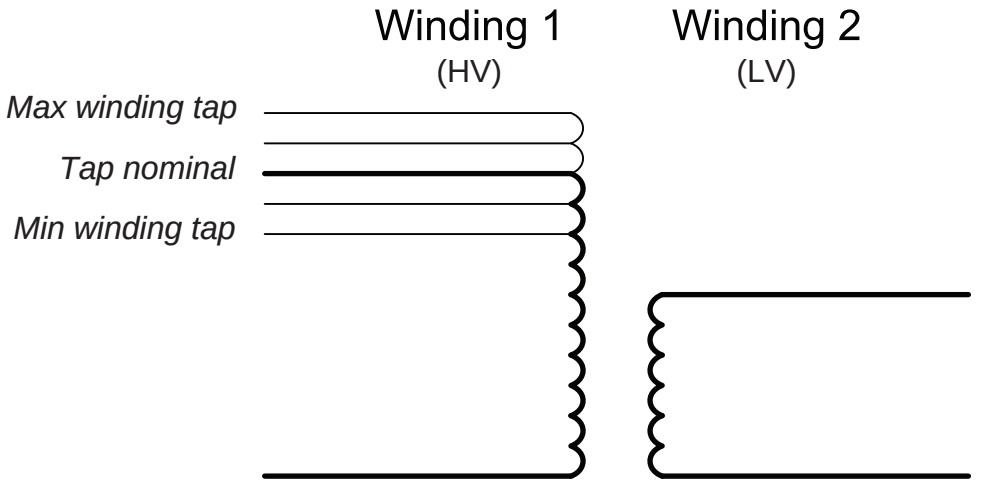

Figure 408: Simplified presentation of the HV and LV windings of a two-winding transformer with demonstration of the settings Max winding tap, Min winding tap and Tap nominal

The position value is available in the Monitored data view on LHMI or through other communication tools in TPOSYLTC. When the quality of the `TAP_POS` input value is not good, the position information in the `TAP_POS` input is not used, and

the last value with the good quality information is used instead. In addition, the minimum sensitivity of the biased stage, set by the *Low operate value* setting, is automatically desensitized with the total range of the tap position correction. The new acting low operate value can be calculated.

$$Desensitized\ Low\ operate\ value = Low\ operate\ value + ABS(Max\ winding\ tap - Min\ winding\ tap) \cdot Step\ of\ tap$$

(Equation 169)

Second harmonic blocking

Transformer-magnetizing inrush currents occur when the transformer is energized after a period of de-energization. The inrush current may be many times the rated current, and the half-life can be up to several seconds. To the differential protection relay, the inrush current represents a differential current that causes the protection relay to operate almost always when the transformer is connected to the network. Typically, the inrush current contains a large amount of second harmonics.

The blocking of the biased low stage of the protection relay at magnetizing inrush current is based on the ratio of the amplitudes of the second harmonic to the fundamental frequency component of the differential current (Id2f / Id1f).

The blocking also prevents an unwanted operation at recovery and a sympathetic magnetizing inrush. At recovery inrush, the magnetizing current of the transformer to be protected increases momentarily when the voltage returns to normal after the clearance of a fault outside the protected area. The sympathetic inrush is caused by the energization of another transformer running in parallel with the protected transformer already connected to the network.

The ratio of the second harmonic to the fundamental component can vary considerably between the phases. Especially when the delta compensation is done for a Ynd1-connected transformer and the two phases of the inrush currents are otherwise equal but opposite in phase angle, their subtraction in a delta compensation results in a very small second harmonic component.

Because of the small second harmonic component, some action must be taken to avoid false tripping of the phase having a too low ratio of the second harmonic to the fundamental component. One way could be to block all phases when the second harmonic blocking conditions are fulfilled at least in one phase. The other way is to calculate weighted ratios of the second harmonic to the fundamental for each phase using the original ratios of the phases. The latter option is used here.

The ratio used for the second harmonic blocking is calculated as a weighted average on the basis of the ratios calculated from the differential currents of the three phases. The ratio of the phase has the most weight compared to the ratios of the other two phases (the weighting factors are 4, 1 and 1, where 4 is the factor of the phase). The operation of the biased stage on the phase is blocked if the weighted ratio of that phase is above the set *Start value 2.H* blocking limit and if the blocking is enabled through the *Restraint mode* setting.

Using separate blocking for the individual phases and weighted averages calculated for the separate phases provides a stable blocking scheme at connection inrush currents.

The switching of the power transformer onto fault inside the protected area does not delay the operation of the tripping, because in such a situation the blocking based on the second harmonic of the differential current is prevented by a separate algorithm based on the different waveform and the different rate of change of the normal inrush current and the inrush current containing the fault current. The

algorithm does not eliminate the blocking at inrush currents unless there is a fault in the protected area.

The feature can be enabled and disabled through the *Harmonic deblock 2.* setting.

Fifth harmonic blocking

The inhibition of the protection relay operation in situations of overexcitation is based on the ratio of the fifth harmonic to the fundamental component of the differential current (Id5f / Id1f). The ratio is calculated separately for each phase without weighting factors. If the ratio exceeds the set value of *Start value 5.H* and blocking is enabled through the *Restraint mode* setting, the operation of the biased stage of the protection relay in the phase is blocked.

At dangerous levels of overvoltage which may cause damage to the transformer, the blocking can be automatically eliminated. The blocking is removed if the ratio of the fifth harmonic to the fundamental component of the differential current exceeds the set value of the *Stop value 5.H* setting, and the blocking removal is enabled. The deblocking feature can be enabled or disabled with the *Harmonic deblock 5.* setting.

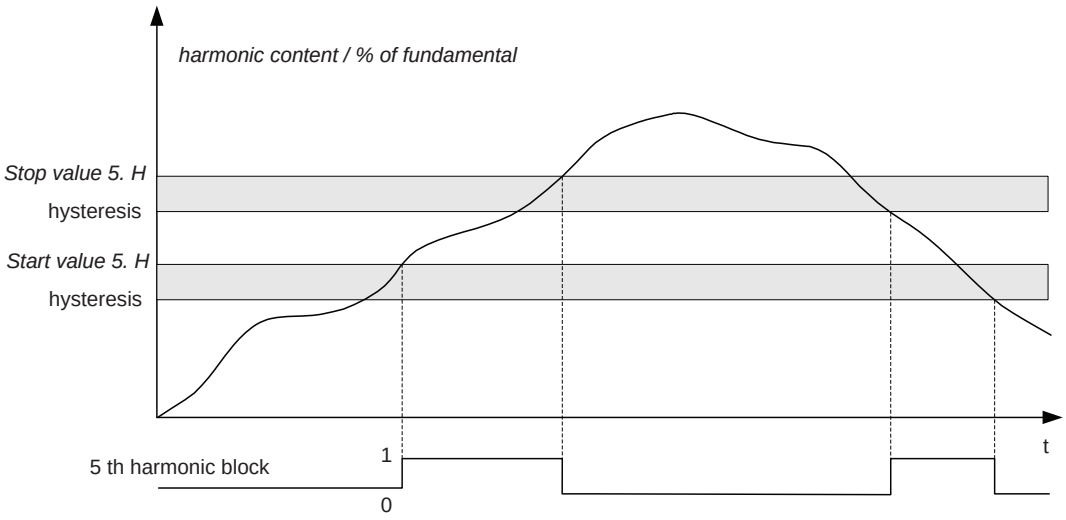

Figure 409: The fifth harmonic blocking limits and the operation when both blocking and deblocking features are enabled through the Harmonic deblock 5. setting

Fifth harmonic blocking has a hysteresis to avoid rapid fluctuation between TRUE and FALSE. The required consecutive fulfillments of the condition can be counted using the blocking counter. When the condition is not fulfilled, the counter is decreased (if >0).

Also fifth harmonic deblocking (based on the higher limit, *Stop value 5.H*, if enabled with *Harmonic deblock 5.*) has a hysteresis and a counter which counts the required consecutive fulfillments of the condition. When the condition is not fulfilled, the counter is decreased (if >0).

Waveform blocking

The biased low stage can always be blocked with waveform blocking; it cannot be disabled with *Restraint mode*. This algorithm has two parts. The first part is intended for external faults while the second is intended for inrush situations. The algorithm has criteria for the low-current periods of differential current during the inrush and external fault.

Blocking reset

All three blocking signals, that is, waveform and the second and fifth harmonic, have a counter or time limit which holds the blocking on for a certain time after the blocking conditions have ceased to be fulfilled. The deblocking takes place when the counters or time have elapsed. This is a normal case of deblocking.

The blocking signals can be reset immediately if a very high differential current is measured or if the phase difference (angle) between the compared currents is close to zero (in normal situations, the phase difference is 180 degrees).

Biased low stage

Biasing of the current differential protection is needed since a possible appearance of a differential current can also be due to something else than an actual fault in the transformer (or generator).

In the case of transformer protection, there can be several reasons for the false differential current.

- CT errors
- Varying tap changer positions (if not automatically compensated)
- Transformer no-load current
- Transformer inrush currents
- Transformer overexcitation during overvoltage situations
- Transformer overexcitation during underfrequency situations
- CT saturation at high currents passing through the transformer

The differential current caused by CT errors and tap changer position increases at the same percentage ratio as the load current.

In the protection of generators, the false differential current can be caused by several reasons.

- CT errors
- CT saturation at high currents flowing through the generator

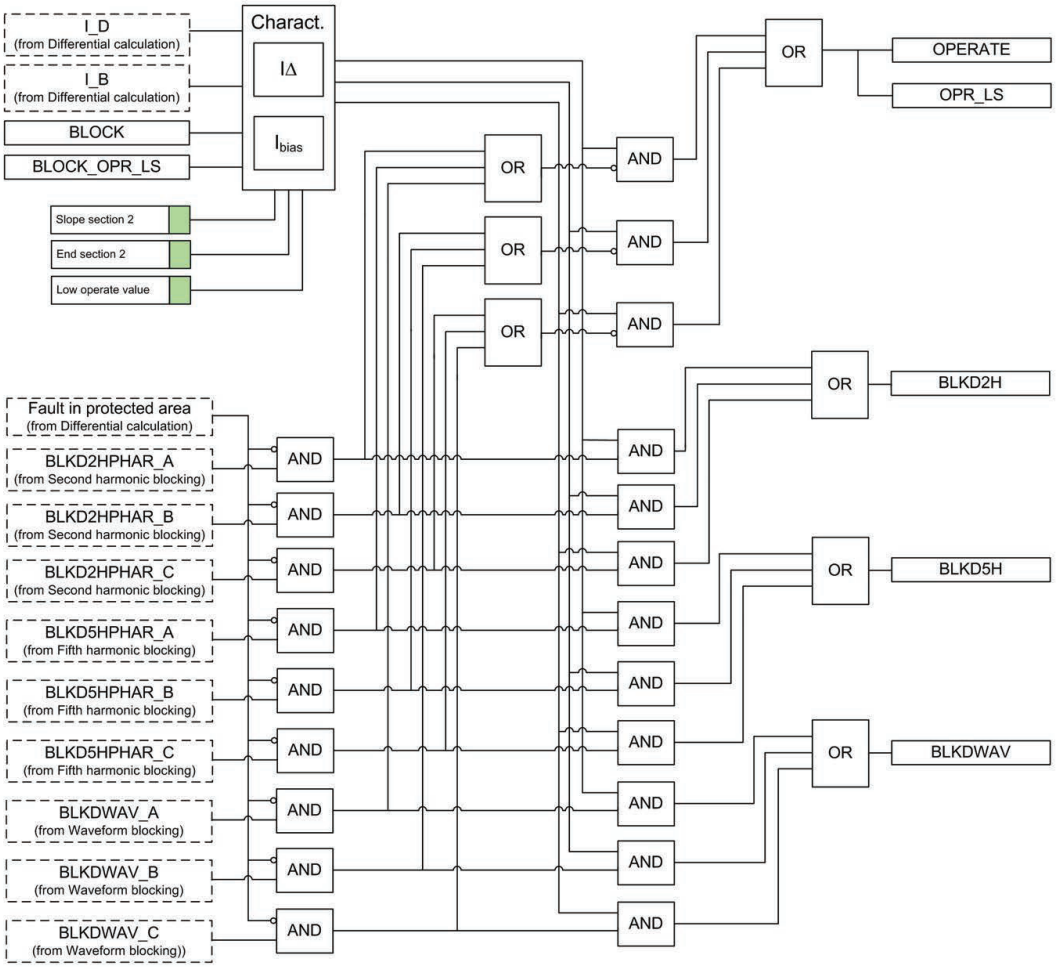

Figure 410: Operation logic of the biased low stage

The high currents passing through a protected object can be caused by the short circuits outside the protected area, the high currents fed by the transformer in a motor startup or transformer inrush situations. Therefore, the operation of the differential protection is biased with respect to the load current. In biased differential protection, the higher the differential current required for the protection to trip, the higher the load current.

The operation characteristic of the biased low stage is determined by *Low operate value*, *Slope section 2* and the second turning point setting of the operating characteristic curve, *End section 2* (the first turning point and the slope of the last part of the characteristic are fixed). The settings are the same for each phase. When the differential current exceeds the operating value determined by the operating characteristic, the differential function is activated. If the differential current stays above the operating value continuously for a suitable period, the `OPR_LS` output is activated. The activation of the `OPR_LS` output activates the **OPERATE** output.

The stage can be blocked internally by the second or the fifth harmonic restraint, or by special algorithms detecting the inrush and current transformer saturation at external faults. When the operation of the biased low stage is blocked by the second harmonic blocking functionality, the `BLKD2H` output is activated.

The `BLKD5H` output is activated when the biased low stage is blocked by the fifth harmonic blocking functionality. Correspondingly, when the operation of the biased

low stage is blocked by the waveform blocking functionality, the BLKDWAV output is activated according to the phase information.

When required, the operating outputs of the biased low stage can be blocked by the external control signals BLK_OPR_LS and BLOCK.

The operation of the protection relay is affected by biasing as shown in *Figure 411*.

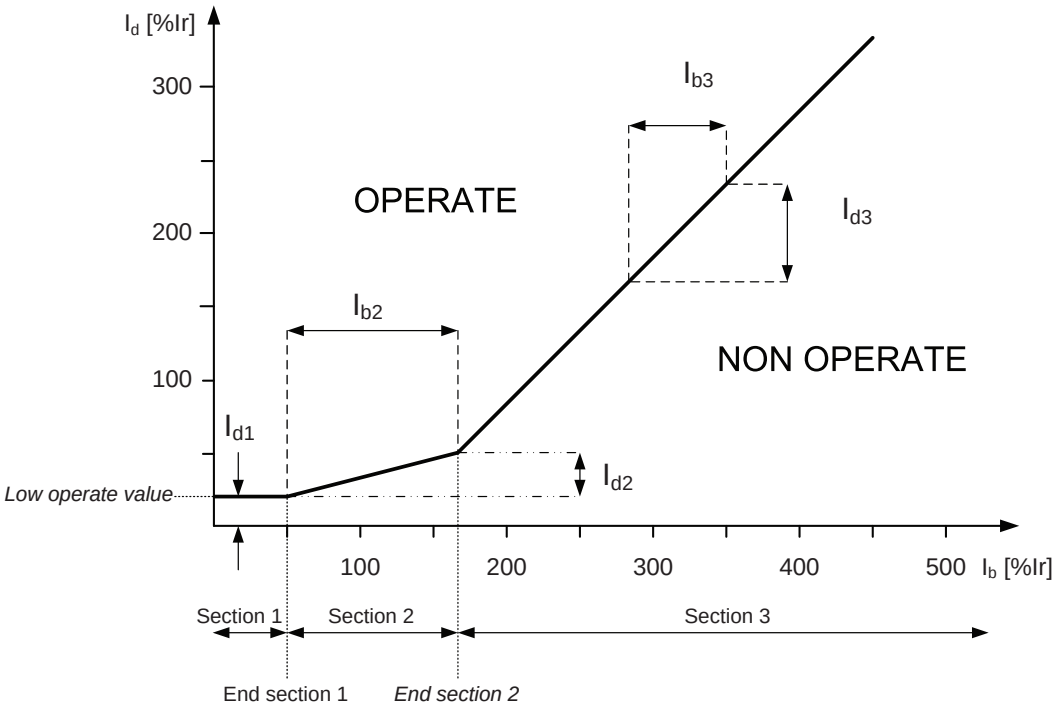

Figure 411: Operation characteristic for biased operation of TR3PTDF

The *Low operate value* setting of the biased stage of the differential function is determined according to the operating characteristics curve:

$$Low\,operate\,value = Id1$$

(Equation 170)

The *Slope section 2* setting is determined correspondingly:

$$Slope\ section\ 2 = \frac{Id2}{Ib2} \cdot 100\,\%$$

(Equation 171)

The second turning point *End section 2* can be set in the range 100...500 %.

The slope of the operating characteristic curve of the differential function varies in three different sections of the range.

Table 666: Different sections of the range and their operation

Sections	Operation
Section 1	In section 1, where 0 percent Ir < Ib < End section 1, with End section 1 being fixed to 50 percent of Ir, the differential current required for tripping is constant. The value of the differential current is the same as the *Low operate value* selected for the function. The *Low operate value* setting allows for the no-load current of the power transformer and small inaccuracies of the current transformers, but it can also be used to influence the overall level of the operation characteristic. At the rated current, the no-load losses of the power transformer are about 0.2 percent. If the supply voltage of the power transformer suddenly increases due to operational disturbances, the magnetizing current of the transformer increases as well. In general, the magnetic flux density of the transformer is rather high at the rated voltage and the rise in voltage by a few percent causes the magnetizing current to increase by tens percent. This should be considered in *Low operate value*.
Section 2	Section 2, where End section 1 < Ib < *End section 2*, is called the influence area of *Slope section 2*. In this section, the variations in the starting ratio affect the slope of the characteristic, that is, how big a change in the differential current is required for tripping compared to the change in the load current. The starting ratio should consider CT errors and variations in the transformer tap changer position (if not compensated). Too high a starting ratio should be avoided, because the sensitivity of the protection for detecting interturn faults depends on the starting ratio.
Section 3	In section 3, where Ib > *End section 2*, the slope of the characteristic is constant. The slope is 100 percent, which means that the increase in the differential current is equal to the corresponding increase in the biasing current.

Curve	*Low operate value*	*Slope section 2*	*End section 2*
1	50 %Ir	50 %	100 %Ir
2	20 %Ir	30 %	150 %Ir
3	5 %Ir	10 %	500 %Ir

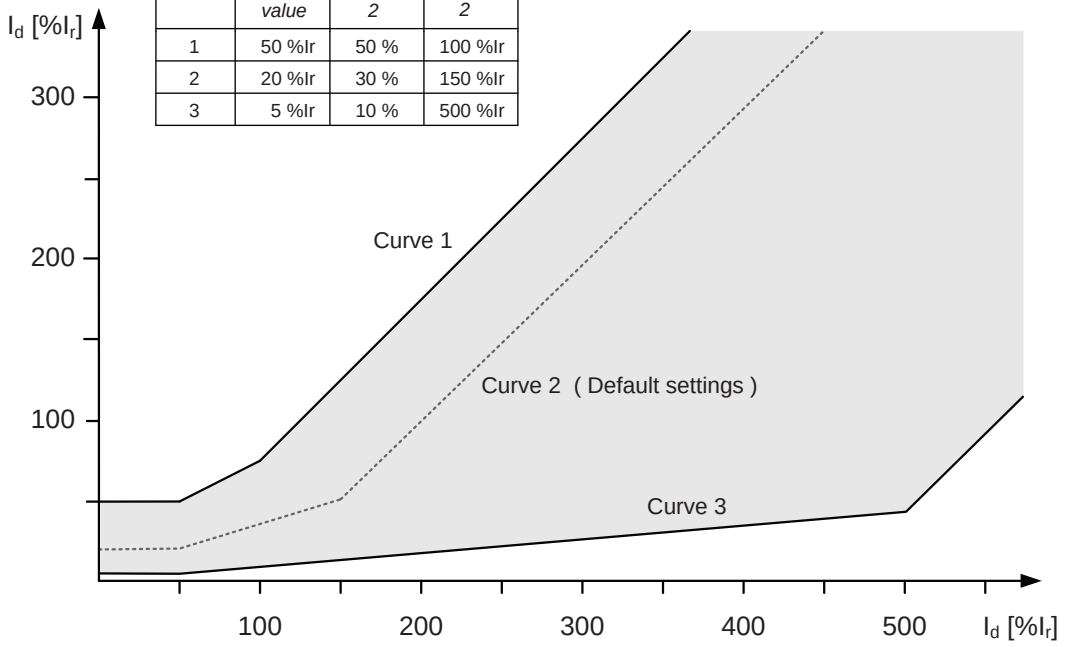

Figure 412: Setting range for biased low stage

If the biasing current is small compared to the differential current or if the phase angle between the currents of two windings with the highest phase current is close to zero (normally, the phase difference is 180 degrees) or the phase angle between the compared phase currents (in case of two-winding transformer) is close to zero, a fault has most certainly occurred in the area protected by the differential protection relay. The internal blocking signals of the biased stage are inhibited.

The operation of the differential protection is based on the fundamental frequency components. The operation is accurate and stable: the DC component and harmonics of the current do not cause unwanted operations.

Instantaneous high stage

Instantaneous high stage can be enabled or disabled with the *Enable high set* setting. The corresponding parameter values are "True" and "False".

The operation of Instantaneous high stage is not biased. The instantaneous stage operates and the `OPR_HS` output is activated when the amplitude of the fundamental frequency component of the differential current exceeds the set operation value *High operate value* or when the instantaneous value of the differential current exceeds 2.5 · *High operate value*. The value 2.5 (=1.8 · √2) is due to the maximum asymmetric short circuit current.

If the biasing current is small compared to the differential current, or if the phase angle between the currents of the two windings with the highest phase current is close to zero (normally, the phase difference is 180 degrees) or the phase angle between the compared phase currents (in case of a two-winding transformer) is close to zero, a fault has occurred in the area protected by the differential protection. The operating value set for the instantaneous stage is automatically halved and the internal blocking signals of the biased stage are inhibited.

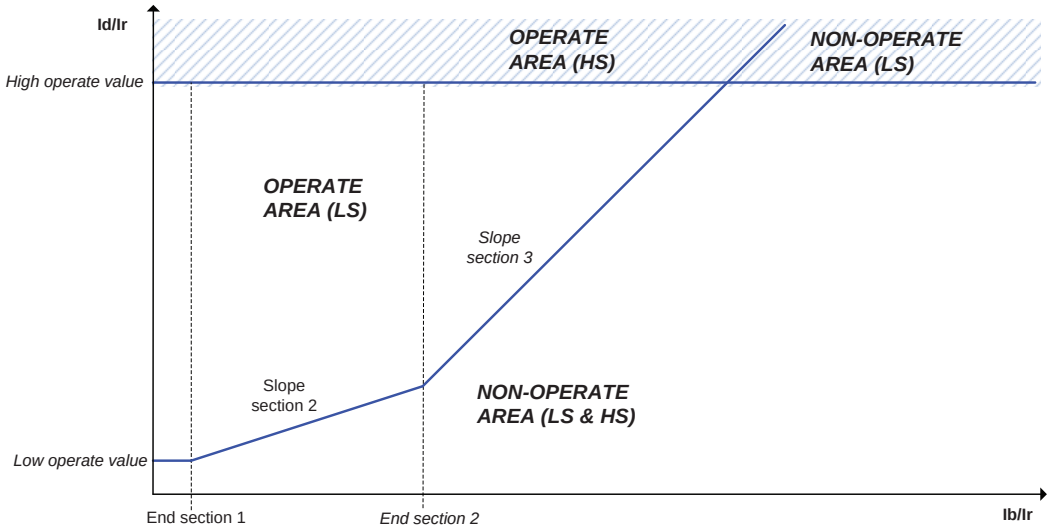

Figure 413: Operating characteristics of the protection. LS stands for the biased low stage and HS for the instantaneous high stage

The OPERATE output is always activated with the OPR_HS output. The internal blocking signals of the differential function do not prevent the trip signal of the instantaneous differential current stage from being activated. When required, the operating outputs of Instantaneous high stage can be blocked by the external control signals BLK_OPR_HS or BLOCK.

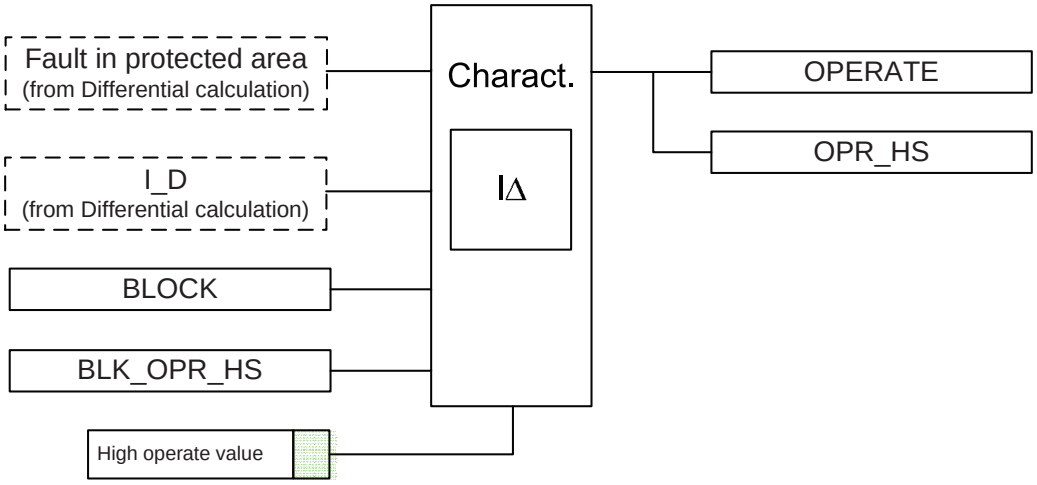

Figure 414: Operation logic of Instantaneous high stage

External blocking functionality

TR3PTDF has three inputs for blocking.

Blocking inputs	Description
BLOCK	When active (TRUE), the operation of the function is blocked; only measurement value outputs are updated.
BLK_OPR_LS	When active (TRUE), TR3PTDF acts normally except that the OPR_LS output is not active or activated in any circumstances. Additionally, the OPERATE output can be activated only by the instantaneous high stage (if not blocked).
BLK_OPR_HS	When active (TRUE), TR3PTDF acts normally except that the OPR_HS output is not active or activated in any circumstances. Additionally, the OPERATE output can be activated only by the biased low stage (if not blocked).

4.3.3.6 Current transformer connections and transformation ratio correction

The combinations of the connections of the primary current transformers are designated as "Type 1" and "Type 2". The type needs to be selected separately for the combination of CT connections on the winding 1 and 2 sides as well as for the combination of CT connections on the winding 1 and 3 sides in case of three-winding transformer.

- If the positive directions of the winding 1 and winding 2 relay currents are opposite, the setting parameter *CT connection 1-2* is "Type 1", as shown in *Figure 415*.
- If the positive directions of the winding 1 and winding 2 relay currents are equal, the setting parameter *CT connection 1-2* is "Type 2", as shown in *Figure 416*.
- 'The default value of the *CT connection 1-2* settings is "Type 1".
- The same applies for the *CT connection 1-3* settings.

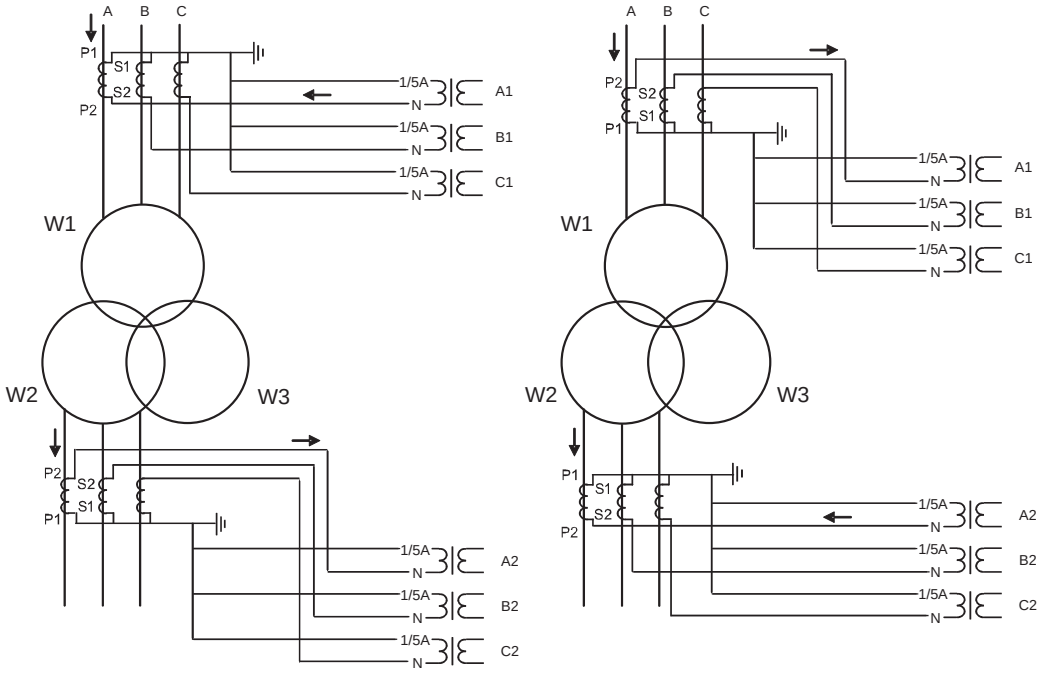

Figure 415: Connection of current transformers of Type 1 and example of currents during an external fault

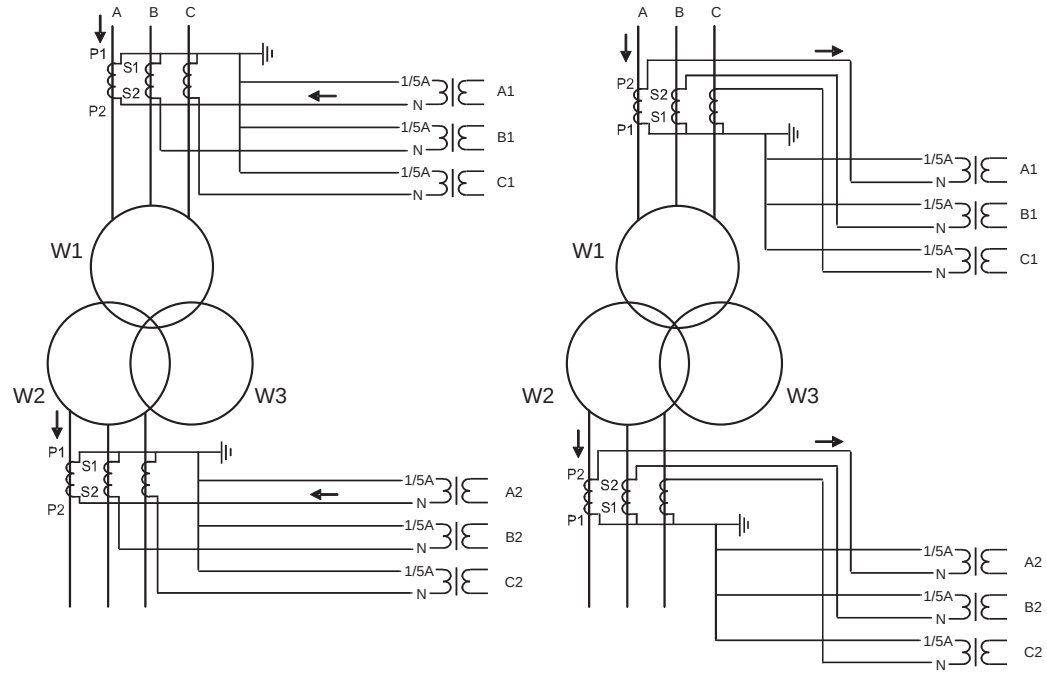

Figure 416: Connection of current transformers of Type 2 and example of currents during an external fault

Similar connections are done for a three-winding transformer.

If the rated primary current of the current transformers is not equal to the rated current of the power transformer on a side of the transformer, setting parameters *CT ratio Cor Wnd 1*, *CT ratio Cor Wnd 2* and *CT ratio Cor 3* must be used to correct

the transformation ratios. *CT ratio Cor Wnd 1* and *CT ratio Cor Wnd 2* are used to correct the ratios on winding 1 and 2 while the use of *CT ratio Cor 3* depends on the setting *Current group 3 type*. If *Current group 3 type* is "Winding 3", the *CT ratio Cor 3* setting is used to correct the ratios on winding 3. If *Current group 3* type is "Wnd 2 restraint", the ratio correction is made to the ratios of the second restraint on winding 2. If *Current group 3 type* is "Wnd 1 restraint", the ratio correction is made to the ratios of the second restraint on winding 1.

4.3.3.7 Application

TR3PTDF is a unit protection. It acts as the main protection of transformers in case of winding failure. The protective zone of a differential protection includes the transformer itself and the bus work or cables between the current transformer and the power transformer. When bushing current transformers are used for the differential protection relay, the protective zone does not include the bus work or cables between the circuit breaker and the power transformer.

In some substations, there is a current differential protection for the busbar. Such a busbar protection includes the bus work or cables between the circuit breaker and the power transformer. The internal electrical faults are serious and cause immediate damage. The short circuits and earth faults in the windings and terminals are normally detected by the differential protection. Inter-turn faults, which are flashovers between conductors within the same physical winding, can also be detected if a large enough number of turns are short-circuited. Inter-turn faults are the most difficult transformer winding faults to detect with electrical protections. A small inter-turn fault including just a few turns results in an undetectable amount of current until it develops into an earth fault. Therefore the differential protection must have a high level of sensitivity and it must be possible to use a sensitive setting without causing unwanted operations for external faults.

The faulty transformer must be disconnected as fast as possible. As the differential protection is a unit protection, it can be designed for fast tripping, thus providing a selective disconnection of the faulty transformer. The differential protection should not operate because of faults outside the protective zone.

A transformer differential protection compares the current flowing into the transformer to the current leaving the transformer. A correct analysis of fault conditions by the differential protection must consider changes to voltages, currents and phase angles. The traditional transformer differential protection functions required auxiliary transformers for the correction of the phase shift and ratio. The numerical microprocessor-based differential algorithm implemented in TR3PTDF compensates for both the turns ratio and the phase shift internally in the software.

The differential current should theoretically be zero during a normal load or external faults if the turns ratio and phase shift are correctly compensated. However, there are several different phenomena other than internal faults that cause unwanted and false differential currents. There can be several main reasons for unwanted differential currents.

- Mismatch due to varying tap changer positions.
- Different characteristics, loads and operating conditions of the CTs.
- Zero-sequence currents that flow only on one side of the power transformer.
- Normal magnetizing currents.
- Magnetizing inrush currents.
- Overexcitation of magnetizing currents.

TR3PTDF is designed mainly for protection of two-winding or three-winding transformers. TR3PTDF can also be used for the protection of generator-transformer blocks as well as short cables and overhead lines. If the distance between the measuring points is relatively long in line protection, interposing CTs might be needed to reduce the burden of the CTs. For the interposing CT, the accuracy limit factor must fulfill the same requirements as for the main CTs. The interposing CT imposes an additional burden to the main CTs.

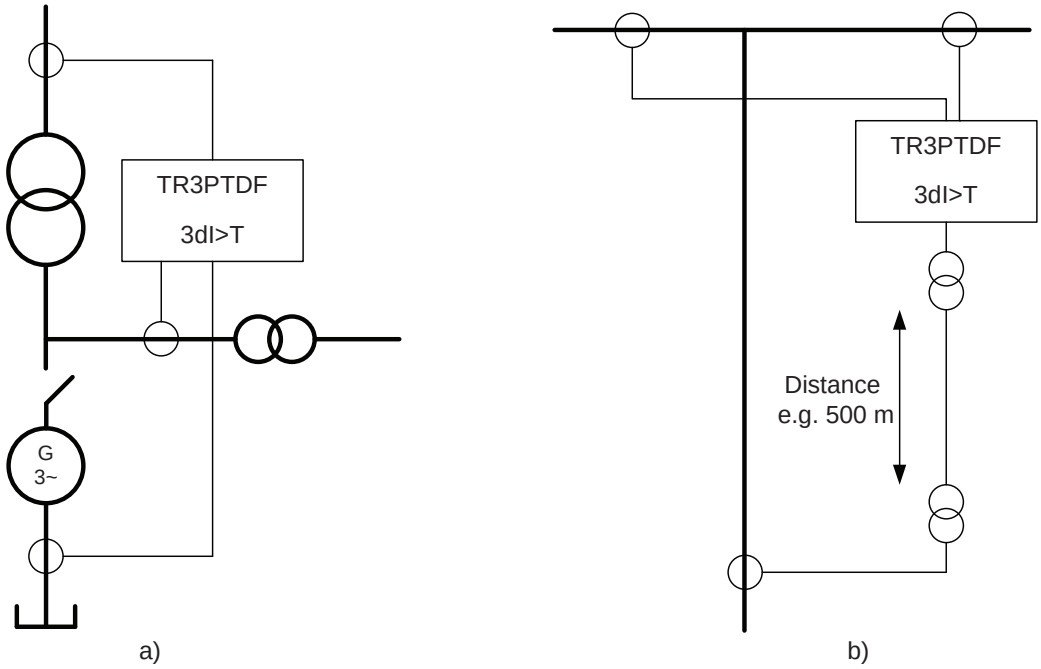

Figure 417: Differential protection of a generator-transformer block and short cable or line

TR3PTDF can be used in three-winding transformer applications or two-winding transformer applications with two output feeders.

On the double-feeder side of the two-winding power transformer, the currents from the other feeder are connected to the third three-phase current set of the protection relay (*Current group 3 type* to be set as "Wnd 2 restraint").

If the double-feeder side is on the input side of the transformer, *Current group 3 type* must be set as "Wnd 1 restraint".

In three-winding transformer applications, currents from winding 3 are always connected to the third three-phase current input set of the protection relay (*Current group 3 type* to be set as "Winding 3").

In the normal two-winding transformer application with one set of three-phase currents on both sides of the transformer, the *Current group 3 type* setting must be set as "Not in use".

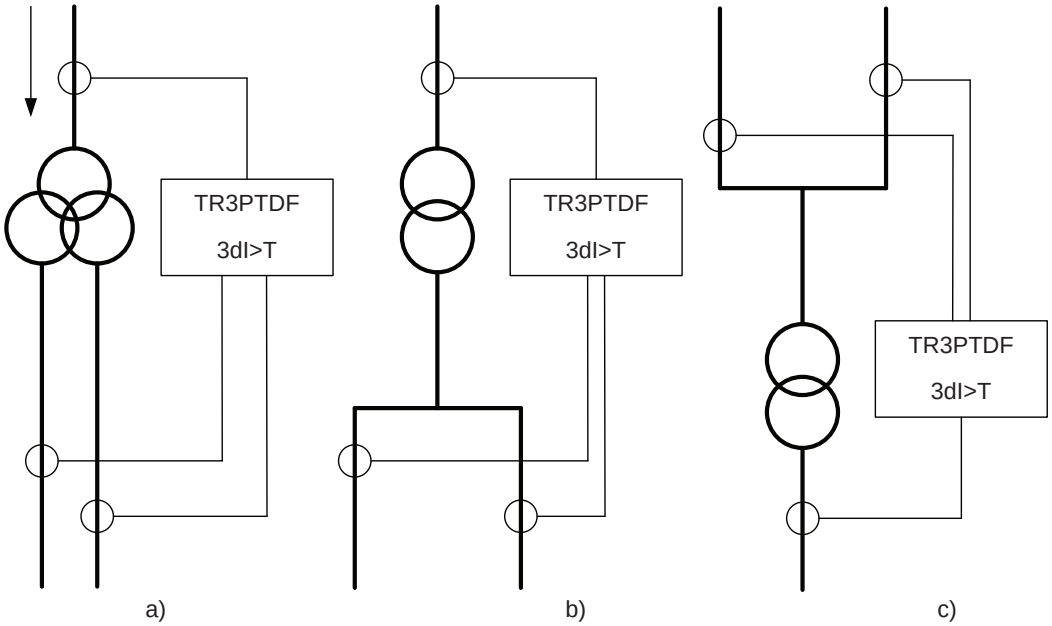

Figure 418: Differential protection of a three-winding transformer, transformer with two output feeders and transformer with two input feeders

Transforming ratio correction of CTs

The CT secondary currents often differ from the rated current at the rated load of the power transformer. The CT transforming ratios can be corrected on all sides of the power transformer with the CT ratio correction settings.

$$I_{nT} = \frac{S_n}{\sqrt{3} \cdot U_n}$$

(Equation 172)

I_{nT}	Rated load of the power transformer
S_n	Rated power of the power transformer
U_n	Rated phase-to-phase voltage

Three-winding transformer with one set of currents on each side of the transformer

100 MVA YNyn0d1 power transformer 154 kV/14.4 kV/4.37 kV. The corresponding rated currents are 375 A, 3007 A and 3303 A. At the HV side, the CT is 400 A, and on the MV sides both are 4000 A.

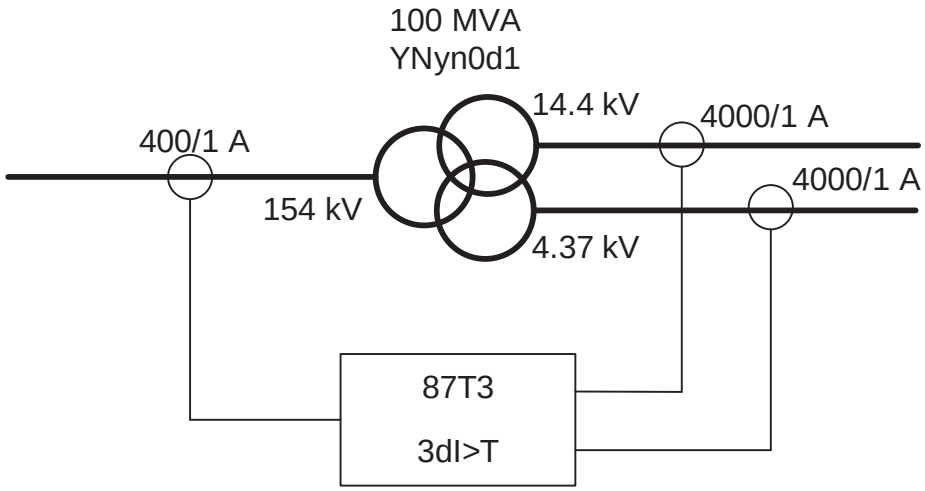

Figure 419: Example of three-winding power transformer differential protection

154 kV side: CT ratio correction factor = 400 A / 375 A = 1.07

The rated current 375 A corresponds to a 100 MVA power but on the MV sides 1.732 · 14.4 kV · 3007 A = 75 MVA and 1.732 · 4.37 kV · 3303 A = 25 MVA. Thus, the MV side rated currents cannot be used for calculations.

14.4kV side: CT ratio correction factor = 4000 A / (375 A · 154 kV / 14.4 kV) = 1.00

4.37kV side: CT ratio correction factor = 4000 A / (375 A · 154 kV / 4.37 kV) = 0.30

Assume for example a 50 MVA load on the 14.4 kV side and zero on the 4.37 kV side.

- 154 kV side current = 50 MVA / (1.732 · 154 kV) = 187.45 A

  TR3PTDF sees this as 185.45 A / 400 A · 1.07 = 0.50 xIr
- 14.4 kV side current = 50 MVA / (1.732 · 14.4 kV) = 2004.7 A

  TR3PDF seez this as 2004.7 A / 4000 A · 1.00 = 0.50 xIr

Assume for example a 20 MVA load on the 4.37 kV side and zero on the 14.4 kV side.

- 154kV side current = 20 MVA / (1.732 · 154 kV) = 75.0 A

  TR3PTDF sees this as 75 A / 400 A · 1.07 = 0.20 xIr
- 4.37kV side current = 20 MVA / (1.732 · 4.37 kV) = 2642.3 A

  TR3PTDF sees this as 2642.3 A / 4000 A · 0.30 = 0.20 xIr

Vector group matching and elimination of the zero-sequence component

The vector group of the power transformer is numerically matched on the windings on different sides of the transformer by the *Phase shift Wnd 1-2* and *Phase shift Wnd 1-3* settings. Thus no interposing CTs are needed if there is only a power transformer inside the protected zone. The matching is based on phase shifting and a numerical delta connection in the function.

If the neutral of a star-connected power transformer is earthed, any earth fault in the network is perceived by the protection as differential current. The elimination of the zero-sequence component can be selected to be on or off for that winding by the *Zro A elimination* setting. By default, the elimination is done for every winding.

Commissioning

The settings for the connection group compensation (*CT connection 1-2*, *Phase shift Wnd 1-2* and, in case of a three-winding transformer, also *CT connection 1-3* and *Phase shift Wnd 1-3* settings) can be verified by monitoring the angle values (I_ANGL_A1_B1, I_ANGL_B1_C1, I_ANGL_C1_A1, I_ANGL_A2_B2, I_ANGL_B2_C2, I_ANGL_C2_A2, I_ANGL_A1_A2, I_ANGL_B1_B2 and I_ANGL_C1_C2 and in case of three-winding transformer also I_ANGL_A3_B3, I_ANGL_B3_C3, I_ANGL_C3_A3, I_ANGL_A1_A3, I_ANGL_B1_B3 and I_ANGL_C1_C3) when injecting the current into the transformer. These angle values are calculated from the compensated currents.

When a station service transformer is available, it can be used to provide current into the winding 1 side, for example, HV windings, while the winding 2 side, for example, LV windings are short-circuited, as shown in *Figure 420* (in case of a three-winding transformer, the tertiary winding side is short-circuited). This way the current can flow both in high-voltage and low-voltage windings (and in winding 3 in case of three-winding transformer). The commissioning signals can also be provided through other means. The currents need to be at least 0.015 pu to allow the phase current and angle monitoring.

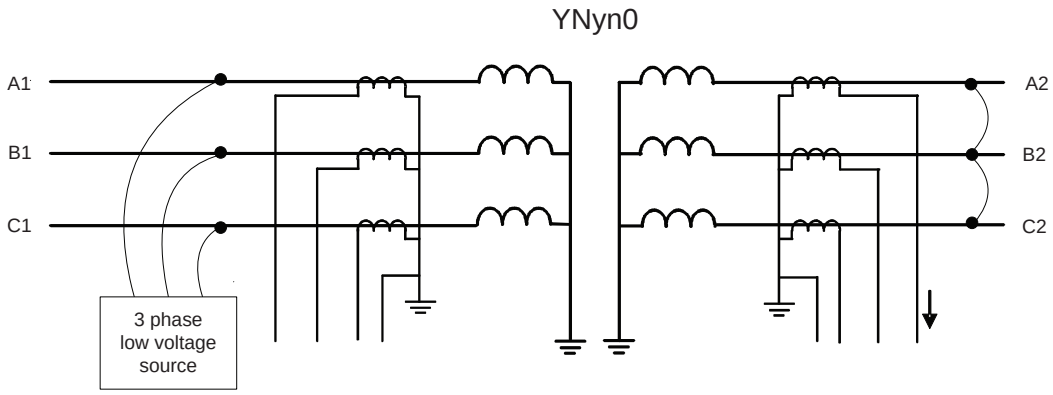

Figure 420: Low-voltage test arrangement. The three-phase low-voltage source can be the station service transformer, for example

The control setting *Tapped winding* should be set to value "Not in use" to ensure that the monitored current values are not scaled by the automatic adaptation to the tap changer position. When only the angle values are taken, this is not needed since the angle values are not affected by the tap changer position.

When injecting the currents into the HV winding, the angle values I_ANGL_A1_B1, I_ANGL_B1_C1, I_ANGL_C1_A1, I_ANGL_A2_B2, I_ANGL_B2_C2 and I_ANGL_C2_A2, and in case of three winding transformer, I_ANGL_A3_B3, I_ANGL_B3_C3 and I_ANGL_C3_A3, should be +120.

Otherwise, the phase order may be wrong or the polarity of one current transformer differs from the polarities of the other current transformers on the same side. If the angle values I_ANGL_A1_B1, I_ANGL_B1_C1 and I_ANGL_C1_A1 show -120°, the phase order is wrong on winding 1, for example, the high-voltage side. If the angle values I_ANGL_A2_B2, I_ANGL_B2_C2 and I_ANGL_C2_A2 show -120°, the phase order is wrong on winding 2, for example, the low-voltage side. If the angle values

I_ANGL_A3_B3, I_ANGL_B3_C3 and I_ANGL_C3_A3 show -120°, the phase order is wrong on winding 3, for example, the tertiary side. If the angle values I_ANGL_A1_B1, I_ANGL_B1_C1 and I_ANGL_C1_A1 do not show the same value (+120°), the polarity of one current transformer may be wrong. For example, if the polarity of the current transformer measuring IL2 is wrong, I_ANGL_A1_B1 shows -60°, I_ANGL_B1_C1 shows -60° and I_ANGL_C1_A1 shows +120°.

When the phase order and the angle values are correct, the angle values I_ANGL_A1_A2, I_ANGL_B1_B2 and I_ANGL_C1_C2 should show ±180° and in case of a three-winding transformer, also the angle values I_ANGL_A1_A3, I_ANGL_B1_B3 and I_ANGL_C1_C3 should show ±180°. There can be several reasons if this is not the case. If the angle values are 0, most probably the value given for *CT connection 1-2* (or *CT connection 1-3*) is wrong. If the angle values are something else, the value for *Phase shift Wnd 1-2* or *Phase shift Wnd 1-3* may be wrong.

Table 667: Angle outputs when settings CT connection 1-2 and CT connection 1-3 match the actual CT connections on windings 1, 2 and 3

4.3.3.8 Recommendations for current transformers

The more important the object to be protected, the more attention should be paid to the CTs. Normally, it is not possible to dimension the CTs so that they repeat currents with high DC components without saturating when the residual flux of the current transformer is high. TR3PTDF operates reliably even though the CTs are partially saturated. The purpose of the following current transformer recommendations is to secure the stability of the relay at high through-currents and the quick and sensitive operation of the relay at faults occurring in the protected area where the fault currents can be high.

The accuracy class recommended for CTs to be used with TR3PTDF is 5P, where the limit of the current error at the rated primary current is 1 percent and the limit of the phase displacement is 60 minutes. The limit of the composite error at the rated accuracy limit primary current is 5 percent.

The approximate value of the accuracy limit factor F_a corresponding to the actual CT burden can be calculated on the basis of the rated accuracy limit factor F_n (ALF)

at the rated burden, the rated burden S_n, the internal burden S_{in} and the actual burden S_a of the CT.

$$F_a = F_n \cdot \frac{S_{in} + S_n}{S_{in} + S_a}$$

(Equation 173)

Example 1

In the example, the rated burden S_n of the CTs 5P20 is 10 VA, the secondary rated current 5A, the internal resistance R_{in} = 0.07 Ω and the accuracy limit factor F_n(ALF) corresponding to the rated burden is 20 (5P20). The internal burden of the current transformer is S_{in} = (5 A)^2 · 0.07 Ω = 1.75 VA. The input impedance of the relay at a rated current of 5 A is < 20 mΩ. If the measurement conductors have a resistance of 0.113 Ω, the actual burden of the current transformer is S_a =(5 A)2 · (0.113 + 0.020) Ω = 3.33 VA. Thus the accuracy limit factor F_a corresponding to the actual burden is 46.

The CT burden can grow considerably at the rated current of 5 A. At the rated current of 1 A, the actual burden of the current transformer decreases, while the repeatability simultaneously improves.

At faults occurring in the protected area, the fault currents can be very high compared to the rated currents of the CTs. Due to the instantaneous stage of the differential function block, it is enough that during the first cycle, the CTs can repeat the current required for instantaneous tripping.

The CTs should be able to reproduce the asymmetric fault current without saturating within the next 10 ms after the occurrence of the fault, to secure that the operating times of the protection relay comply with the times stated in *Chapter 4.3.3.12 Technical data* .

The accuracy limit factors corresponding to the actual burden of the phase current transformer to be used in differential protection fulfill the requirement of the equation.

$$Fa > K_r \; I_{kmax} \cdot (T_{dc} \cdot \omega \cdot (1 - e^{-\frac{Tm}{Tdc}}) + 1)$$

(Equation 174)

I_{kmax}	Maximum through-going fault current (in pu) at which the protection is not allowed to operate
T_{dc}	Primary DC time constant related to I_{kmax}
ω	Angular frequency, that is, 2 · π · 50 Hz
T_m	Time to saturate, that is, the duration of the saturation-free transformation
K_r	Remanence factor, 1/(1-r)

The parameter *r* gives the maximum remanence flux density in the CT core. The value of the parameter *r* depends on the magnetic material used and on the construction of the CT. For example, the value *r* = "0.4" means that the remanence flux density may be 40 percent of the saturation flux density. The manufacturer of the CT should be contacted when an accurate value for the parameter *r* is needed. The value *r* = "0.4" is recommended to be used when an accurate value is not available.

The minimum time to saturate (T_m) in TR3PTDF is 10 ms.

Two typical cases considered for the determination of the sufficient accuracy limit factor (F_a) are a fault occurring at the substation bus and re-energizing against a fault occurring further down in the network.

A fault occurring at the substation bus

The protection must be stable when a fault occurs during a normal operating situation. Re-energizing the transformer against a bus fault leads to very high fault currents and thermal stress. Therefore, re-energizing is not preferred in this case.

With this assumption, the remanence can be neglected.

The maximum through-going fault current I_{kmax} is typically 10 pu for a substation's main transformer. At a short circuit fault close to the supply transformer, the DC time constant (T_{dc}) of the fault current is almost the same as that of the transformer, the typical value being 100 ms.

$$F_a > K_r \cdot I_{kmax} \cdot (T_{dc} \cdot \omega \cdot (1 - e^{-\frac{Tm}{Tdc}}) + 1) \approx 40$$

(Equation 175)

I_{kmax}	10 (pu)
T_{dc}	100 (ms)
ω	100π (Hz)
T_m	10 (ms)
K_r	1

Re-energizing against a fault occurring further down in the network

The protection must be stable during the re-energization against a fault on the line. In this case, the existence of remanence is very probable. In this example, it is 40 percent.

The fault current is now smaller and since the ratio of the resistance to the reactance is greater in this location, having a full DC offset is not possible. Furthermore, the DC time constant (T_{dc}) of the fault current is now smaller, here 50 ms.

Assuming a maximum fault current is 30 percent lower than in the bus fault and a DC offset 90 percent of the maximum.

$$F_a > K_r \cdot I_{kmax} \cdot 0.9 \cdot (T_{dc} \cdot \omega \cdot (1 - e^{-\frac{Tm}{Tdc}}) + 1) \approx 40$$

(Equation 176)

I_{kmax}	0.7 · 10 = 7 (pu)
T_{dc}	50 (ms)
ω	100π (Hz)
T_m	10 (ms)
K_r	1/(1-0.4) = 1.6667

If the actual burden of the current transformer (S_a) in *Equation 173* cannot be reduced enough to provide a sufficient value for F_a, there are two alternatives.

- A current transformer with a higher rated burden S_n can be chosen (which also means a higher rated accuracy limit F_n) or
- A current transformer with a higher nominal primary current $I1_n$ (but the same rated burden) can be chosen.

Example 2

Assuming that the actions according to the current transformer with a higher nominal primary current $I1_n$ (but the same rated burden) are taken to improve the actual accuracy limit factor (F_a):

I_{rTR} = 1000 A	Rated secondary current of the transformer
I_{rCT} = 1500 A	Rated primary current of the CT on the transformer secondary side
F_n = 30	Rated accuracy limit factor of the CT
$F_a = (I_{rCT} / I_{rTR}) \cdot F_n$	Actual accuracy limit factor due to oversizing the CT

$F_a = (1500/1000) \cdot 30 = 45$

In differential protection it is important that the accuracy limit factors (F_a) at both sides of the phase CTs correspond with each other, that is, the burdens of the CTs on both sides should be as equal as possible. If high inrush or start currents with high DC components flow through the protected object when it is connected to the network, special attention should be paid to the performance and the burdens of the CTs and to the settings of the function block.

4.3.3.9 Signals

TR3PTDF Input signals

Table 671: TR3PTDF Input signals

Name	Type	Default	Description
I3P1	SIGNAL	-	Three-phase currents 1
I3P2	SIGNAL	-	Three-phase currents 2
I3P3	SIGNAL	-	Three-phase currents 3
BLOCK	BOOLEAN	0=False	Block
BLK_OPR_LS	BOOLEAN	0=False	Blocks operate outputs from biased stage

[2] Measured with static power output (SPO)

4.3.4.3 Functionality

The numerical stabilized low-impedance restricted earth-fault protection function LREFPNDF for a two-winding transformer is based on the numerically stabilized differential current principle. No external stabilizing resistor or non-linear resistor are required.

The fundamental components of the currents are used for calculating the residual current of the phase currents, the neutral current, differential currents and stabilizing currents. The operating characteristics are according to the definite time.

LREFPNDF contains a blocking functionality. The neutral current second harmonic is used for blocking during the transformer inrush situation. It is also possible to block function outputs, timers or the function itself.

4.3.4.4 Analog channel configuration

LREFPDIF has two analog group inputs which must be properly configured.

Table 678: Analog inputs

Input	Description
I3P	Three-phase currents
IRES	Residual current (measured)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 679: Special conditions

Condition	Description
IRES measured	The function requires that the current measured from the neutral side is connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of LREFPNDF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

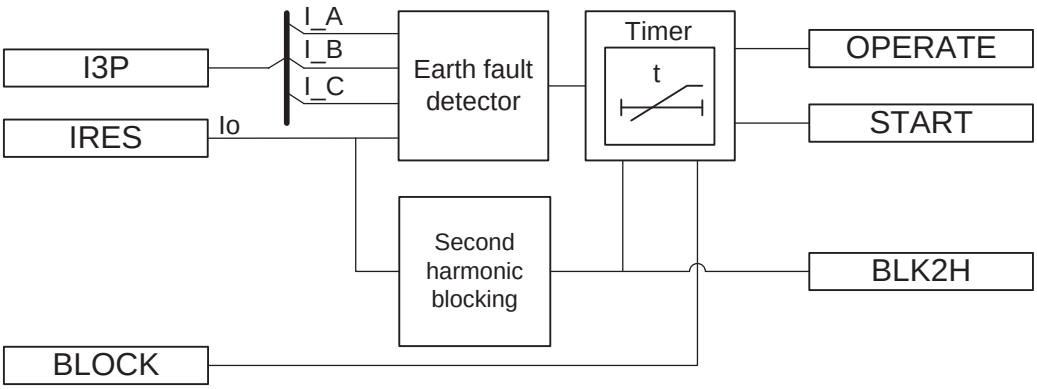

Figure 422: Functional module diagram

Earth-fault detector

The operation is based on comparing the amplitude and the phase difference between the sum of the fundamental frequency component of the phase currents (ΣI, residual current) and the fundamental frequency component of the neutral current (Io) flowing in the conductor between the transformer or generator's neutral point and earth. The differential current is calculated as the absolute value of the difference between the residual current, that is, the sum of the fundamental frequency components of the phase currents I_A, I_B and I_C, and the neutral current. The directional differential current ID_COSPHI is the product of the differential current and cosϕ. The value is available in the monitored data view.

$$ID_COSPHI = (\left|\overline{\Sigma I} - \overline{Io}\right|) \times \cos\varphi$$

(Equation 177)

$\overline{\Sigma I}$	Residual current
φ	Phase difference between the residual and neutral currents
$\overline{Io}$	Neutral current

An earth fault occurring in the protected area, that is, between the phase CTs and the neutral connection CT, causes a differential current. The directions, that is, the phase difference of the residual current and the neutral current, are considered in the operation criteria to maintain selectivity. A correct value for *CT connection type* is determined by the connection polarities of the current transformer.

The current transformer ratio mismatch between the phase current transformer and neutral current transformer (residual current in the analog input settings) is taken into account by the function with the properly set analog input setting values.

During an earth fault in the protected area, the currents ΣI and Io are directed towards the protected area. The factor cosϕ is 1 when the phase difference of the residual current and the neutral current is 180 degrees, that is, when the currents are in opposite direction at the earth faults within the protected area. Similarly, ID_COSPHI is specified to be 0 when the phase difference between the residual current and the neutral current is less than 90 degrees in situations where there is

no earth fault in the protected area. Thus tripping is possible only when the phase difference between the residual current and the neutral current is above 90 degrees.

The stabilizing current IB used by the stabilizing current principle is calculated as an average of the phase currents in the windings to be protected. The value is available in the monitored data view.

$$IB = \frac{\left|\overline{I_A}\right| + \left|\overline{I_B}\right| + \left|\overline{I_C}\right|}{3}$$

(Equation 178)

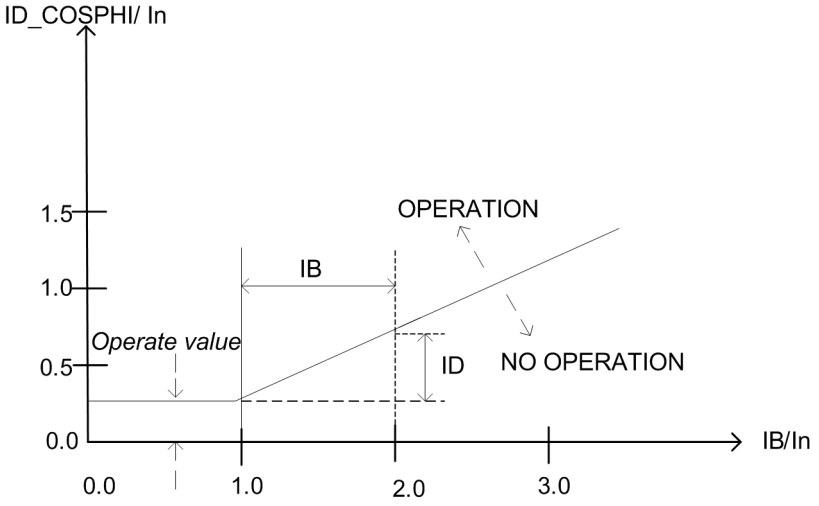

Figure 423: Operating characteristics of the stabilized earth-fault protection function

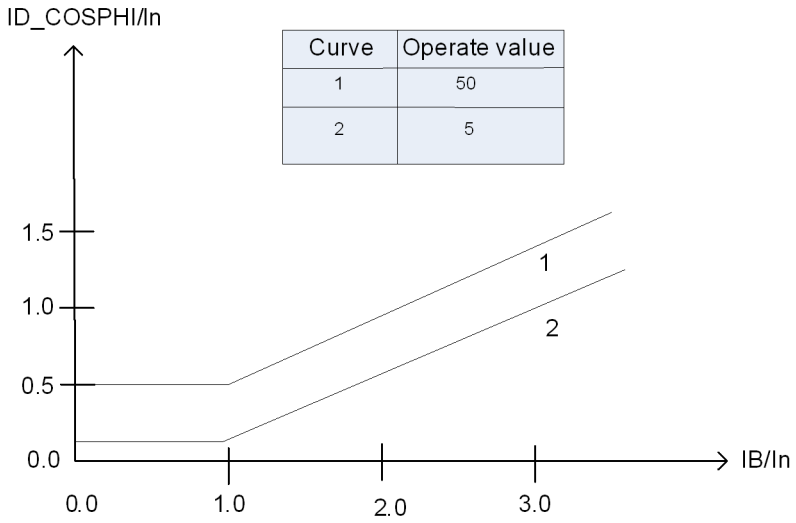

Figure 424: Setting range of the operating characteristics for the stabilized differential current principle of the earth-fault protection function

The *Operate value* setting is used for defining the characteristics of the function. The differential current value required for tripping is constant at the stabilizing current values 0.0 < IB/In < 1.0, where In is the nominal current, and the In in this context refers to the nominal of the phase current inputs. When the stabilizing

current is higher than 1.0, the slope of the operation characteristic (ID/IB) is constant at 50 percent. Different operating characteristics are possible based on the *Operate value* setting.

For the protection of the trip, the measured neutral current has to be above 4 percent. When the condition has been fulfilled, the measured neutral current must stay above 2 percent, otherwise reset time is started.

To calculate the directional differential current ID_COSPHI, the fundamental frequency amplitude of both the residual and neutral currents has to be above 4 percent of In. If neither or only one condition is fulfilled at a time, the cosϕ term is forced to 1. After the conditions are fulfilled, both currents must stay above 2 percent of In to allow the continuous calculation of the cosϕ term.

Second harmonic blocking

This module compares the ratio of the current second harmonic (I_0_2H) and fundamental component of I_0 to the set value *Start value 2.H*. If the ratio (I_0_2H / I_0) value exceeds the set value, the BLK2H output is activated.

The blocking also prevents unwanted operation at the recovery and sympathetic magnetizing inrushes. At the recovery inrush, the magnetizing current of the transformer to be protected increases momentarily when the voltage returns to normal after the clearance of a fault outside the protected area. The sympathetic inrush is caused by the energization of a transformer running in parallel with the protected transformer connected to the network.

The second harmonic blocking is disabled when *Restraint mode* is set to "None" and enabled when set to "Harmonic2".

Timer

Once activated, the Timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Minimum operate time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the reset timer resets and the START output is deactivated.

The Timer calculates the start duration value START_DUR which indicates the percentage ratio of the start situation and the set operate time. The value is available through the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated. The activation of the output of the second harmonic blocking signal BLK2H deactivates the OPERATE output.

4.3.4.6 Application

An earth-fault protection using an overcurrent element does not adequately protect the transformer winding in general and the star-connected winding in particular.

The restricted earth-fault protection is mainly used as a unit protection for the transformer windings. LREFPNDF is a sensitive protection applied to protect the star-connected winding of a transformer. This protection system remains stable for all the faults outside the protected zone.

LREFPNDF provides higher sensitivity for the detection of earth faults than the overall transformer differential protection. This is a high-speed unit protection scheme applied to the star-connected winding of the transformer. LREFPNDF is normally applied when the transformer is earthed solidly or through low-impedance resistor (NER). LREFPNDF can be also applied on the delta side of the transformer if an earthing transformer (zig-zag transformer) is used there. In LREFPNDF, the difference of the fundamental component of all three phase currents and the neutral current is provided to the differential element to detect the earth fault in the transformer winding based on the numerical stabilized differential current principle.

Connection of current transformers

The connections of the primary current transformers are designated as "Type 1" and "Type 2".

- If the positive directions of the winding 1 and winding 2 protection relay currents are opposite, the *CT connection type* setting parameter is "Type 1". The connection examples of "Type 1" are as shown in figures *Figure 425* and *Figure 426*.
- If the positive directions of the winding 1 and winding 2 protection relay currents equate, the *CT connection type* setting parameter is "Type 2". The connection examples of "Type 2" are as shown in figures *Figure 427* and *Figure 428*.
- The default value of the *CT connection type* setting is "Type 1".

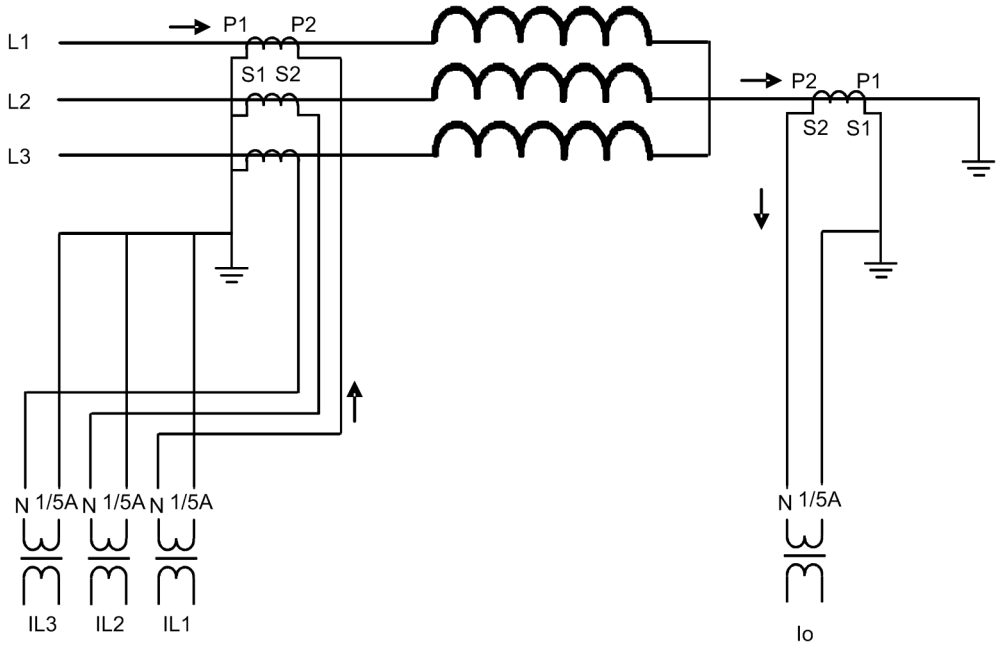

Figure 425: Connection of the current transformers of Type 1. The connected phase currents and the neutral current have opposite directions at an external earth-fault situation.

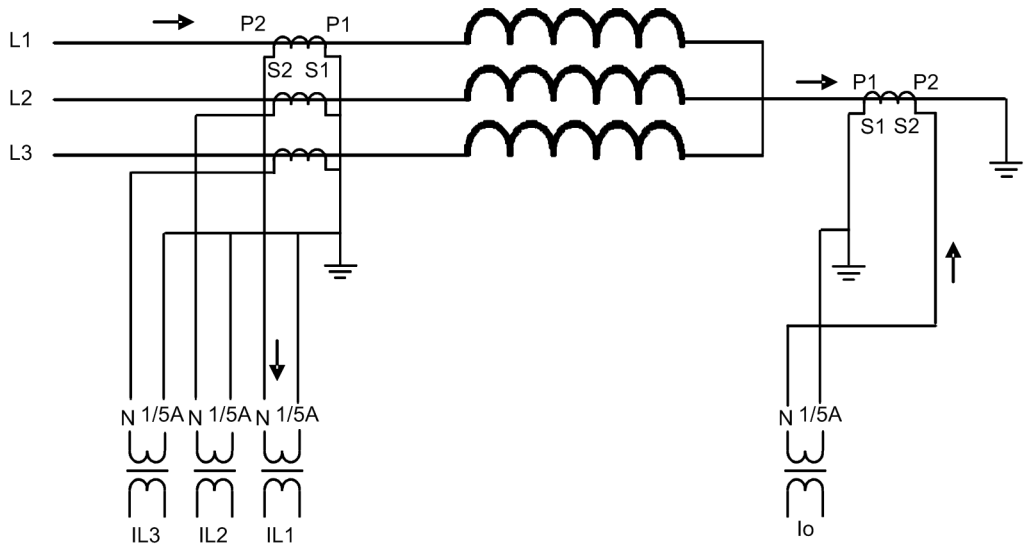

Figure 426: Connection of the current transformers of Type 1. The connected phase currents and the neutral current have opposite directions at an external earth-fault situation.

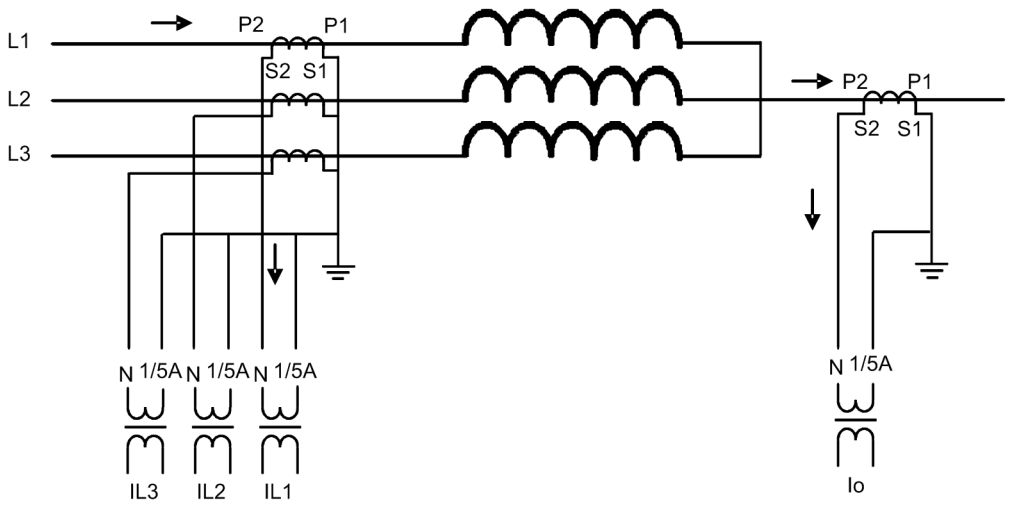

Figure 427: Connection of the current transformers of Type 2. The phase currents and the neutral current have equal directions at an external earth-fault situation.

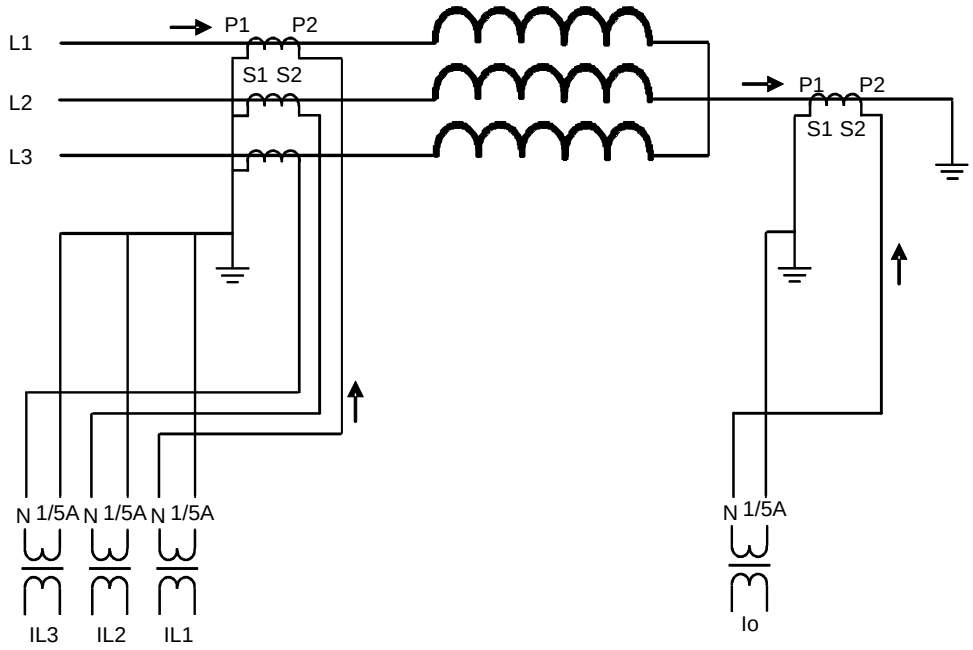

Figure 428: Connection of the current transformers of Type 2. The phase currents and the neutral current have equal directions at an external earth-fault situation.

Internal and external faults

LREFPNDF does not respond to any faults outside the protected zone. An external fault is detected by checking the phase angle difference of the neutral current and the sum of the phase currents. When the difference is less than 90 degrees, the operation is internally restrained or blocked. Hence the protection is not sensitive to an external fault. *Figure 429* and *Figure 430* are valid for CT connection type 1.

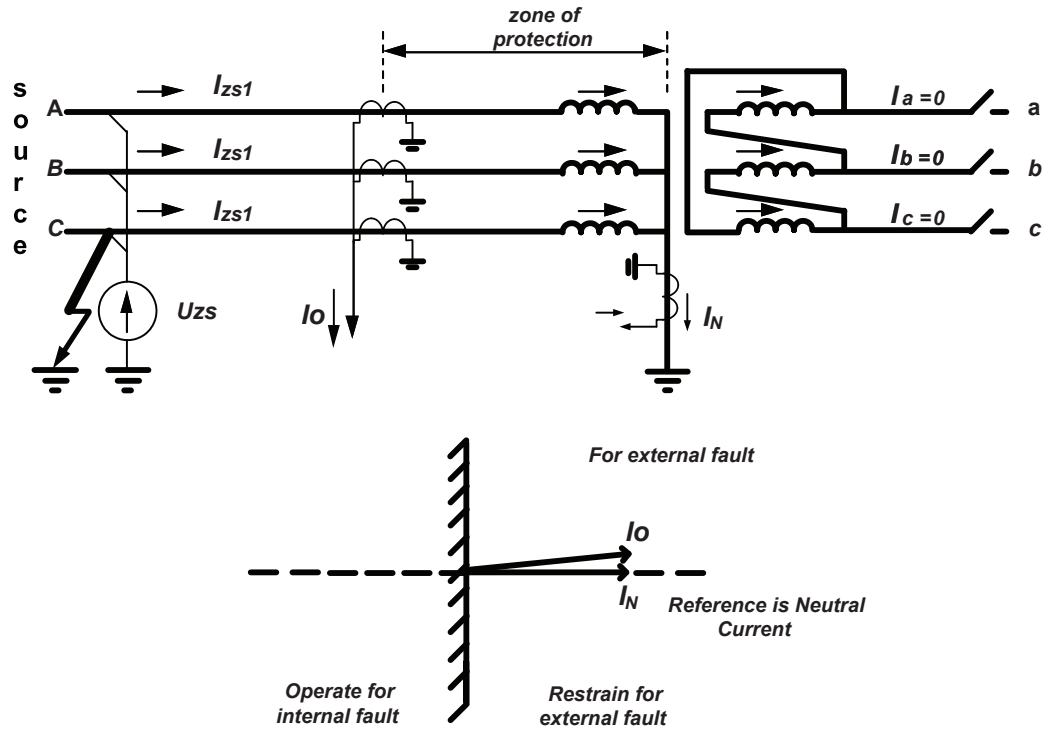

Figure 429: Current flow in all the CTs for an external fault

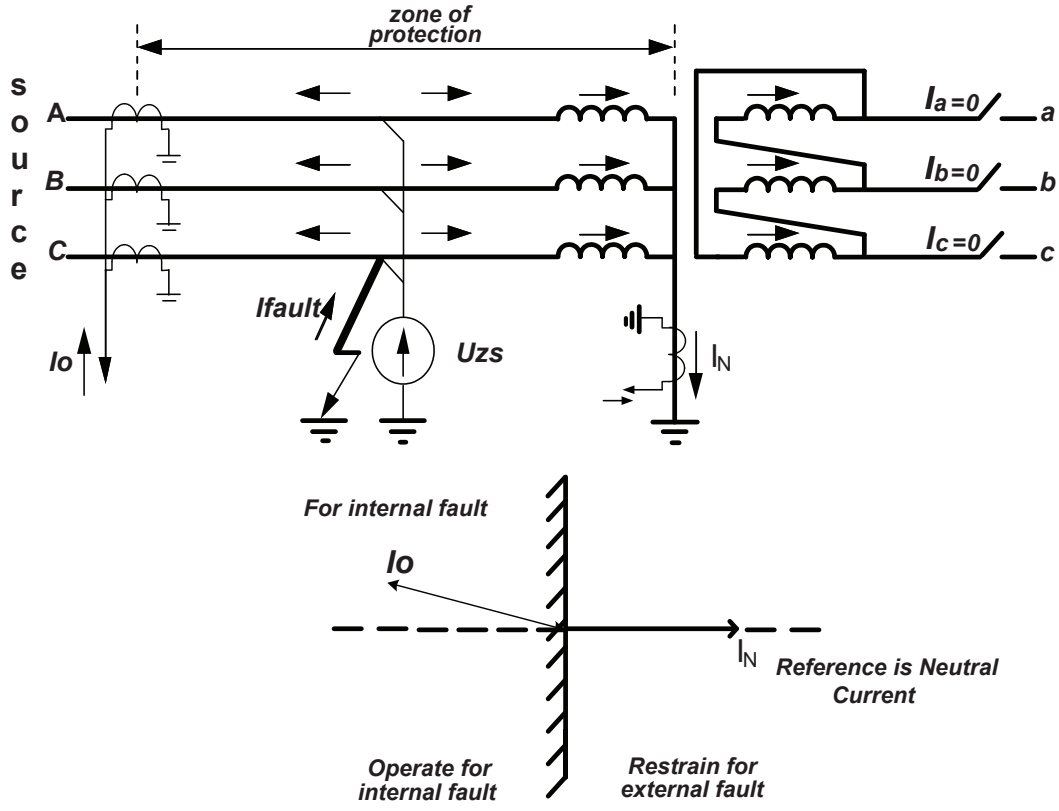

Figure 430: Current flow in all the CTs for an internal fault

LREFPNDF does not respond to phase-to-phase faults either, as in this case the fault current flows between the two line CTs and so the neutral CT does not experience this fault current.

Blocking based on the second harmonic of the neutral current

The transformer magnetizing inrush currents occur when the transformer is energized after a period of de-energization. The inrush current can be many times the rated current, and the halving time can be up to several seconds. For the differential protection relay, the inrush current represents the differential current, which causes the protection relay to operate almost always when the transformer is connected to the network. Typically, the inrush current contains a large amount of second harmonics.

The blocking also prevents unwanted operation at the recovery and sympathetic magnetizing inrushes. At the recovery inrush, the magnetizing current of the transformer to be protected increases momentarily when the voltage returns to normal after the clearance of a fault outside the protected area. The sympathetic inrush is caused by the energization of a transformer running in parallel with the protected transformer already connected to the network.

Blocking the starting of the restricted earth-fault protection at the magnetizing inrush is based on the ratio of the second harmonic and the fundamental frequency amplitudes of the neutral current Io_2H / Io. Typically, the second harmonic content of the neutral current at the magnetizing inrush is higher than that of the phase currents.

High-impedance based restricted earth-fault protection	HREFPDIF	dIoHi>	87NHI

4.3.5.2 Function block

Figure 431: Function block

4.3.5.3 Functionality

The high-impedance based restricted earth-fault protection function HREFPDIF is used for the restricted earth-fault protection of generators and power transformers.

The function starts when the differential neutral current exceeds the set limit. HREFPDIF operates with the DT characteristic.

[1] Current before fault = 0.0, f_n = 50 Hz, results based on statistical distribution of 1000 measurements

[2] Includes the delay of the signal output contact

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.3.5.4 Analog channel configuration

HREFPDIF has one analog group input which must be properly configured.

Table 688: Analog inputs

Input	Description
IRES	Residual current (measured)

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of HREFPDIF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

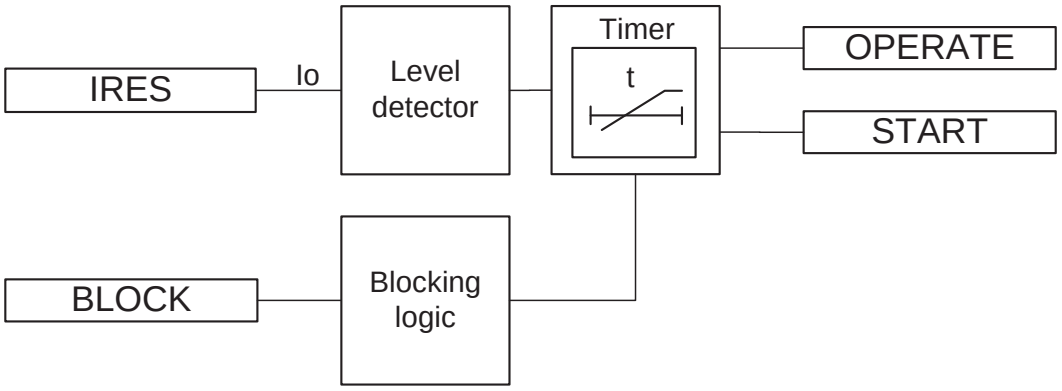

Figure 432: Functional module diagram

Level detector

The level detector compares the differential neutral current IDo to the set value of the *Operate value* setting. If the differential neutral current exceeds the *Operate value* setting, the level detector sends an enable signal to the timer module to start the definite timer.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Minimum operate time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration/System/ Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.3.5.6 Application

In solidly earthed systems, the restricted earth-fault protection is always deployed as a complement to the normal transformer differential protection. The advantage of the restricted earth-fault protection is its high sensitivity. Sensitivities of close to 1.0 percent can be achieved, whereas normal differential protection relays have their minimum sensitivity in the range of 5 to 10 percent. The level for HREFPDIF is dependent on the current transformers' magnetizing currents. The restricted earth-fault protection is also very fast due to the simple measuring principle as it is a unit type of protection.

The differences in measuring principle limit the biased differential protection relay's possibility to detect the earth faults. Such faults are then only detected by the restricted earth-fault function.

The restricted earth-fault protection relay is connected across each directly or to low-ohmic earthed transformer winding. If the same CTs are connected to other protection relays,, separate cores are to be used.

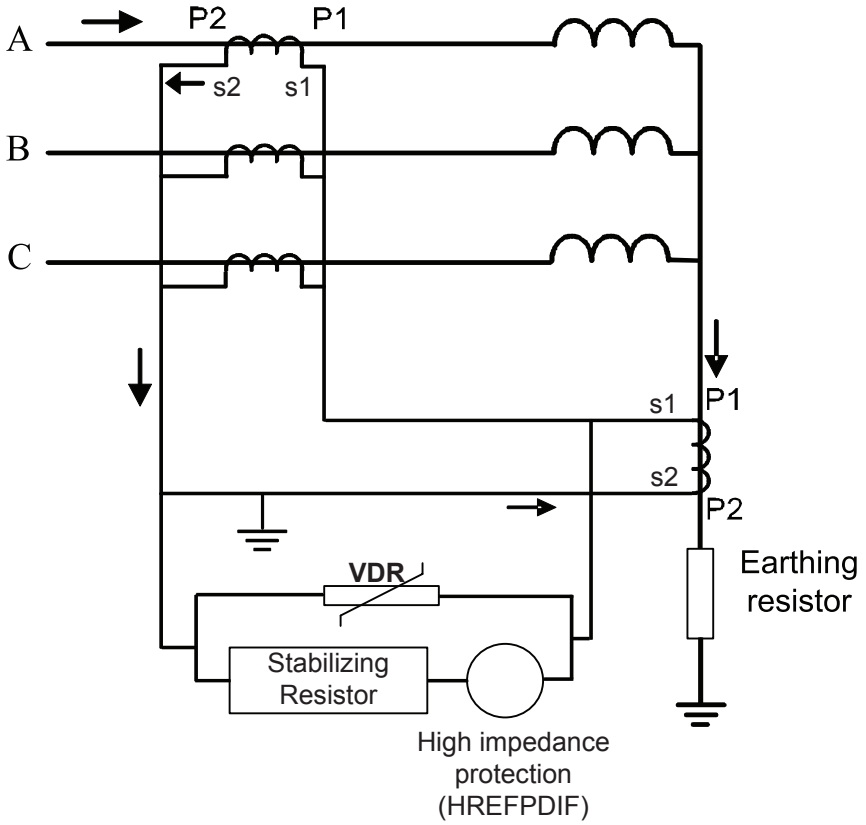

Figure 433: Connection scheme for the restricted earth-fault protection according to the high-impedance principle

High-impedance principle

High-impedance principle is stable for all types of faults outside the zone of protection. The stabilization is obtained by a stabilizing resistor in the differential circuit. This method requires that all the CTs used have a similar magnetizing characteristic, same ratio and relatively high knee point voltage. CTs on each sides are connected in parallel along with a relay-measuring branch as shown in *Figure 434*. The measuring branch is a series connection of stabilizing resistor and protection relay.

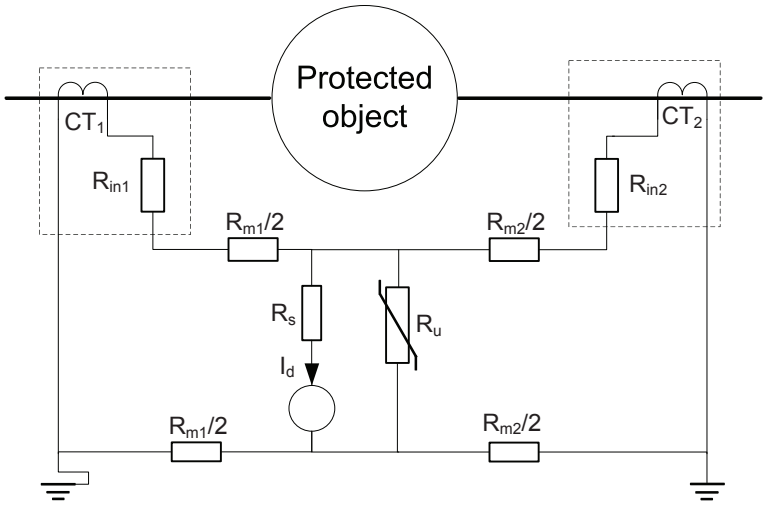

Figure 434: High-impedance principle

The stability of the protection is based on the use of the stabilizing resistor (Rs) and the fact that the impedance of the CT secondary quickly decreases as the CT saturates. The magnetization reactance of a fully saturated CT goes to zero and the impedance is formed only by the resistance of the winding (R_{in}) and lead resistance (R_m).

The CT saturation causes a differential current which now has two paths to flow: through the saturated CT because of the near-zero magnetizing reactance and through the measuring branch. The stabilizing resistor is selected as such that the current in the measuring branch is below the relay operating current during out-of-zone faults. As a result, the operation is stable during the saturation and can still be sensitive at the non-saturated parts of the current waveform as shown in *Figure 435*.

In case of an internal fault, the fault current cannot circulate through the CTs but it flows through the measuring branch and the protection operates. Partial CT saturation can occur in case of an internal fault, but the non-saturated part of the current waveform causes the protection to operate.

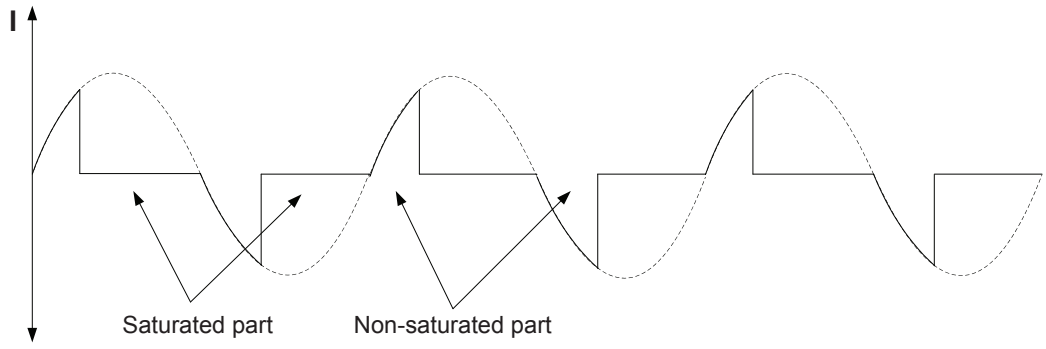

Figure 435: Secondary waveform of a saturated CT

At internal fault, the secondary circuit voltage can easily exceed the isolation voltage of the CTs, connection wires and IED. To limit this voltage, a voltage-dependent resistor VDR is used as shown in *Figure 434*.

The whole scheme, that is, the stabilizing resistor, voltage-dependent resistor and wiring, must be adequately maintained (operation- and insulation-tested regularly) to be able to withstand the high-voltage pulses which appear during an internal fault throughout the lifetime of the equipment. Otherwise, during a fault within the zone of protection, any flashover in the CT secondary circuits or in any other part of the scheme may prevent a correct operation of the high-impedance differential function.

4.3.5.7 The measuring configuration

The external measuring configuration is composed of four current transformers measuring the currents and a stabilizing resistor. A varistor is needed if high overvoltages are expected.

The value of the stabilizing resistor is calculated with the formula:

$$R_s = \frac{U_s}{I_{rs}}$$

(Equation 179)

R_s	the resistance of the stabilizing resistor
U_s	the stabilizing voltage of the IED
I_{rs}	the value of the *Low operate value* setting

The stabilizing voltage is calculated with the formula:

$$U_s = \frac{I_{k\max}}{n}(R_{in} + R_m)$$

(Equation 180)

I_{kmax}	the highest through-fault current
n	the turns ratio of the CT
R_{in}	the secondary internal resistance of the CT
R_m	the resistance of the longest loop of secondary circuit

Additionally, it is required that the current transformers' knee-point voltages U_k are at least twice the stabilizing voltage value U_s.

4.3.5.8 Recommendations for current transformers

The sensitivity and reliability of the protection depends a lot on the characteristics of the current transformers. The CTs must have an identical transformation ratio. It is recommended that all current transformers have an equal burden and characteristics and are of same type, preferably from the same manufacturing batch, that is, an identical construction should be used. If the CT characteristics and burden values are not equal, calculation for each branch in the scheme should be done separately and the worst-case result is then used.

First, the stabilizing voltage, that is, the voltage appearing across the measuring branch during the out-of-zone fault, is calculated assuming that one of the parallel connected CT is fully saturated. The stabilizing voltage can be calculated with the formula

$$U_s = \frac{I_{k\max}}{n}(R_{in} + R_m)$$

(Equation 181)

I_{kmax}	the highest through-fault current in primary amps. The highest earth-fault or short circuit current during the out-of-zone fault.
n	the turns ratio of the CT
R_{in}	the secondary internal resistance of the CT in ohms
R_m	the resistance (maximum of R_{in} + R_m) of the CT secondary circuit in ohms

The current transformers must be able to force enough current to operate the protection relay through the differential circuit during a fault condition inside the zone of protection. To ensure this, the knee point voltage U_{kn} should be at least two times higher than the stabilizing voltage U_s.

The required knee point voltage U_{kn} of the current transformer is calculated using the formula

$$U_{kn} \geq 2 \times U_s$$

(Equation 182)

U_{kn}	the knee point voltage
U_s	the stabilizing voltage

The factor two is used when no delay in the operating time of the protection in any situation is acceptable. To prevent the knee point voltage from growing too high, it is advisable to use current transformers, the secondary winding resistance of which is of the same size as the resistance of the measuring loop.

As the impedance of the protection relay alone is low, a stabilizing resistor is needed. The value of the stabilizing resistor is calculated with the formula

$$R_s = \frac{U_s}{I_{rs}}$$

(Equation 183)

R_s	the resistance of the stabilizing resistor
U_s	the stabilizing voltage of the protection relay
I_{rs}	the value of the *Operate value* setting in secondary amps.

The stabilizing resistor should be capable to dissipate high energy within a very short time; therefore, the wire wound-type resistor should be used. Because of the possible CT inaccuracy, which might cause some current through the stabilizing resistor in a normal load situation, the rated power should be 25 W minimum.

If U_{kn} is high or the stabilizing voltage is low, a resistor with a higher power rating is needed. Often resistor manufacturers allow 10 times rated power for 5 seconds. Thus the power of the resistor can be calculated with the equation

$$\frac{U_{kn}^2}{R_s \times 10}$$

(Equation 184)

The actual sensitivity of the protection is affected by the protection relay setting, the magnetizing currents of the parallel connected CTs and the shunting effect of the voltage-dependent resistor (VDR). The value of the primary current I_{prim} at which the protection relay operates at a certain setting can be calculated with the formula

$$I_{prim} = n \times (I_{rs} + I_u + m \times I_m)$$

(Equation 185)

I_{prim}	the primary current at which the protection is to start
n	the turn ratio of the current transformer
I_{rs}	the value of the *Operate value* setting
I_u	the leakage current flowing through the VDR at the U_s voltage
m	the number of current transformers included in the protection per phase (=4)
I_m	the magnetizing current per current transformer at the U_s voltage

The I_e value given in many catalogs is the excitation current at the knee point voltage. Assuming $U_{kn} \approx 2 \times U_s$, the value of $I_m \approx \frac{I_e}{2}$ gives an approximate value for *Equation 185*.

The selection of current transformers can be divided into procedures:

1. In principle, the highest through-fault should be known. However, when the necessary data are not available, approximates can be used:
   - Small power transformers: $I_{kmax} = 16 \times I_n$ (corresponds to $z_k = 6\%$ and infinite grid)
   - Large power transformers: $I_{kmax} = 12 \times I_n$ (corresponds to $z_k = 8\%$ and infinite grid)
   - Generators and motors: $I_{kmax} = 6 \times I_n$

   Where I_n = rated current and z_k = short circuit impedance of the protected object
2. The rated primary current I_{1n} of the CT has to be higher than the rated current of the machine.

   The choice of the CT also specifies R_{in}.
3. The required U_{kn} is calculated with *Equation 182*. If the U_{kn} of the CT is not high enough, another CT has to be chosen. The value of the U_{kn} is given by the manufacturer in the case of Class X current transformers or it can be estimated with *Equation 186*.
4. The sensitivity I_{prim} is calculated with *Equation 185*. If the achieved sensitivity is sufficient, the present CT is chosen. If a better sensitivity is needed, a CT with a bigger core is chosen.

If other than Class X CTs are used, an estimate for U_{kn} is calculated with the equation

$$U_{kn} = 0.8 \times F_n \times I_{2n} \times \left(R_{in} + \frac{S_n}{I_{2n}^2} \right)$$

(Equation 186)

F_n	the rated accuracy limit factor corresponding to the rated burden S_n
I_{2n}	the rated secondary current of the CT
R_{in}	the secondary internal resistance of the CT
S_n	the volt-amp rating of the CT

The formulas are based on choosing the CTs according to *Equation 182*, which results an absolutely stable scheme. In some cases, it is possible to achieve stability with knee point voltages lower than stated in the formulas. The conditions in the network, however, have to be known well enough to ensure the stability.

1. If $U_k \geq 2 \times U_s$, fast protection relay operation is secure.
2. If $U_k \geq 1.5 \times U_s$ and $< 2 \times U_s$, protection relay operation can be slightly prolonged and should be studied case by case.

   If $U_k < 1.5 \times U_s$, the protection relay operation is jeopardized. Another CT has to be chosen.

The need for the VDR depends on certain conditions.

First, voltage U_{max}, ignoring the CT saturation during the fault, is calculated with the equation

$$U_{max} = \frac{I_{k\,max\,in}}{n} \times \left(R_{in} + R_m + R_s \right) \approx \frac{I_{k\,max\,in}}{n} \times R_s$$

(Equation 187)

I_{kmaxin}	the maximum fault current inside the zone, in primary amps
n	the turns ration of the CT
R_{in}	the internal resistance of the CT in ohms
R_m	the resistance of the longest loop of the CT secondary circuit, in ohms
R_s	the resistance of the stabilized resistor, in ohms

Next, the peak voltage û, which includes the CT saturation, is estimated with the formula (given by P.Mathews, 1955)

$$\hat{u} = 2\sqrt{2U_{kn}\left(U_{max} - U_{kn}\right)}$$

(Equation 188)

U_{kn}	the knee point voltage of the CT

The VDR is recommended when the peak voltage û ≥ 2kV, which is the insulation level for which the protection relay is tested.

If R_s was smaller, the VDR could be avoided. However, the value of R_s depends on the protection relay operation current and stabilizing voltage. Thus, either a higher setting must be used in the protection relay or the stabilizing voltage must be lowered.

4.3.5.9 Setting examples

Example 1

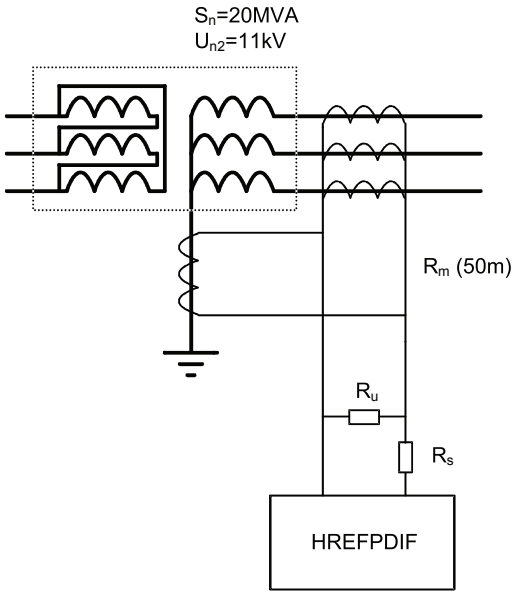

Figure 436: Restricted earth-fault protection of a transformer

The data for the protected power transformer are:

S_n = 20 MVA

U_{2n} = 11 kV

The longest distance of the secondary circuit is 50 m (the whole loop is 100 m) and the area of the cross section is 10 mm ^{2}.

$I_n = S_n / (\sqrt{3} \cdot U_n)$ = 1050 A

$I_{kmax} = 12 \cdot I_n$= 12600 A

In this example, the CT type is IHBF 12, the core size is 35 percent, the primary current is 1200 A and the secondary current is 5 A.

R_{in} = 0.26 Ω (value given by the manufacturer).

U_k = 40 V (value given by the manufacturer).

I_e = 0.055 A (value given by the manufacturer).

R_m = 1.81 Ω/km · 2 · 0.05 km = 0.181 Ω ≈ 0.18 Ω

$$U_s = \frac{12600 \times (0.26 + 0.18)}{240} V \approx 23V$$

According to the criterion, the value of U_k should be $2 \cdot U_s = 2 \cdot 23$ V = 46 V. It depends on if the stability of the scheme is achieved with U_k = 40 V. Otherwise, it is possible to choose a bigger core of 65 percent with:

R_{in} = 0.47 Ω (value given by the manufacturer).

U_k = 81 V (value given by the manufacturer).

R_m = 0.18 Ω

$$U_s = \frac{12600 \times (0.47 + 0.18)}{240} V \approx 34 V$$

$U_k = 2 \cdot U_s = 68$ V (required value).

As mentioned earlier, $I_m = 0.5 \cdot I_e$ gives a realistic value for I_{prim} in *Equation 185*. If $I_u = 0$ and $I_{rs} = m \cdot 0.5 \cdot I_o$, the value for the sensitivity is:

$I_{prim} = n \cdot m \cdot I_e = 240 \cdot 4 \cdot 0.055$ A ≈ 53 A

$I_{rs} = 4 \cdot 0.5 \cdot 0.055$ A = 0.11 A

The setting value can be calculated with:

$$Operate\ value = \left(\frac{I_{rs}}{I_{CT_n2}} \right) = \left(\frac{0.11 A}{5 A} \right) \approx 2.2\%$$

The resistance of the stabilizing resistor can be calculated:

$R_s = U_s / I_{rs} = 34$ V / 0.11 A ≈ 309 Ω

However, the sensitivity can be calculated more accurately when the actual values of I_u and I_{rs} are known. The stabilizing resistor of the relay is chosen freely in the above example and it is assumed that the resistor value is not fixed.

Example 2a

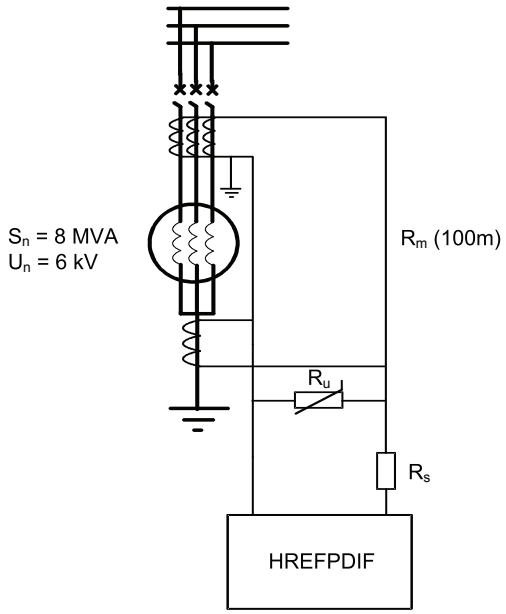

Figure 437: Restricted earth-fault protection of a generator

In the protected generator:

$S_n = 8$ MVA

$U_n = 6$ kV.

I_n = 770 A

$I_{kmax} = 6 \cdot I_n = 6 \cdot 770\ A = 4620\ A$

In this example, the CT type is KOFD 12 A 21 with:

I_{CT_1n} = 1000 A (value given by the manufacturer).

I_{CT_2n} = 1 A (value given by the manufacturer).

U_k = 323 V (value given by the manufacturer).

R_{in} = 15.3 Ω (value given by the manufacturer).

I_e = 0.012 A (value given by the manufacturer).

If the length of the secondary circuit is 100 m (the whole loop is 200 m) and the area of the cross section is 2.5 mm^2:

$R_m = 7.28\ \Omega/km \cdot 2 \cdot 0.1\ km \approx 1.46\ \Omega$

The required knee-point voltage can be calculated using equation

$U_k = 2 \cdot (4620\ A / 1000) \cdot (15.3 + 1.46) \approx 155\ V$.

The value 155 V is lower than the value 323 V, which means that the value of U_k is high enough.

As mentioned earlier, $I_m = 0.5 \cdot I_e$ gives a realistic value for I_{prim} in *Equation 185*. If $I_u = 0$ and $I_{rs} = m \cdot 0.5 \cdot I_e$, the value for the sensitivity is:

$I_{prim} = n \cdot m \cdot I_e = 1000 \cdot 4 \cdot 0.012\ A = 48\ A$ (≈ 6 % x I_n).

$I_{rs} = 4 \cdot 0.5 \cdot 0.012\ A = 0.024\ A$.

The setting value can be calculated with:

$$Operate\ value = \left(\frac{I_{rs}}{I_{CT_2n}} \right) = \left(\frac{0.024\ A}{1A} \right) \approx 2.4\%$$

The resistance of the stabilizing resistor can now be calculated:

$R_s = U_s / I_{rs} = 78\ V / (2 \cdot I_e) = 78\ V / (2 \cdot 0.012\ A) = 3250\ \Omega$.

Example 2b

In this example, I_{rs} = 4 x 12 mA = 48 mA and I_u = 30 mA. This results in the sensitivity:

$I_{prim} = n \cdot (I_{rs} + I_u + m \cdot I_m) = 1000 \cdot (48 + 30 + 24)\ mA = 102\ A$

The setting value can be calculated with:

$$Operate\ value = \left(\frac{I_{rs}}{I_{CT_2n}} \right) = \left(\frac{0.048\ A}{1A} \right) \approx 4.8\%$$

The resistance of the stabilizing resistor is now:

$R_s = U_s / I_{rs} = 78\ V / 48\ mA \approx 1630\ \Omega$

In this example, the relay is of such a type that the stabilizing resistor can be chosen freely.

4.3.5.10 Signals

HREFPDIF Input signals

Table 689: HREFPDIF Input signals

Name	Type	Default	Description
IRES	SIGNAL	-	Residual current
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode

4.3.6.2 Function block

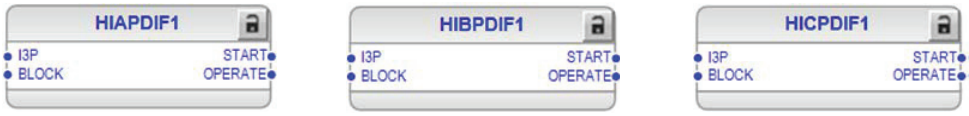

Figure 438: Function block

4.3.6.3 Functionality

The high-impedance differential protection function HIxPDIF is a general differential protection. It provides a phase-segregated short circuit protection for the busbar. However, the function can also be used for providing generator, motor, transformer and reactor protection.

The function starts and operates when the differential current exceeds the set limit. The operate time characteristics are according to definite time (DT).

The function contains a blocking functionality. It is possible to block the function outputs, timer or the whole function.

4.3.6.4 Analog channel configuration

HIxPDIF has one analog group input which must be properly configured.

Table 696: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.6.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of HIxPDIF can be described with a module diagram. All the modules in the diagram are explained in the next sections.

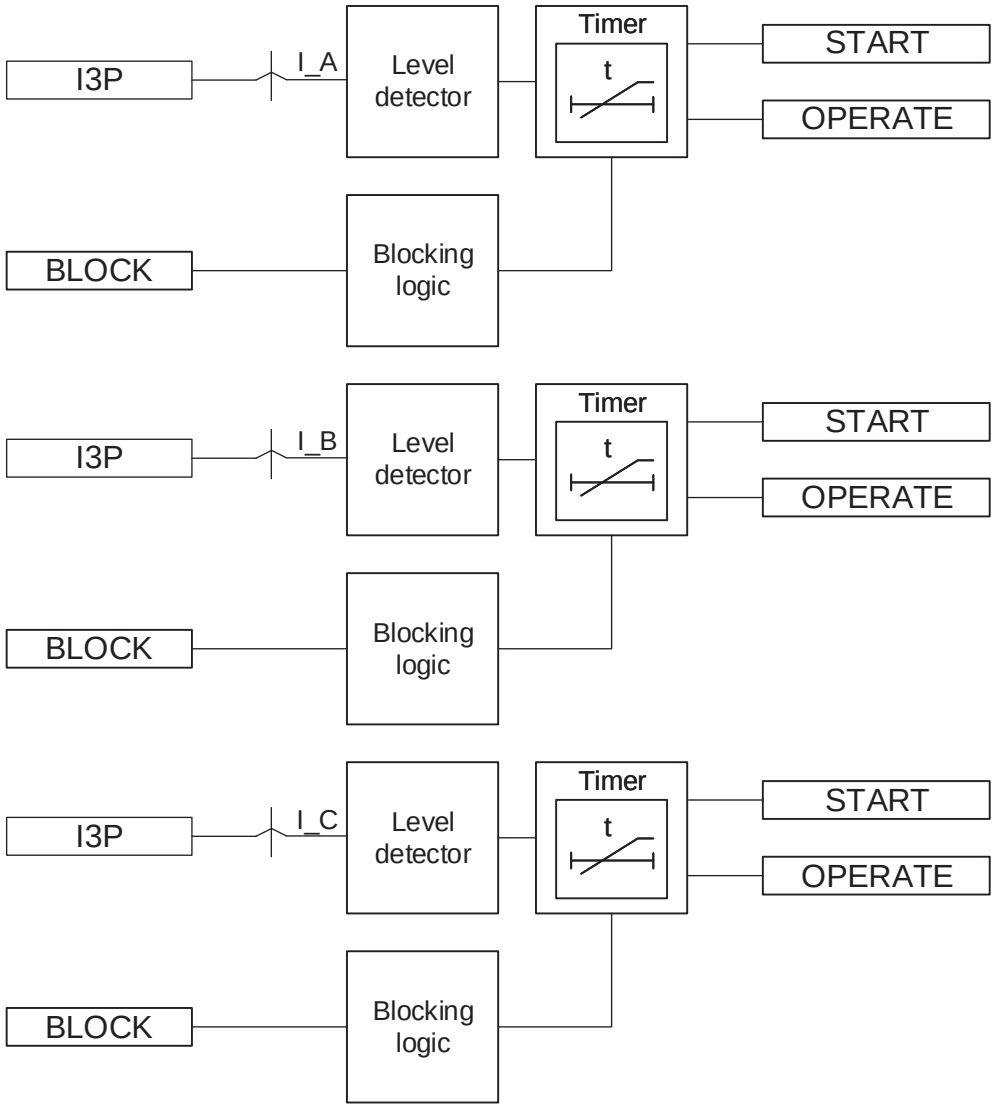

Figure 439: Functional module diagram

The module diagram illustrates all the phases of the function. Functionality for phases A, B and C is identical.

All three phases have independent settings.

Level detector

The module compares differential currents I_A calculated by the peak-to-peak measurement mode to the set *Operate value*. The Timer module is activated if the differential current exceeds the value of the *Operate value* setting.

Timer

Once activated, Timer activates the START output. The time characteristic is according to DT. When the operation timer reaches the value set by *Minimum operate time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

Timer calculates the start duration START_DUR value, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the Monitored data view.

The activation of the BLOCK input resets Timer and deactivates the START and OPERATE outputs.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.3.6.6 Application

HIxPDIF provides a secure and dependable protection scheme against all types of faults. The high-impedance principle is used for differential protection due to its capability to manage the through-faults also with the heavy current transformer (CT) saturation.

For current transformer recommendations, see the Requirements for measurement transformers section in this manual.

High-impedance principle

The phase currents are measured from both the incoming and the outgoing feeder sides of the busbar. The secondary of the current transformer in each phase is connected in parallel with a protection relay measuring branch. Hence, the relay measures only the difference of the currents. In an ideal situation, there is a differential current to operate the relay only if there is a fault between the CTs, that is, inside the protected zone.

If there is a fault outside the zone, a high current, known as the through-fault current, can go through the protected object. This can cause partial saturation in the CTs. The relay operation is avoided with a stabilizing resistor (R_s) in the protection relay measuring branch. R_s increases the impedance of the protection relay; hence the name high-impedance differential scheme.

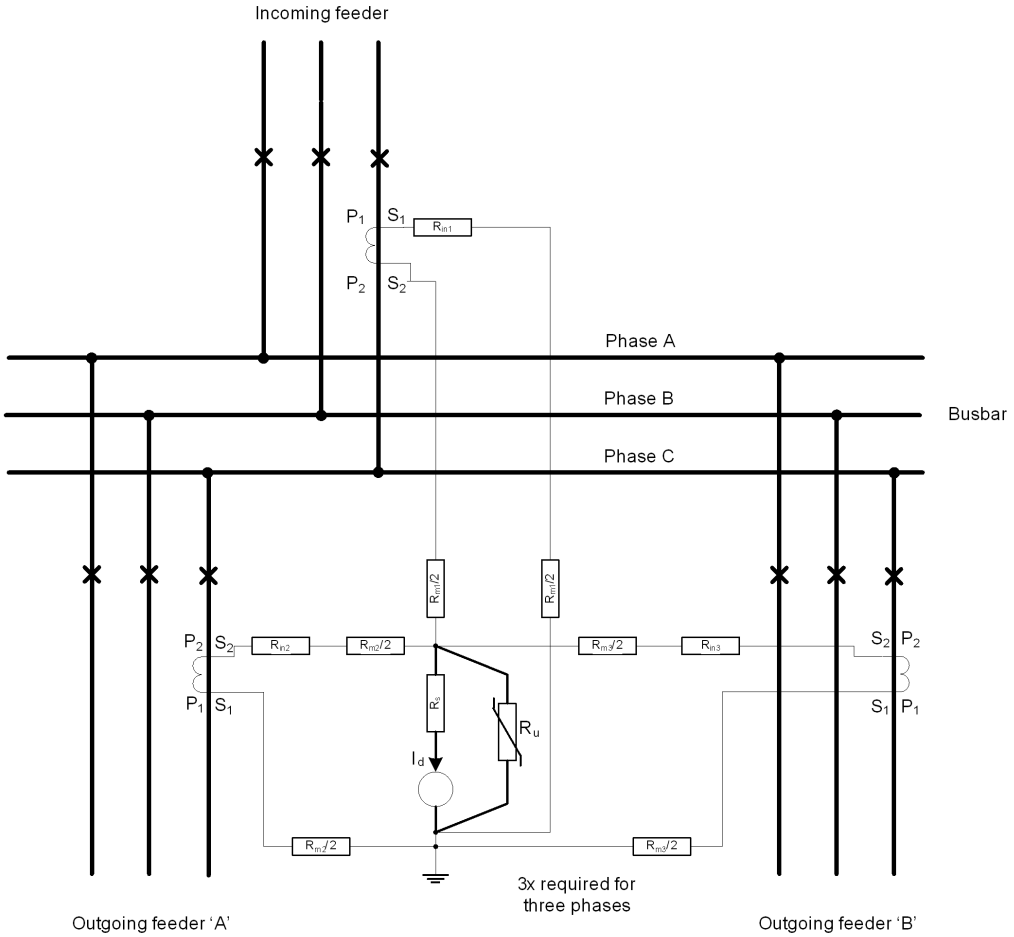

Figure 440: Phase-segregated bus differential protection based on high-impedance principle

CT secondary winding resistances (R_{in}) and connection wire resistances ($R_m/2$) are also shown in *Figure 441*.

Figure 441 demonstrates a simplified circuit consisting only of one incoming and outgoing feeder. To keep it simple, the voltage-dependent resistor (R_u) is not included. The wiring resistances are presented as total wiring resistances R_{m1} and R_{m2}.

R_{m1} is the maximum wiring resistance concerning all incoming feeder sets, whereas R_{m2} is the maximum wiring resistance concerning all outgoing feeder sets.

The lower part of *Figure 441* shows the voltage balance when there is no fault in the system and no CT saturation.

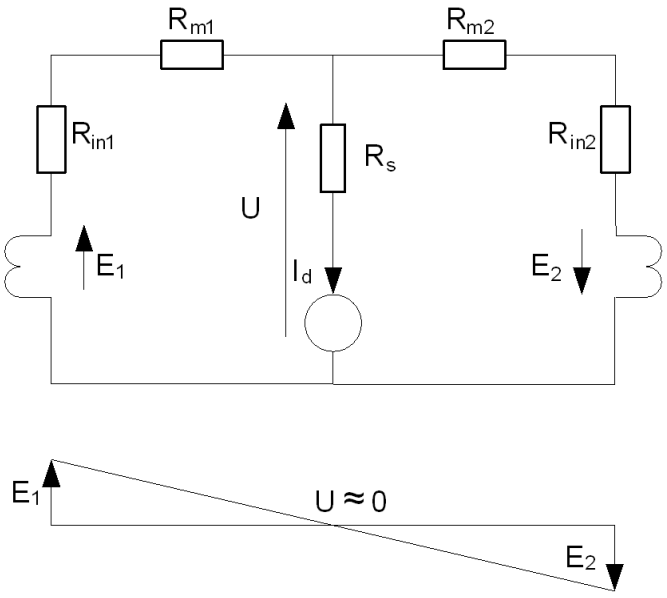

Figure 441: Equivalent circuit when there is no fault or CT saturation

When there is no fault, the CT secondary currents and their emf voltages, E_1 and E_2, are opposite and the protection relay measuring branch has no voltage or current. If an in-zone fault occurs, the secondary currents have the same direction. The relay measures the sum of the currents as a differential and trips the circuit breaker. If the fault current goes through only one CT, its secondary emf magnetizes the opposite CT, that is, $E_1 \approx E_2$.

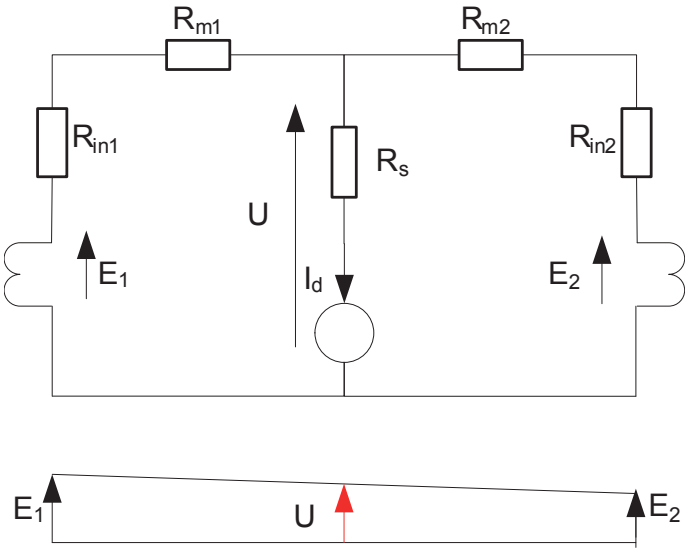

Figure 442: Equivalent circuit in case of in-zone fault

Figure 443 shows CT saturation at a through-fault, that is, out-of-zone, situation. The magnetization impedance of a saturated CT is almost zero. The saturated CT winding can be presented as a short circuit. When one CT is saturated, the current of the non-saturated CT follows two paths, one through the protection relay measuring branch (R_s + relay) and the other through the saturated CT ($R_m + R_{in2}$).

The protection relay must not operate during the saturation. This is achieved by increasing the relay impedance by using the stabilizing resistor (R_s) which forces the majority of the differential current to flow through the saturated CT. As a result, the relay operation is avoided, that is, the relay operation is stabilized against the CT saturation at through-fault current. The stabilizing voltage U_s is the basis of all calculations.

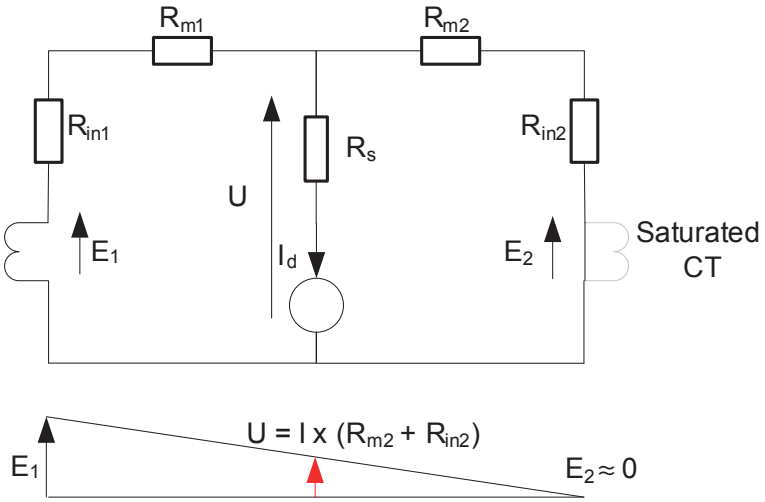

Figure 443: Equivalent circuit in case of the CT saturation at through-fault

The CT saturation happens most likely in the case of an in-zone fault. This is not a problem, because although the operation remains stable (non-operative) during the saturated parts of the CT secondary current waveform, the non-saturated part of the current waveform causes the protection to operate.

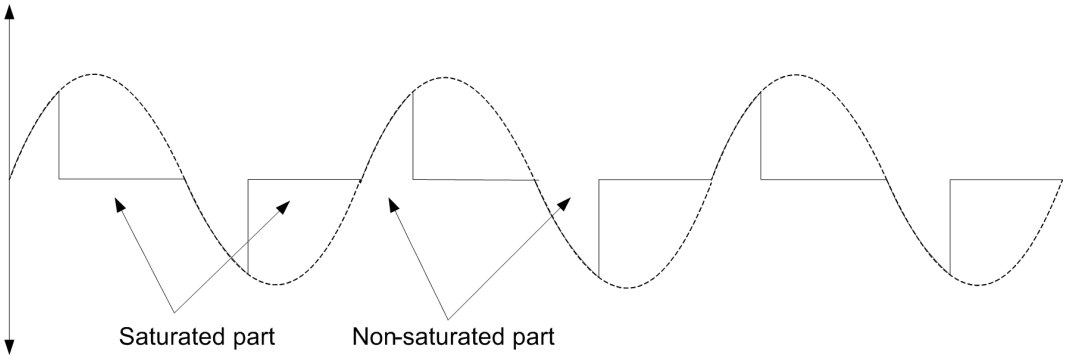

Figure 444: Secondary waveform of a saturated CT

The secondary circuit voltage can easily exceed the isolation voltage of the CTs, connection wires and the protection relay because of the stabilizing resistance and CT saturation. A voltage dependent resistor (VDR, R_u) is used to limit the voltage as shown in *Figure 440*.

Busbar protection scheme

The basic concept for any bus differential protection relay is a direct use of Kirchoff's first law that the sum of all currents connected to one differential protection zone is zero. If the sum is not zero, an internal fault has occurred. In other words, as seen by the busbar differential protection, the sum of all currents that

flow into the protection zone, that is, currents with positive value, must be equal to currents that flow out of the protection zone, that is, currents with negative value, at any instant of time.

Figure 445 shows an example of a phase segregated single busbar protection employing high-impedance differential protection. The example system consists of a single incoming busbar feeder and two outgoing busbar feeders. The CTs from both the outgoing busbar feeders and the incoming busbar feeders are connected in parallel with the polarity. During normal load conditions, the total instantaneous incoming current is equal to the total instantaneous outgoing current and the difference current is negligible. A fault in the busbar results in an imbalance between the incoming and the outgoing current. The difference current flows through the protection relay, which generates a trip signal.

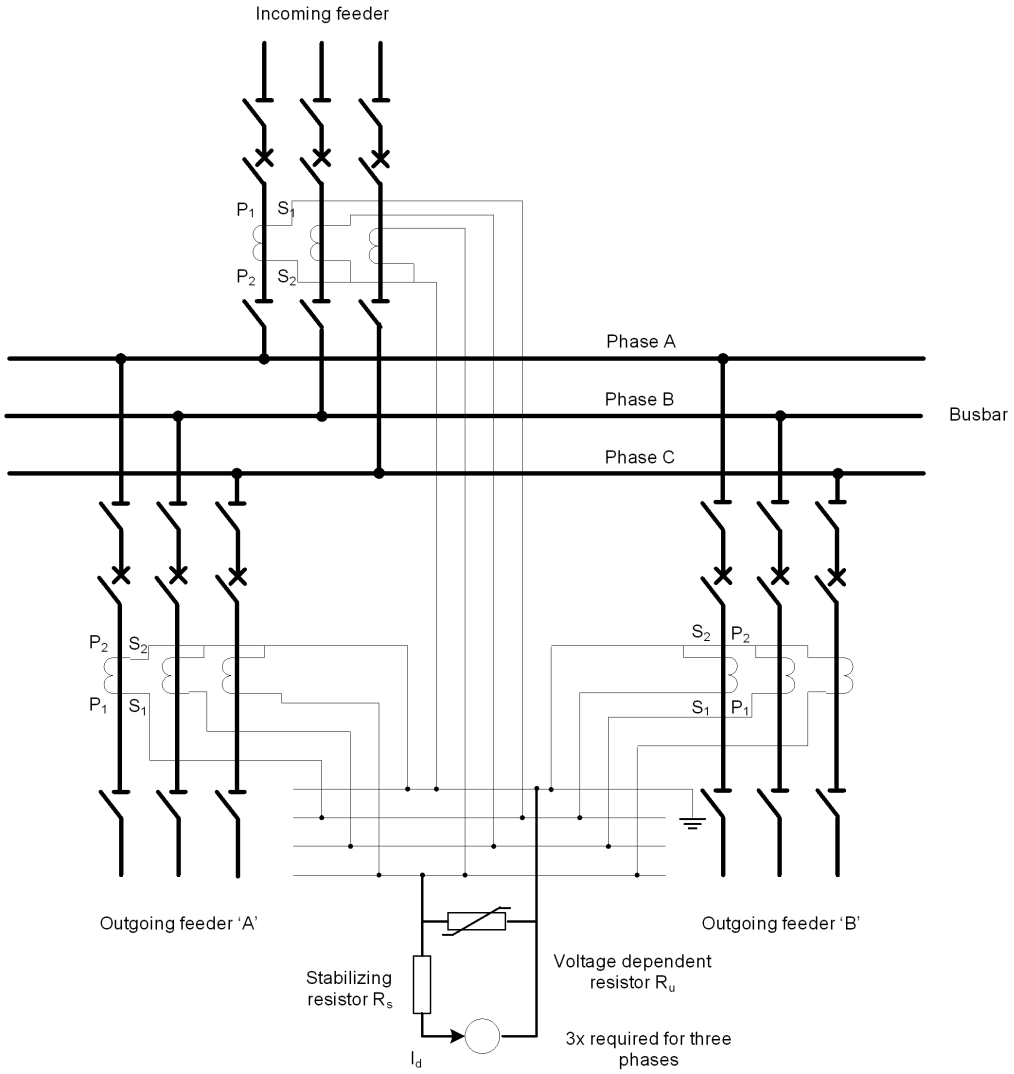

Figure 445: Phase-segregated single busbar protection employing high-impedance differential protection

Figure 446 shows an example for a system consisting of two busbar section coupled with a bus coupler. Each busbar section consists of two feeders and both sections are provided with a separate differential protection to form different zones. The formed zones overlap at the bus coupler.

When the bus coupler is in the open position, each section of the busbar handles the current flow independently, that is, the instantaneous incoming current is equal to the total instantaneous outgoing current and the difference current is negligible. The difference current is no longer zero with a fault in the busbar and the protection operates.

With the bus coupler in the closed position, the current also flows from one busbar section to another busbar section. Thus, the current flowing through the bus coupler needs to be considered in calculating differential current. During normal condition, the summation of the current on each bus section is zero. However, if there is a fault in any busbar section, the difference current is no longer zero and the protection operates.

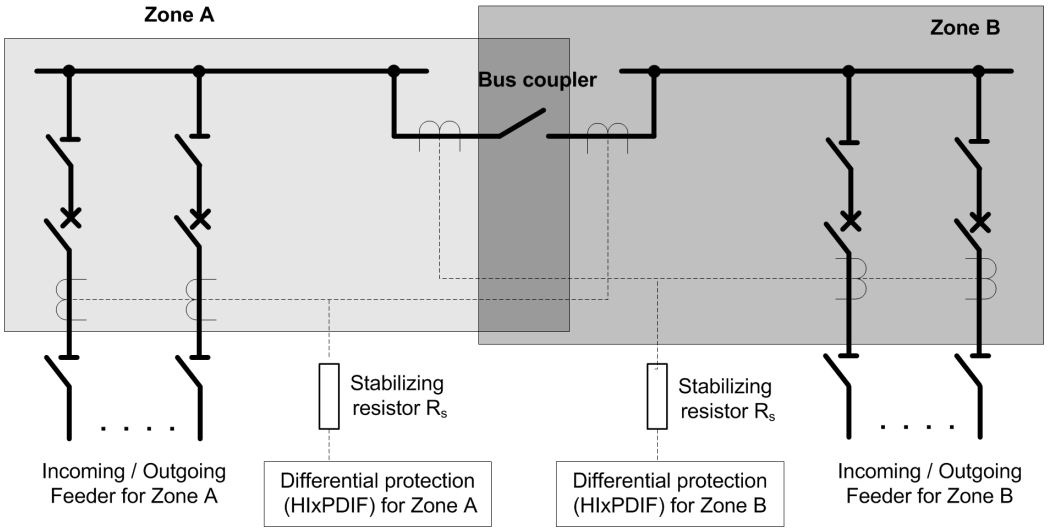

Figure 446: Differential protection on busbar with bus coupler (Single-phase representation)

4.3.6.7 Example calculations for busbar high-impedance differential protection

The protected object in the example for busbar differential protection is a single-bus system with two zones of protection.

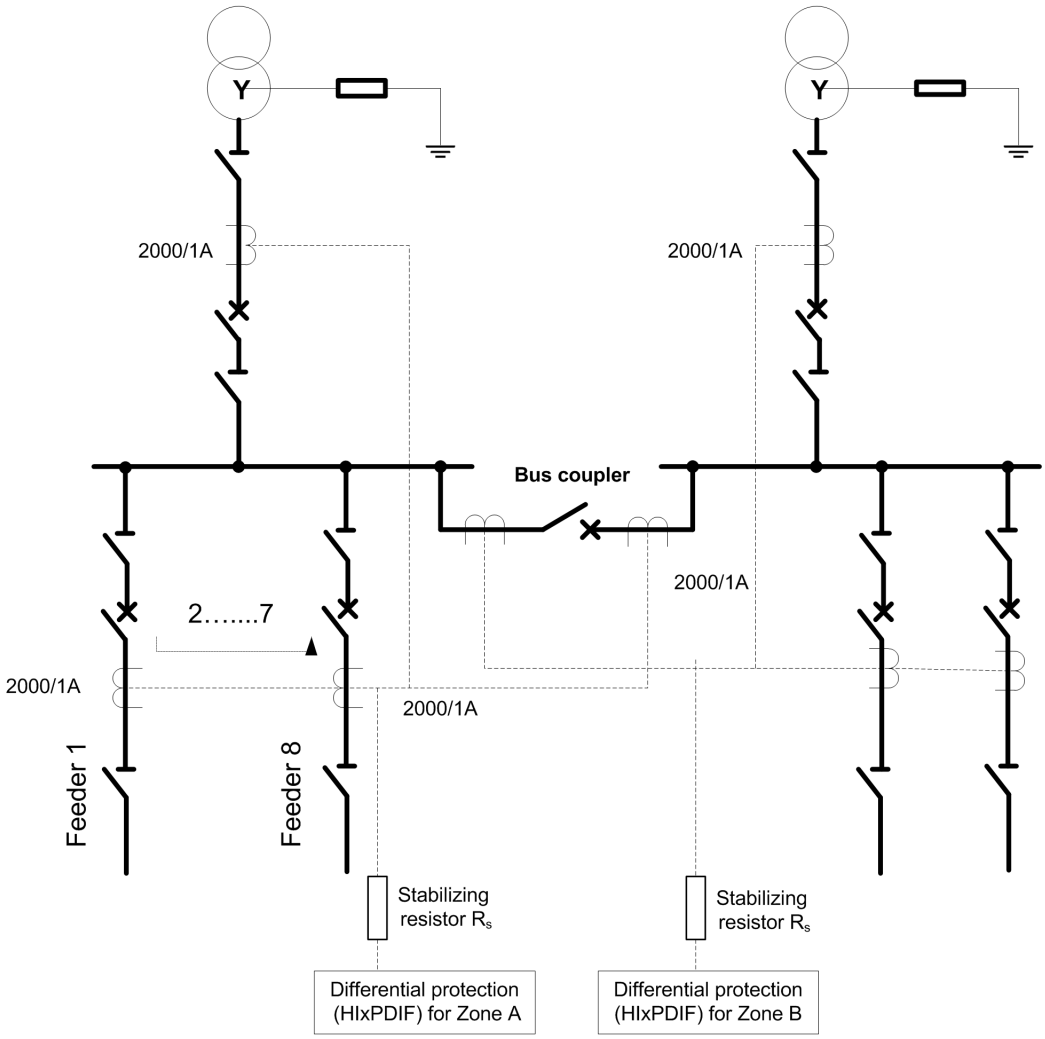

Figure 447: Example for busbar differential protection

Bus data:

U_n	20 kV
I_n	2000 A
I_{kmax}	25 kA

10 feeders per protected zone including bus coupler and incomer.

CT data is assumed to be:

CT	2000/1 A
R_{in}	15.75 Ω
U_{kn}	436 V
I_e	<7 mA (at U_{kn})
R_m	1Ω

The stabilizing voltage is calculated using the formula:

$$U_s = \frac{25000A}{2000}(15.75\Omega + 1.\Omega) \approx 209.37\ V$$

(Equation 189)

In this case, the requirement for the current transformer knee point voltage is fulfilled because $U_{kn} > 2U_s$.

The magnetizing curve of the CT is assumed to be linear. The magnetizing current at the stabilizing voltage can be estimated as:

$$I_m = \frac{U_s}{U_{kn}} \cdot I_e$$

(Equation 190)

$$I_m = \frac{209.37V}{436V} \cdot 7mA \approx 3.4mA$$

(Equation 191)

To obtain adequate protection stability, the setting current I_{rs} must be at the minimum of the sum of magnetizing currents of all connected CTs.

$$I_{rs} = 10 \cdot 3.4mA \approx 34\,mA$$

(Equation 192)

The resistance of the stabilizing resistor is calculated based on *Equation 193*.

$$R_S = \frac{209.37\ V}{0.034A} \approx 6160\,\Omega$$

(Equation 193)

The calculated value is the maximum value for the stabilizing resistor. If the value is not available, the next available value below should be selected and the protection relay setting current is tuned according to the selected resistor. For example, in this case, the resistance value 5900 Ω is used.

$$I_{rs} = \frac{209.37V}{5900\,\Omega} \approx 35\,mA$$

(Equation 194)

The sensitivity of the protection is obtained as per *Equation 195*, assuming $I_u = 0$.

$$I_{prim} = 2000 \cdot (0.035\,A + 10 \cdot 0.0034\,A + 0\,A) \approx 140A$$

(Equation 195)

The power of the stabilizing resistor is calculated:

$$P \geq \frac{(436V)^2}{5900\Omega} \approx 32W$$

(Equation 196)

Based on *Equation 197* and *Equation 198*, the need for voltage-dependent resistor is checked.

$$U_{max} = \frac{25000A}{2000}(5900\Omega + 15.75\Omega + 1.00\Omega) \approx 74.0kV$$

(Equation 197)

$$\breve{u} = 2 \cdot \sqrt{2 \cdot 436V \cdot (74000V - 436V)} \approx 16.0kV$$

(Equation 198)

The voltage-dependent resistor (one for each phase) is needed in this case as the voltage during the fault is higher than 2 kV.

The leakage current through the VDR at the stabilizing voltage can be available from the VDR manual, assuming that to be approximately 2 mA at stabilizing voltage $Iu \approx 0.002\,A$

(Equation 199)

The sensitivity of the protection can be recalculated taking into account the leakage current through the VDR as per *Equation 200*.

$$I_{prim} = 2000 \cdot (0.035\,A + 10 \cdot 0.0034\,A + 0.002\,A) \approx 142A$$

(Equation 200)

Stabilized and instantaneous differential protection for machines	MPDIF	3dI>G/M	87M/87G

4.3.7.2 Function block

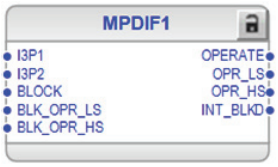

Figure 448: Function block

4.3.7.3 Functionality

The stabilized and instantaneous differential protection for machines function MPDIF is a unit protection function. The possibility of internal failures of the machine is relatively low. However, the consequences in terms of cost and production loss are often serious, which makes the differential protection an important protection function.

The stability of the differential protection is enhanced by a DC restraint feature. This feature decreases the sensitivity of the differential protection optionally for a temporary time period to avoid an unnecessary disconnection of the machine during the external faults that have a fault current with high DC currents. MPDIF also includes a CT saturation-based blocking which prevents unnecessary tripping in case of the detection of the magnetizing inrush currents which can be present at the switching operations, overvoltages or external faults.

4.3.7.4 Analog channel configuration

MPDIF has two analog group inputs which must be properly configured.

Table 716: Analog inputs

Input	Description
I3P1	Three-phase currents
I3P2	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.7.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of MPDIF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

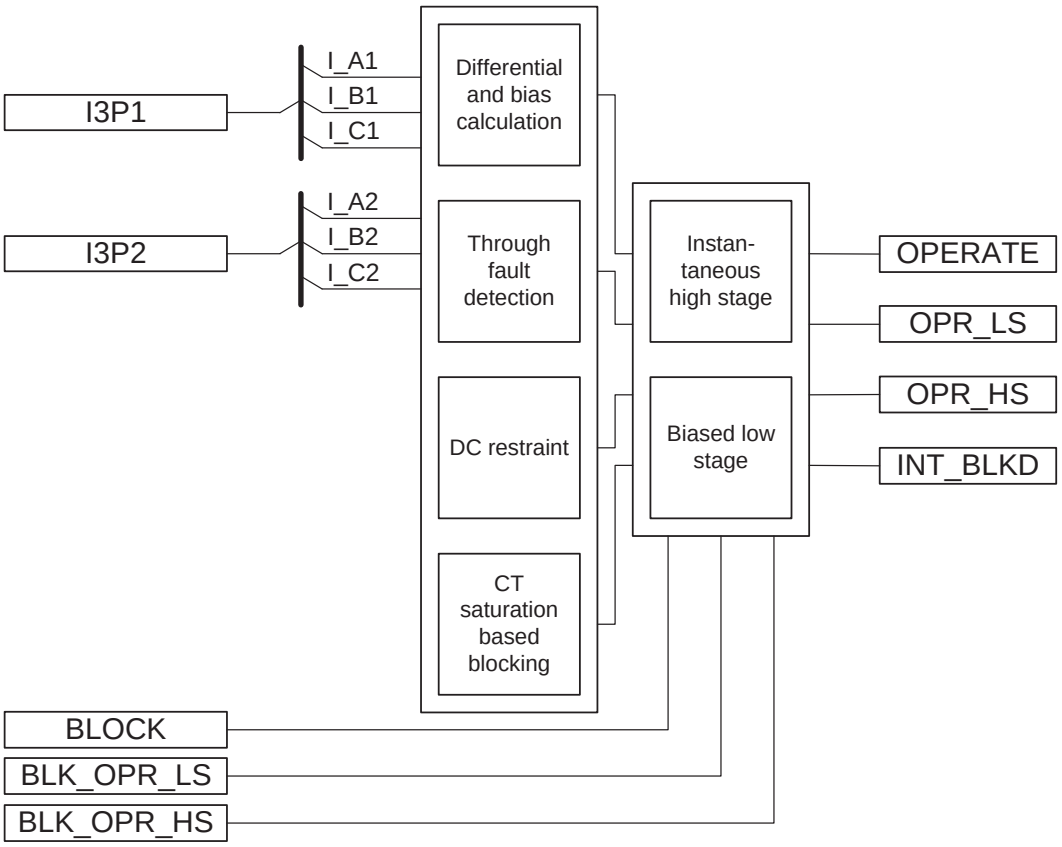

Figure 449: Functional module diagram

Differential and bias calculation

Differential calculation module calculates the differential current. The differential current is the difference in current between the phase and neutral sides of the machine.

The phase currents $\bar{I}_1$ and $\bar{I}_2$ denote the fundamental frequency components on the phase and neutral sides of the current. The amplitude of the differential current I_d is obtained using the equation (assuming that the positive direction of the current is towards the machine):

$$I_d = \left| \bar{I}_1 + \bar{I}_2 \right|$$

(Equation 201)

During normal conditions, there is no fault in the area protected by the function block, so the currents $\bar{I}_1$ and $\bar{I}_2$ are equal and the differential current $I_d = 0$. However, in practice some differential current exists due to inaccuracies in the current transformer on the phase and neutral sides, but it is very small during normal conditions.

The module calculates the differential current for all three phases.

The low-stage differential protection is stabilized with a bias current. The bias current is also known as the stabilizing current. Stabilization means that the differential current required for tripping increases according to the bias current and the operation characteristics. When an internal fault occurs, the currents on both sides of the protected object are flowing into it. This causes the biasing current to be considerably smaller, which makes the operation more sensitive during internal faults.

The traditional way for calculating the stabilized current is:

$$I_b = \left| \frac{\bar{I}_1 - \bar{I}_2}{2} \right|$$

(Equation 202)

The module calculates the bias current for all three phases.

Through-fault detection

Through-fault (TF) detection module is for detecting whether the fault is external, that is, going through, or internal. This information is essential for ensuring the correct operation of the protection in case of the CT saturation.

- In a through-fault situation, CTs can saturate because of a high fault current magnitude. Such AC saturation does not happen immediately when the fault begins. Thus, the TF module sees the fault as external because the bias current is high but the differential current remains low. If the AC saturation then occurs, a CT saturation-based blocking is allowed to work to prevent tripping.
- Normally, the phase angle between the machine neutral and line side CTs is 180 degrees. If an internal fault occurs during a through fault, an angle less than 50 degrees clearly indicates an internal fault and the TF module overrules, that is, deblocks the presence of any blocking due to CT saturation.

CT saturation-based blocking

Higher currents during the motor startup or abnormally high magnetizing currents at an overvoltage (transformer-fed motor) or an external fault may saturate the current transformers. The uneven saturation of the star and line side CTs (for example, due to burden differences) may lead to a differential current which can cause a differential protection to operate. This module blocks the operation of MPDIF biased low stage internally in case of the CT saturation. Once the blocking is activated, it is held for a certain time after the blocking conditions have ceased to be fulfilled.

DC restraint

On detection of a DC component, the function temporarily desensitizes the differential protection. The functioning of this module depends on the *DC restrain Enable* setting. The DC components are continuously extracted from the three instantaneous differential currents. The highest DC component of all three is taken as a kind of DC restraint in a sense that the highest effective, temporary sensitivity of the protection is temporarily decreased as a function of this highest DC offset. The calculated DC restraint current is not allowed to decay (from its highest ever measured value) faster than with a time constant of one second. The value of the temporarily effective sensitivity limit is limited upwards to the rated current of the machine or 3.3 times that of *Low operate value*, whichever is smaller. The temporary extra limit decays exponentially from its maximum value with a time constant of one second.

This feature should be used in case of networks where very long time constants are expected. The temporary sensitivity limit is higher to the set operating characteristics. In other words, the temporary limit has superposed the unchanged operating characteristics and temporarily determines the highest sensitivity of the protection. The temporary sensitivity is less than the sensitivity in section 1 of the operating characteristic and is supposed to prevent an unwanted trip during the external faults with lower currents.

Biased low stage

The current differential protection needs to be biased because of the possible appearance of a differential current which can be due to something else than an actual fault in the machine. In case of differential protection, a false differential current can be caused by:

- CT errors
- CT saturation at high currents passing through the machine

The differential current caused by CT errors increases at the same percent ratio as the load current.

The high currents passing through the protected object can be caused by the through fault. Therefore, the operation of the differential protection is biased with respect to the load current. In the biased differential protection, the higher the differential current required for the protection of operation, the higher the load current.

Based on the conditions checked from the through-fault module, the DC (component) detection module and the CT saturation-based blocking modules, the biased low-stage module decides whether the differential current is due to the internal faults or some false reason. In case of detection of the TF, DC or CT saturation, the internal differential blocking signal is generated, which in turn blocks the operating signal. In case of internal faults, the operation of the differential protection is affected by the bias current.

The *Low operate value* setting for the stabilized stage of the function block is determined with the equation:

$$Low\,operate\,value = I_{d1}$$

(Equation 203)

The *Slope section 2* and *Slope section 3* settings are determined correspondingly:

$$Slope\ section\ 2 = \frac{I_{d2}}{I_{b2}} \cdot 100\%$$

(Equation 204)

$$Slope\ section\ 3 = \frac{I_{d3}}{I_{b3}} \cdot 100\%$$

(Equation 205)

The end of the first section *End section 1* can be set at a desired point within the range of 0 to 100 percent (or % I_r). Accordingly, the end of the second section *End section 2* can be set within the range of 100 percent to 300 percent (or % I_r).

The slope of the operating characteristic for the function block varies in different parts of the range.

In section 1, where 0.0 < I_b/I_n < *End section 1*, the differential current required for tripping is constant. The value of the differential current is the same as the *Low operate value* setting selected for the function block. The *Low operate value* setting allows for small inaccuracies of the current transformers but it can also be used to influence the overall level of the operating characteristic.

Section 2, where *End section 1* < I_b/I_n < *End section 2*, is called the influence area of the setting *Slope section 2*. In this section, variations in *End section 2* affect the slope of the characteristic, that is, how big the change in the differential current required for tripping is in comparison to the change in the load current. The *End section 2* setting allows for CT errors.

In section 3, where I_b/I_n > *End section 2*, the slope of the characteristic can be set by *Slope section 3* that defines the increase in the differential current to the corresponding increase in the biasing current.

The required differential current for tripping at a certain stabilizing current level can be calculated using the formulae:

For a stabilizing current lower than *End section 1*

$$I_{doperate}[\%I_r] = Set\ Low operate\ value$$

(Equation 206)

For a stabilizing current higher than *End section 1* but lower than *End section 2*

$$I_{doperate}[\%I_r] = Low operate\ value + (I_b[\%Ir] - End\ section\ 1) \cdot Slope\ section\ 2$$

(Equation 207)

For higher stabilizing current values exceeding *End section 2*

$$I_{d\,operate}[\%I_r] = Low operate\ value + (End\ section\ 2 - End\ section\ 1) \cdot Slope\ section\ 2 + (I_b[\%I_r] - End\ section\ 2) \cdot Slope\ section\ 3$$

(Equation 208)

When the differential current exceeds the operating value determined by the operating characteristics, the OPR_LS output is activated. The OPERATE output is always activated when the OPR_LS output activates.

The operate signal due to the biased stage can be blocked by the activation of the BLK_OPR_LS or BLOCK input. Also, when the operation of the biased low stage is

blocked by the waveform blocking functionality, the INT_BLKD output is activated according to the phase information.

The phase angle difference between the two currents I_A1 and I_A2 is theoretically 180 electrical degrees for the external fault and 0 electrical degrees for the internal fault conditions. If the phase angle difference is less than 50 electrical degrees or if the biasing current drops below 30 percent of the differential current, a fault has most likely occurred in the area protected by MPDIF. Then the internal blocking signals (CT saturation and DC blocking) of the biased stage are inhibited.

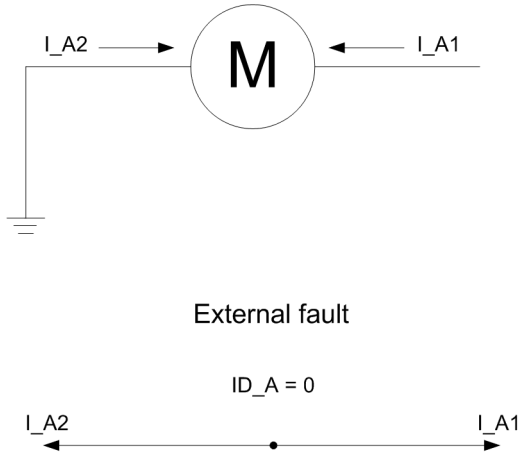

Figure 450: Positive direction of current

Instantaneous high stage

The differential protection includes an unbiased instantaneous high stage. The instantaneous stage operates and the OPR_HS output is activated when the amplitude of the fundamental frequency component of the differential current exceeds the set *High operate value* or when the instantaneous peak values of the differential current exceed 2.5 · *High operate value*. The factor 2.5 (= 1.8 · √2) is due to the maximum asymmetric short circuit current.

The OPERATE output is always activated when the OPR_HS output activates.

The internal blocking signals of the function block do not prevent the operation of the instantaneous stage. When required, the operate signal due to instantaneous operation can be blocked by the binary inputs BLK_OPR_HS or BLOCK.

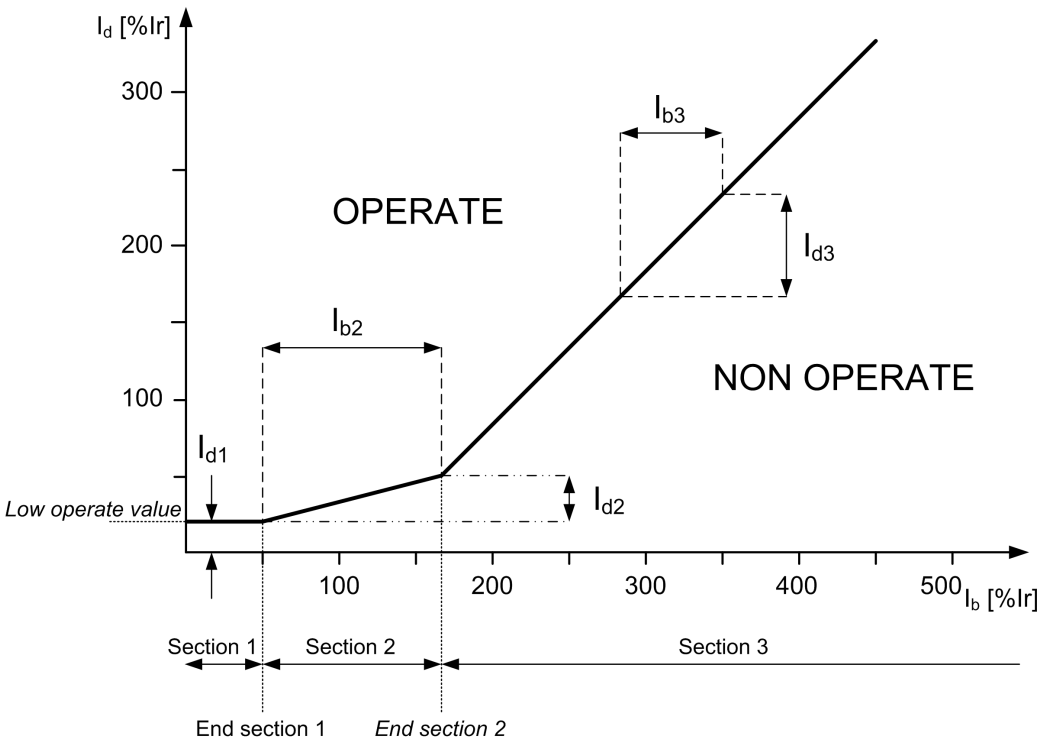

Figure 451: Operating characteristic for the stabilized stage of the generator differential protection function

4.3.7.6 Application

The differential protection works on the principle of calculating the differential current at the two ends of the winding, that is, the current entering the winding is compared to the current exiting the winding. In case of any internal fault, the currents entering and exiting the winding are different, which results in a differential current, which is then used as a base for generating the operating signal. Due to this principle, the differential protection does not trip during external faults. However, it should be noted that interturn faults in the same phase are usually not detected unless they developed into some other kind of fault.

The short circuit between the phases of the stator windings normally causes high fault currents. The short circuit creates a risk of damages to the insulation, windings and stator core. The high short circuit currents cause strong current forces which can damage other components in the machine. The short circuit can also initiate explosion and fire. When a short circuit occurs in a machine, there is a damage that has to be repaired. The severity and the repair time depend on the degree of damage, which is highly dependent on the fault time. The fast fault clearance of this fault type is of greatest importance to limit the damages and the economic loss.

To limit the damages in connection to the stator winding short circuits, the fault clearance time must be as short as possible (instantaneous). The fault current contributions from both the external power system (via the machine or the block circuit breaker) and from the machine itself must be disconnected as fast as possible.

The DC restraint feature should be used in case of an application with a long DC time constant in the fault currents is present. This fault current may be of a lesser magnitude (less than rated current) but is unpleasant and tends to saturate the CT and operate the differential protection for external faults. This feature is effective at moderate through-currents and ineffective at higher through-currents.

Although the short circuit fault current is normally very high, that is, significantly higher than the rated current of the machine, it is possible that a short circuit can occur between phases close to the neutral point of the machine, causing a relatively small fault current. The fault current fed from the synchronous machine can also be limited due to a low excitation of the synchronous generator. This is normally the case at the run-up of the synchronous machine, before synchronization to the network. Therefore, it is desired that the detection of the machine phase-to-phase short circuits shall be relatively sensitive, thus detecting the small fault currents.

It is also important that the machine short circuit protection does not trip for external faults when a high fault current is fed from the machine. To combine fast fault clearance, sensitivity and selectivity, the machine current differential protection is normally the best alternative for the phase-to-phase short circuits.

The risk of an unwanted differential protection operation caused by the current transformer saturation is a universal differential protection problem. If a big synchronous machine is tripped in connection to an external short circuit, it gives an increased risk of a power system collapse. Besides, there is a production loss for every unwanted trip of the machine. Therefore, preventing the unwanted disconnection of machines has a great economical value.

Recommendations for current transformers

The more important the object to be protected is, the more attention is paid to the current transformers. It is not normally possible to dimension the current transformers so that they repeat the currents with high DC components without saturating when the residual flux of the current transformer is high. The differential protection function block operates reliably even though the current transformers are partially saturated.

The accuracy class recommended for current transformers to be used with the differential function block is 5P, in which the limit of the current error at the rated primary current is 1 percent and the limit of the phase displacement is 60 minutes. The limit of the composite error at the rated accuracy limit primary current is 5 percent.

The approximate value of the actual accuracy limit factor F_a corresponding to the actual CT burden can be calculated on the basis of the rated accuracy limit factor F_n (ALF) at the rated burden, the rated burden S_n, the internal burden S_{in} and the actual burden S_a of the current transformer.

$$F_a = F_n \times \frac{S_{in} + S_n}{S_{in} + S_a}$$

(Equation 209)

Example 1

The rated burden S_n of the current transformer 5P20 is 10 VA, the secondary rated current 5A, the internal resistance R_{in} = 0.07 Ω and the rated accuracy limit factor F_n corresponding to the rated burden is 20 (5P20). The internal burden of the current transformer is $S_{in} = (5A)^2 \times 0.07\ \Omega = 1.75$ VA. The input impedance of the protection relay at a rated current of 5A is < 20 mΩ. If the

measurement conductors have a resistance of 0.113 Ω, the actual burden of the current transformer is $S_a = (5A)^2 \times (0.113 + 0.020)\ \Omega = 3.33$ VA. Thus, the accuracy limit factor F_a corresponding to the actual burden is about 46.

The CT burden can grow considerably at the rated current 5A. The actual burden of the current transformer decreases at the rated current of 1 A while the repeatability simultaneously improves.

At faults occurring in the protected area, the fault currents can be very high compared to the rated currents of the current transformers. Due to the instantaneous stage of the differential function block, it is sufficient that the current transformers are capable of repeating the current required for an instantaneous tripping during the first cycle.

Thus the current transformers usually are able to reproduce the asymmetric fault current without saturating within the next 10 ms after the occurrence of the fault to secure the operating times of the protection relay comply with the retardation time.

The accuracy limit factors corresponding to the actual burden of the phase current transformer to be used in differential protection must fulfill the requirement:

$$F_a > K_r \times Ik_{\max} \times (T_{dc} \times \omega \times (1 - e^{\frac{-T_m}{T_{dc}}}) + 1)$$

(Equation 210)

Ik_{max}	The maximum through-going fault current (in I_R) at which the protection is not allowed to operate
T_{dc}	The primary DC time constant related to Ik_{max}
ω	The angular frequency, that is, $2 \times \pi \times f_n$
T_m	The time to saturate, that is, the duration of the saturation-free transformation
K_r	The remanence factor 1/(1-r), where r is the maximum remanence flux in pu from the saturation flux

The parameter r is the maximum remanence flux density in the CT core in pu from the saturation flux density. The value of the parameter r depends on the magnetic material used and also on the construction of the CT. For instance, if the value r = 0.4, the remanence flux density can be 40 percent of the saturation flux density. The manufacturer of the CT has to be contacted when an accurate value for the parameter r is needed. The value r = 0.4 is recommended to be used when an accurate value is not available.

The required minimum time-to-saturate T_m in MPDIF is half-fundamental cycle period (10 ms when f_n = 50 Hz).

Two typical cases are considered for the determination of the sufficient actual accuracy limit factor F_a:

1. A fault occurring at the substation bus.

   The protection must be stable at a fault arising during a normal operating situation. The reenergizing of the transformer against a bus fault leads to very high fault currents and thermal stress. Therefore, reenergizing is not preferred in this case. The remanence can be neglected.

   The maximum through-going fault current Ik_{max} is typically 6 I_R for a motor. At a short circuit fault close to the supply transformer, the DC time constant T_{dc} of the fault current is almost the same as that of the transformer, the typical value being 100 ms.

Ik_{max}	= 6 I_R
T_{dc}	= 100 ms
ω	= 100π Hz
T_m	= 10 ms
K_r	= 1

   Equation 210 with these values gives the result:

   $$F_a > K_r \times Ik_{\max} \times (T_{dc} \times \omega \times (1 - e^{\frac{-T_m}{T_{dc}}}) + 1) \approx 24$$

2. Reenergizing against a fault occurring further down in the network.

   The protection must be stable also during reenergization against a fault on the line. In this case, the existence of remanence is very probable. It is assumed to be 40 percent here.

   On the other hand, the fault current is now smaller and since the ratio of the resistance and reactance is greater in this location, having a full DC offset is not possible. Furthermore, the DC time constant (T_{dc}) of the fault current is now smaller, assumed to be 50 ms here.

   Assuming the maximum fault current is 30 percent lower than in the bus fault and a DC offset 90 percent of the maximum.

Ik_{max}	= 0.7 × 6 = 4.2 (I_R)
T_{dc}	= 50 ms
ω	= 100π Hz
T_m	= 10 ms
K_r	= 1/(1-0.4) = 1.6667

   Equation 210 with these values gives the result:

   $$F_a > K_r \times Ik_{\max} \times 0.9 \times (T_{dc} \times \omega \times (1 - e^{\frac{-T_m}{T_{dc}}}) + 1) \approx 24$$

If the actual burden of the current transformer S_a in the accuracy limit factor equation cannot be reduced low enough to provide a sufficient value for F_a, there are two alternatives to deal with the situation.

1. A current transformer with a higher rated burden S_n can be chosen (which also means a higher rated accurate limit F_n).
2. A current transformer with a higher nominal primary current I_{1n} (but the same rated burden) can be chosen.

Alternative 2 is more cost-effective and therefore often better, although the sensitivity of the scheme is slightly reduced.

Example 2

Here the actions according to alternative 2 are taken to improve the actual accuracy limit factor.

$$F_a = \left(\frac{I_R CT}{I_R Motor} \right) \times F_n$$

(Equation 211)

I_RCT	rated primary current of the CT, for example, 1500A
I_RMotor	rated current of the motor under protection, for example, 1000A
F_n	rated accuracy limit factor of the CT, for example, 30
F_a	actual accuracy limit factor due to oversizing the CT, substituting the values in the equation, F_a = 45

In differential protection it is important that the accuracy limit factors F_a of the phase current transformers at both sides correspond with each other, that is, the burdens of the current transformers on both sides are to be as close to each other as possible. If high inrush or start currents with high DC components pass through the protected object when it is connected to the network, special attention is required for the performance and the burdens of the current transformers and the settings of the function block.

Connection of current transformers

The connections of the primary current transformers are designated as Type 1 and Type 2.

- If the positive directions of the winding 1 and winding 2 protection relay currents are opposite, the *CT connection type* is of "Type 1". The connection examples of "Type 1" are as shown in figures *Figure 452* and *Figure 453*.
- If the positive directions of the winding 1 and winding 2 protection relay currents equate, the *CT connection type* setting parameter is "Type 2". The connection examples of "Type 2" are as shown in figures *Figure 454* and *Figure 455*.
- The default value of the *CT connection type* setting is "Type 1".

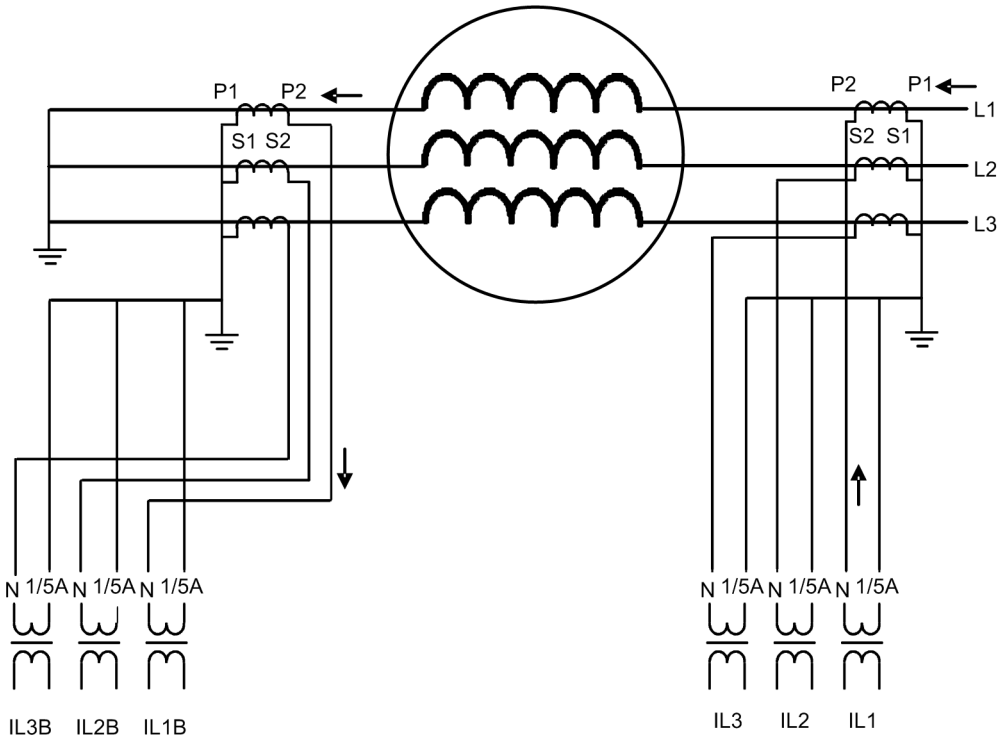

Figure 452: Connection of current transformer of Type 1, example 1

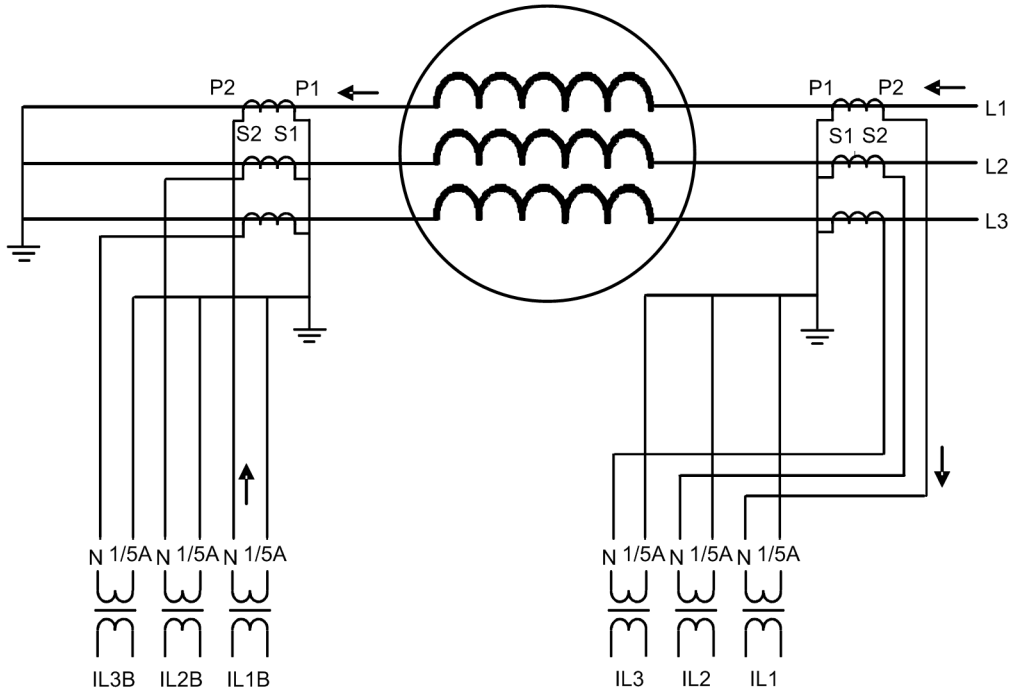

Figure 453: Connection of current transformer of Type 1, example 2

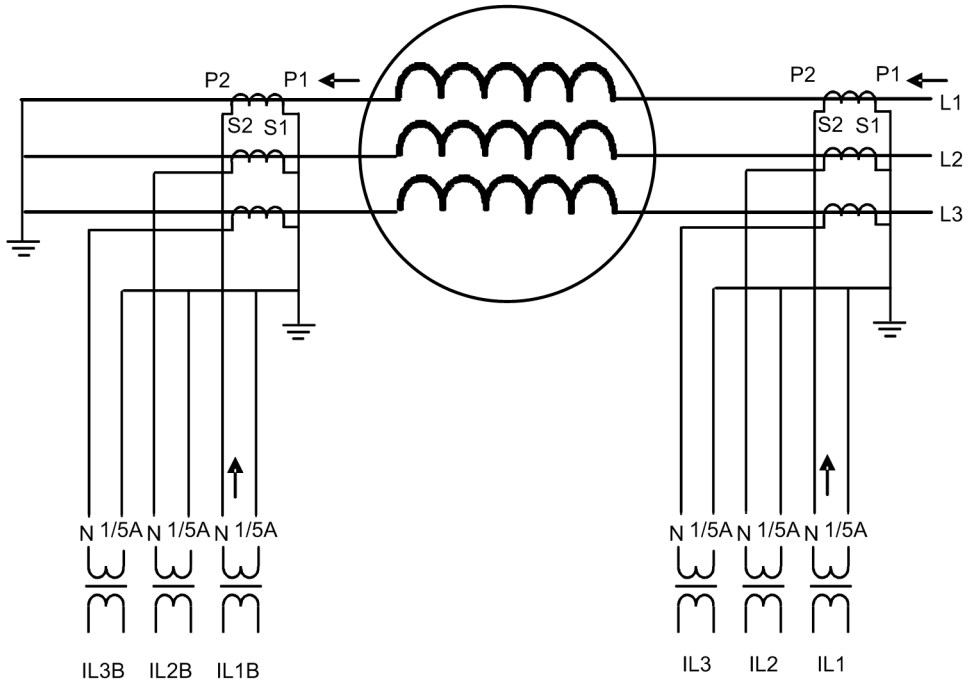

Figure 454: Connection of current transformer of Type 2, example 1

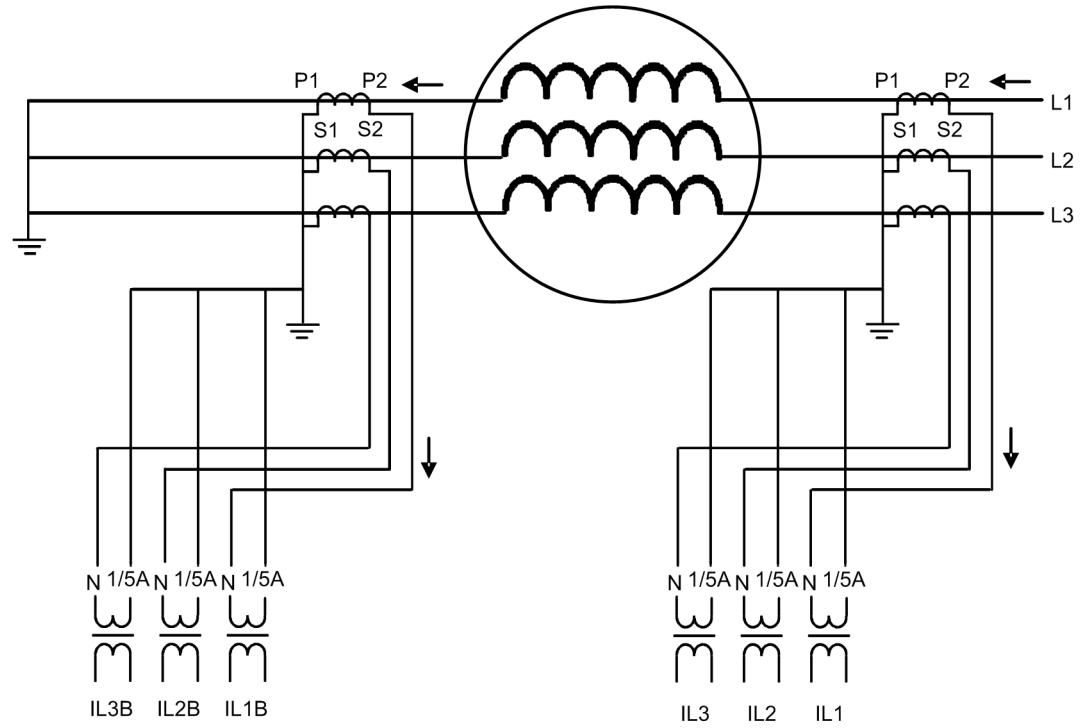

Figure 455: Connection of current transformer of Type 2, example 2

Saturation of current transformers

There are basically two types of saturation phenomena that have to be detected: the AC saturation and the DC saturation. The AC saturation is caused by a high fault current where the CT magnetic flux exceeds its maximum value. As a result, the secondary current is distorted as shown in *Figure 456*. A DC component in the current also causes the flux to increase until the CT saturates. This is known as DC saturation.

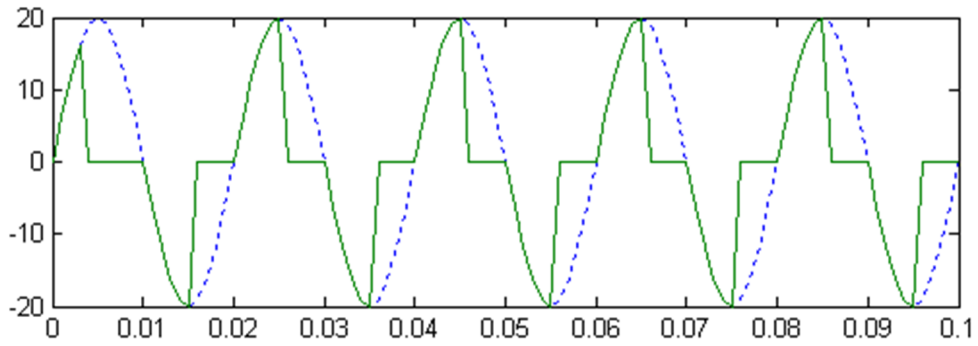

Figure 456: AC saturation

When having a short circuit in a power line, the short circuit current contains a DC component. The magnitude of the DC component depends on the phase angle when the short circuit occurs. *Figure 457* shows the secondary current of the CT in the fault situation. Because of the DC component, the flux reaches its maximum value at 0.07 seconds, causing saturation. As the DC component decays, the CT recovers gradually from the saturation.

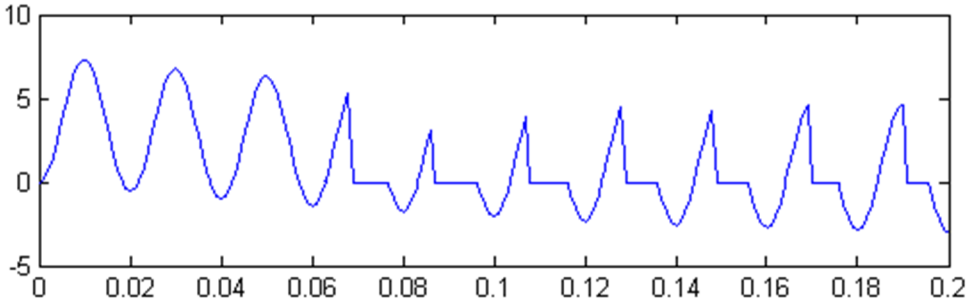

Figure 457: DC saturation

High-impedance or flux-balance based differential protection	MHZPDIF	3dIHi>M	87HIM

4.3.8.2 Function block

Figure 458: Function block

4.3.8.3 Functionality

The high-impedance/flux-balance based differential protection for motors function MHZPDIF provides winding short circuit protection for motors.

MHZPDIF starts and operates when any of the three-phase differential currents, ID_A, ID_B or ID_C, exceeds the set limit. The operation timer characteristic is according to the definite time (DT).

This function contains a blocking functionality. It is possible to block the function outputs, timers or the function itself.

4.3.8.4 Analog channel configuration

MHZPDIF has one analog group input which must be properly configured.

Table 724: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.3.8.5 Operation principle

The function can be enabled and disabled with the *Operation setting*. The corresponding parameter values are "On" and "Off".

The operation of MHZPDIF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

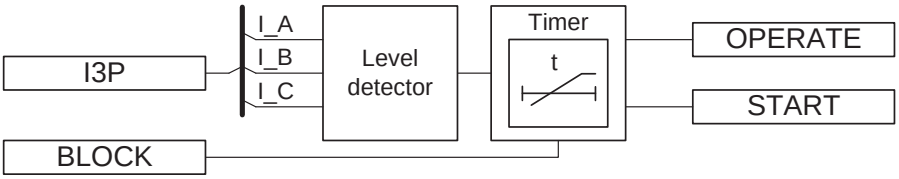

Figure 459: Functional module diagram

Level detector

This module compares the three-phase differential currents to the set *Operate value*. If any of the differential currents ID_A, ID_B or ID_C exceeds the set *Operate value*, the Level detector module sends an enable signal to the Timer module to start the definite timer (DT).

Timer

Once activated, the Timer activates the `START` output. The Timer characteristic is according to DT. When the operation timer has reached the value set by *Minimum operate time*, the `OPERATE` output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the `START` output is deactivated.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

The activation of the `BLOCK` signal resets the Timer and deactivates the `START` and `OPERATE` outputs.

4.3.8.6 Application

MHZPDIF provides the winding short circuit and earth-fault protection for motors. The high-impedance or flux-balance principle has been used through many years for differential protection due to the capability to manage through-faults with a heavy current transformer (CT) saturation.

High-impedance principle

The high-impedance principle is stable for all types of faults outside the protection zone. The stabilization is obtained by a stabilizing resistor in the differential circuit. This method requires all the CTs to have a similar magnetizing characteristic, same ratio and a relatively high knee point voltage. The CTs in each phase are connected in parallel with a relay measuring branch. The measuring branch is a series connection of the stabilizing resistor and the protection relay.

The stability of the protection is based on the use of the stabilizing resistor (R_s) and the fact that the impedance of the CT secondary quickly decreases as the CT

saturates. The magnetization reactance of a fully saturated CT drops to zero and the impedance is formed only by the resistance of the winding (R_{in}) and lead resistance (R_m).

The CT saturation causes a differential current which can flow through the saturated CT, because of the near-zero magnetizing reactance, or through the measuring branch. The stabilizing resistor is selected so that the current in the measuring branch is below the protection relay's operating current during out-of-zone faults. As a result, the operation is stable during the saturation and can still be sensitive at the undistorted parts of the current waveform.

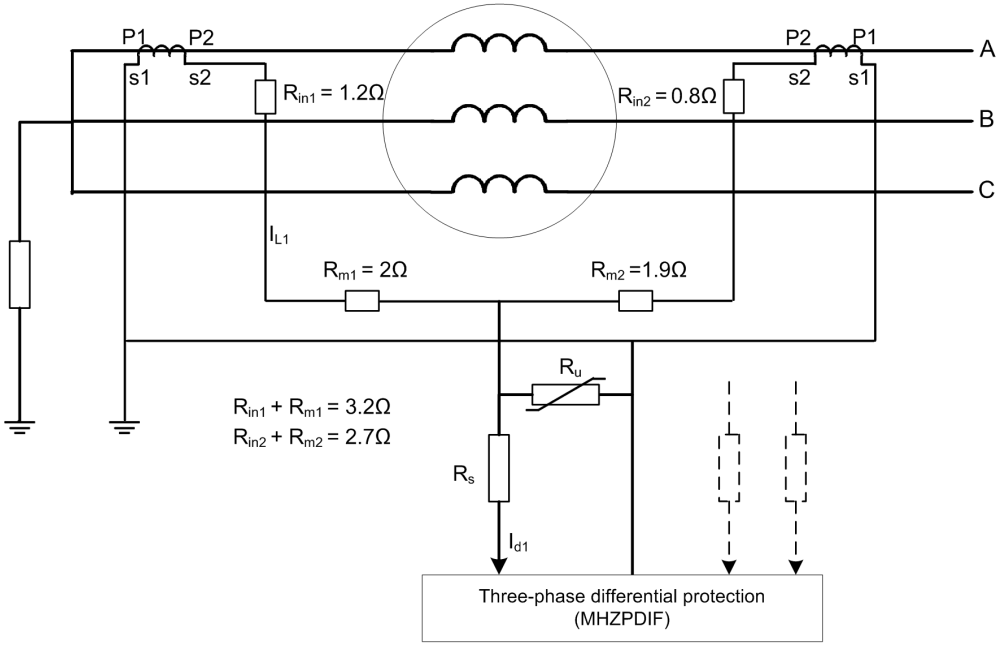

Figure 460: Three-phase differential protection for motors based on highimpedance principle

In case of an internal fault, the fault current cannot circulate through the CTs. It flows through the measuring branch, and the protection operates. A partial CT saturation can occur in case of an internal fault, but the undistorted part of the current waveform causes the protection to operate.

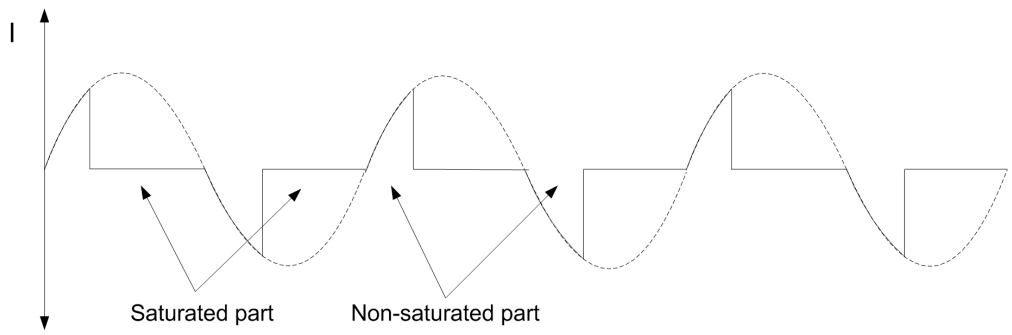

Figure 461: Secondary waveform of a saturated CT

At an internal fault, the secondary circuit voltage can easily exceed the isolation voltage of the CTs, connection wires and the protection relay. To limit this voltage, a voltage-dependent resistor (VDR) is used.

The whole scheme, that is, the stabilizing resistor, voltage-dependent resistor and wiring, must be adequately maintained (operation and insulation tested regularly) to be able to withstand the high-voltage pulses that appear during an internal fault throughout the lifetime of the equipment. Otherwise, during a fault within the zone of protection, any flashover in the CT secondary circuits or any other part of the scheme can prevent the correct operation of MHZPDIF.

Flux-balancing principle

In a measuring configuration for the three-phase differential currents according to the flux-balancing principle, no stabilizing resistors are needed. The configuration, however, requires the use of core balance current transformers. The compared currents, the one at the line end and the other at the neutral end, are both measured by the same core balance current transformer.

In this scheme, the currents flowing through one core balance transformer cancel each other out when there is no fault within the protected zone. When a fault occurs within the protected zone, the currents flowing through the core balance transformer amplify each other and the differential protection operates.

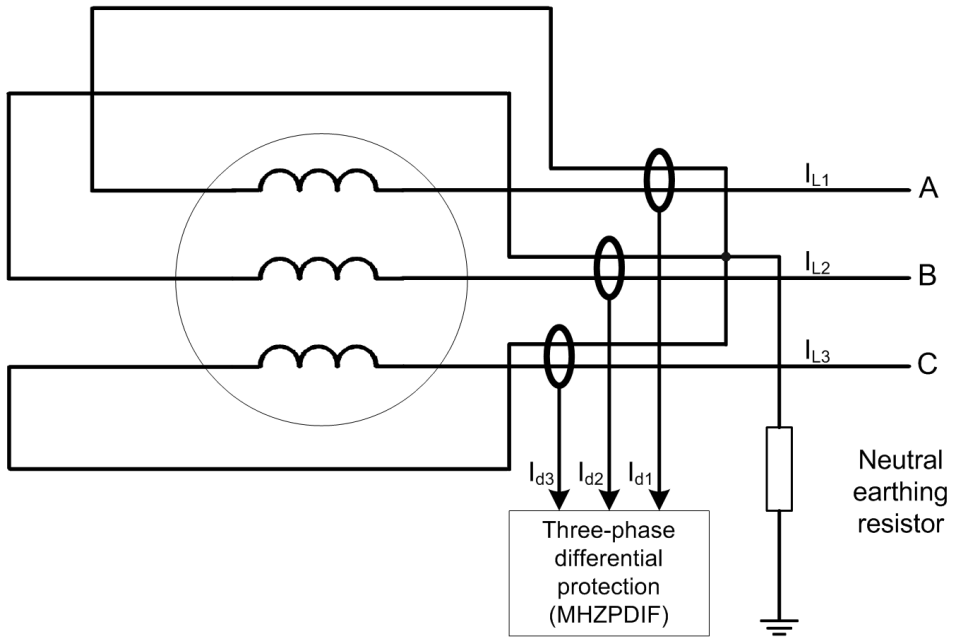

Figure 462: Three-phase differential protection for motors based on fluxbalancing principle

The advantage of this scheme is that the CT rated primary current can be selected smaller than the rated current of the machine.

If six current transformers are used, the flux-balancing principle, that is, summing two CTs in each phase, cannot be used. Instead, the high-

impedance principle or stabilized three-phase differential protection must be used.

4.3.8.7 Recommendations for current transformers

High-impedance principle

The sensitivity and reliability of the protection depend on the characteristics of the current transformers. The CTs must have an identical transformation ratio. It is recommended that all current transformers have an equal burden and characteristics and that they are of the same type. This means that they should be preferably from the same manufacturing batch, that is, an identical construction is used. If the CT characteristics and the burden values are not equal, the calculation for each branch in the scheme should be done separately and the worst-case result is used. If the CT winding resistance and the burden of the branches are not equal, the maximum burden equal to 3.2 Ω should be used for calculating the stabilized voltage.

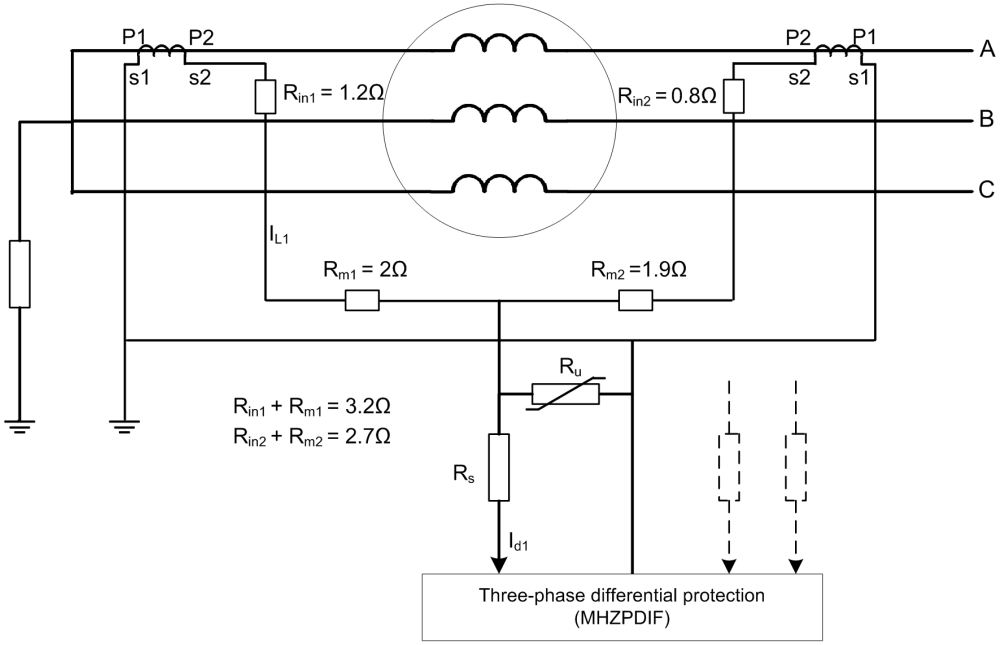

Figure 463: High-impedance differential protection with different CT burden value on each branch

The stabilizing voltage, that is the voltage appearing across the measuring branch during an out-of-zone fault, is calculated assuming that one of the CTs connected in parallel is fully saturated. The stabilizing voltage can be calculated using the formula

$$U_s = \frac{I_{k\max}}{n}(R_{in} + R_m)$$

(Equation 212)

I_{kmax}	The highest through-fault current in primary amps. The highest earth-fault or short circuit current during the out-of-zone fault.
n	The turns ratio of the CT
R_{in}	The secondary internal resistance of the CT in ohms
R_m	The resistance (maximum of $R_{in} + R_m$) of the CT secondary circuit in ohms

The current transformers must be able to force enough current to operate the IED through the differential circuit during a fault condition inside the zone of protection. To ensure this, the knee point voltage U_{kn} should be at least two times higher than the stabilizing voltage U_s.

The required knee point voltage U_{kn} of the current transformer is calculated using the formula

$$U_{kn} \geq 2 \times U_s$$

(Equation 213)

U_{kn}	The knee point voltage
U_s	The stabilizing voltage

The factor two is used when no delay in the operating time of the protection in any situation is acceptable. To prevent the knee point voltage from growing too high, it is advisable to use current transformers, the secondary winding resistance of which is of the same size as the resistance of the measuring loop.

As the impedance of the IED alone is low, a stabilizing resistor is needed. The value of the stabilizing resistor is calculated with the formula

$$R_s = \frac{U_s}{I_{rs}}$$

(Equation 214)

R_s	The resistance of the stabilizing resistor
U_s	The stabilizing voltage of the protection relay
I_{rs}	The value of the *Operate value* setting in secondary amps.

The stabilizing resistor should be capable to dissipate high energy within a very short time; therefore, the wire wound-type resistor should be used. Because of the possible CT inaccuracy, which might cause some current through the stabilizing resistor in a normal load situation, the rated power should be 25 W minimum.

If U_{kn} is high or the stabilizing voltage is low, a resistor with a higher power rating is needed. Often resistor manufacturers allow 10 times rated power for 5 seconds. Thus the power of the resistor can be calculated with the equation

$$\frac{U_{kn}^2}{R_s \times 10}$$

(Equation 215)

The actual sensitivity of the protection is affected by the protection relay setting, the magnetizing currents of the parallel connected CTs and the shunting effect of the voltage-dependent resistor (VDR). The value of the primary current I_{prim} at which the protection relay operates at a certain setting can be calculated with the formula

$$I_{prim} = n \cdot \left(I_{rs} + I_u + m \cdot I_m \right)$$

(Equation 216)

I_m	The magnetizing current per current transformer at the U_s voltage
I_{prim}	The primary current at which the protection is to start
I_{rs}	The value of the *Operate value* setting
I_u	The leakage current flowing through the VDR at the U_s voltage
n	The turn ratio of the current transforme
m	The number of current transformers included in the protection per phase (=2)

The I_e value given in many catalogs is the excitation current at the knee point voltage.

Assuming $U_{kn} \approx 2 \times U_s$, the value of $I_m \approx \frac{I_e}{2}$ gives an approximate value for *Equation 216*.

The selection of current transformers can be divided into the following steps.

1. The rated current In of the protected machine should be known. The value of In also affects the magnitude of I_{kmax}. Normally the I_{kmax} value for motors is $6 \cdot I_n$.
2. The rated primary current I_{1n} of the CT has to be higher than the rated current of the machine.

   The choice of the CT also specifies R_{in}.
3. The required U_{kn} is calculated with *Equation 213*. If the U_{kn} of the CT is not high enough, another CT has to be chosen. The value of the U_{kn} is given by the manufacturer in the case of Class X current transformers or it can be estimated with *Equation 217*.
4. The sensitivity I_{prim} is calculated with *Equation 216*. If the achieved sensitivity is sufficient, the present CT is chosen. A CT with a bigger core is chosen if a better sensitivity is needed.

If a Class X CT is not used, an estimate for Ukn is calculated using *Equation 216*.

$$U_{kn} = 0.8 \times F_n \times I_{2n} \times \left(R_{in} + \frac{S_n}{I_{2n}^2} \right)$$

(Equation 217)

F_n	The rated accuracy limit factor corresponding to the rated burden S_n
I_{2n}	The rated secondary current of the CT
R_{in}	The secondary internal resistance of the CT
S_n	The volt-amp rating of the CT

The formulas are based on choosing the CTs according to *Equation 213*, which results an absolutely stable scheme. In some cases, it is possible to achieve stability with knee point voltages lower than stated in the formulas. However, the network conditions have to be known well enough to ensure the stability.

- If $U_k \geq 2 \times U_s$, fast relay operation is secure.
- If $U_k \geq 1.5 \times U_s$ and $< 2 \times U_s$, relay operation can be slightly prolonged and should be studied case by case.
- If $U_k < 1.5 \times U_s$, the relay operation is jeopardized. Another CT has to be chosen.

The need for voltage dependent resistor (VDR) depends on the insulation level for which the protection relays are tested.

Voltage Umax, ignoring the CT saturation during the fault is calculated using

First, voltage U_{max}, ignoring the CT saturation during the fault, is calculated with the equation *Equation 218*.

$$U_{max} = \frac{I_{k\,max\,in}}{n} \times \left(R_{in} + R_m + R_s \right) \approx \frac{I_{k\,max\,in}}{n} \times R_s$$

(Equation 218)

I_{kmaxin}	Maximum fault current inside the zone, in primary amps
n	Turns ration of the CT
R_{in}	Internal resistance of the CT in ohms
R_m	Resistance of the longest loop of the CT secondary circuit, in ohms
R_s	Resistance of the stabilized resistor, in ohms

The peak voltage û, which includes the CT saturation, is estimated by using *Equation 219* (given by P. Mathews 1955).

$$\hat{u} = 2\sqrt{2U_{kn}\left(U_{max} - U_{kn}\right)}$$

(Equation 219)

U_{kn}	Knee point voltage of the CT

The VDR is recommended when the peak voltage û ≥ 2kV, which is the insulation level for which the IED is tested.

For example, the maximum fault current in case of a fault inside the zone is 12.6 kA in primary, CT is of 1250/5 A, that is, ratio n = 240, and knee point voltage is 81 V. The stabilizing resistor is 330 Ohms.

$$U_{max} = \frac{12600\,A}{240} \cdot 330\,\Omega = 17325\,V$$

(Equation 220)

$$\check{u} = 2\sqrt{2 \cdot 81 \cdot (17325 - 81)} \approx 3.34\,kV$$

(Equation 221)

As the peak voltage û = 3.2 kV, VDR must be used. In some cases, VDR can be avoided if R_s is smaller. The value of R_s depends on the protection relay operation current and stabilizing voltage. Thus, a higher setting in the protection relay must be used or the stabilizing voltage lowered.

Flux-balancing principle

When the function block is used with the flux-balancing principle, there are no extra requirements for the measuring devices. The core-balance transformers used in an ordinary overcurrent protection are adequate here as well.

4.3.8.8 Example calculations for high-impedance differential protection

The example shows the calculations for the *Operate value* setting, stabilizing resistor value (R_s) and required knee point voltage (U_{kn}) of the CTs.

Table 725: Protected generator values

Quantity	Value
S_n	8 MVA
U_n	6 kV
I_n	770 A
I_{kmax}	4620 A (6 × I_n) out-of-zone fault
I_{kmaxin}	9.24 kA (12 × I_n) in-zone fault

Table 726: Assumed CT data

Quantity	Value
CT	1000/1 A
R_{in}	15.3 Ω
U_{kn}	323 V
I_e	35 mA (at U_{kn})

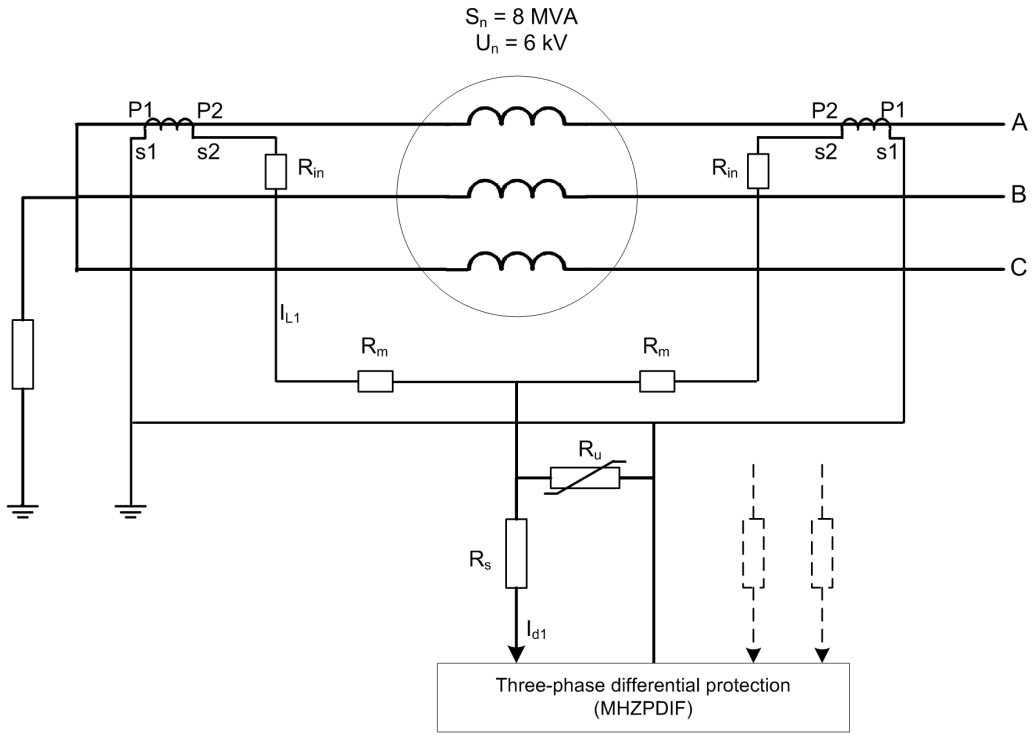

Figure 464: Example calculation for high-impedance differential protection (only one phase is presented in detail)

The length of the secondary circuit loop is 200 m and the area of the cross-section is 2.5 mm^2. Resistance at 75°C is 0.00865 Ω/m.

$$R_m = 0.00865 \frac{\Omega}{m} \cdot 200m \approx 1.73\Omega$$

(Equation 222)

First the stabilizing voltage is calculated based on equation

$$U_s = \frac{6 \cdot 770\,A}{1000} \cdot (15.3\,\Omega + 1.73\,\Omega) \approx 78.7\,V$$

(Equation 223)

In this case the requirement for the current transformer knee point voltage is fulfilled because $U_{kn} > 2U_s$.

The magnetising curve of the CT is assumed to be linear. The magnetizing current at the stabilizing voltage can be estimated.

$$I_m = \frac{U_s}{U_{kn}} \cdot I_e$$

(Equation 224)

$$I_m = \frac{78.7\,V}{323\,V} \cdot 35mA \approx 8.5mA$$

(Equation 225)

The setting current I_{rs} should be at the minimum of the sum of the magnetizing currents of all connected CTs to obtain adequate protection stability.

$$I_{rs} = 2 \cdot 8.5\,mA \approx 17\,mA$$

(Equation 226)

The resistance of the stabilizing resistor is calculated based on equation

$$R_s = \frac{78.7\,V}{0.017\,A} \approx 4629\,\Omega$$

(Equation 227)

The calculated value 4629 Ω is the maximum value for the stabilizing resistor. If this value is not available, the next available value downwards should be chosen and the protection relay setting current is to be tuned according to the selected resistor. For example in this case the resistance value 3900 Ω is used.

$$I_{rs} = \frac{78.7\,V}{3900\,V} \approx 20\,mA$$

(Equation 228)

The sensitivity of the protection is obtained as per equation (assuming I_u to be zero)

$$I_{prim} = 1000 \cdot (0.020\,A + 2 \cdot 0.0085\,A + 0\,A) \approx 37\,A$$

(Equation 229)

The power of the stabilizing resistor is calculated as follows.

$$P \geq \frac{(323\,V)^2}{3900\,\Omega} \approx 27\,W$$

(Equation 230)

The need for voltage dependent resistor is checked with equations

$$U_{max} = \frac{12 \cdot 770\,A}{1000} \cdot (3900\,\Omega + 15.3\,\Omega + 1.73\,\Omega + 0.10\,\Omega) \approx 36.2\,kV$$

(Equation 231)

$$\check{u} = 2\sqrt{2 \cdot 323\,V \cdot (36200\,V - 323\,V)} \approx 9.6\,kV$$

(Equation 232)

The voltage dependent resistor, one for each phase, is needed in this case because the voltage during the fault is much higher than 2 kV.

The leakage current through the varistor at the stabilizing voltage can be available from the varistor manual, assuming that to be approximately 2 mA at stabilizing voltage.

$$Iu \approx 0.002\,A$$

(Equation 233)

The sensitivity of the protection can be re-calculated taking into account the leakage current through the varistor as per equation

$$I_{prim} = 1000 \cdot (0.020\,A + 2 \cdot 0.0085\,A + 0.002\,A) \approx 39\,A$$

(Equation 234)

Negative-sequence overcurrent protection	NSPTOC	I2>M	46M

[1] *Measurement mode* = “Peak-to-Peak”, current before fault = 0.0 × I_n, f_n = 50 Hz, fault current with nominal frequency injected from random phase angle, results based on statistical distribution of 1000 measurements

[2] Includes the delay of the signal output contact

4.4.1.2 Function block

Figure 465: Function block

4.4.1.3 Functionality

The negative-sequence overcurrent protection function NSPTOC is used for increasing sensitivity to detect single-phase and phase-to-phase faults or unbalanced loads due to, for example, broken conductors or unsymmetrical feeder voltages.

NSPTOC can also be used for detecting broken conductors.

The function is based on the measurement of the negative sequence current. In a fault situation, the function starts when the negative sequence current exceeds the set limit. The operate time characteristics can be selected to be either definite time (DT) or inverse definite minimum time (IDMT). In the DT mode, the function operates after a predefined operate time and resets when the fault current disappears. The IDMT mode provides current-dependent timer characteristics.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.4.1.4 Analog channel configuration

NSPTOC has one analog group input which must be properly configured.

Table 734: Analog signals

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.4.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of NSPTOC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

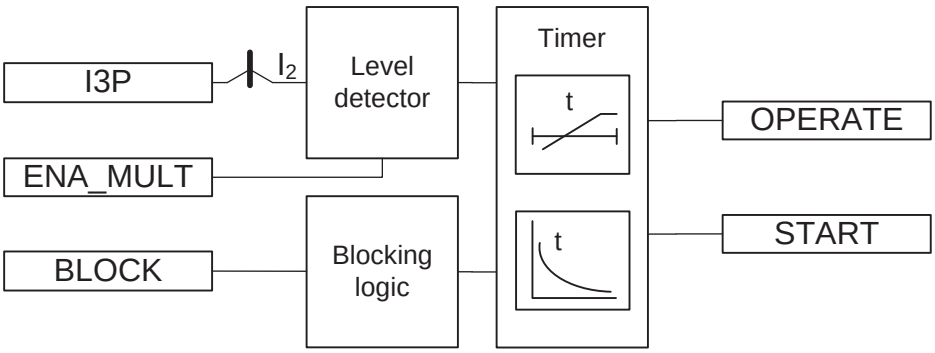

Figure 466: Functional module diagram

Level detector

The measured negative-sequence current is compared to the set *Start value* . If the measured value exceeds the set *Start value* , Level detector activates the Timer module. If the ENA_MULT input is active, the set *Start value* is multiplied by the set *Start value Mult*.

The protection relay does not accept the *Start value* or *Start value Mult* setting if the product of the settings exceeds the *Start value* setting range.

Timer

Once activated, Timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of Operate delay time in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the *Type of reset curve* setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation. The START output is deactivated when the reset timer has elapsed.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. The functionality of the timer in the reset state depends on the combination of the *Operating curve type*, *Type of reset curve* and *Reset delay time* settings. When the DT characteristic

is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, the Type of reset curve setting can be set to "Immediate", "Def time reset" or "Inverse reset". The reset curve type "Immediate" causes an immediate reset. With the reset curve type "Def time reset", the reset time depends on the *Reset delay time* setting. With the reset curve type "Inverse reset", the reset time depends on the current during the drop-off situation and the value of START_DUR. The START output is deactivated when the reset timer has elapsed.

The "Inverse reset" selection is only supported with ANSI or user programmable types of the IDMT operating curves. If another operating curve type is selected, an immediate reset occurs during the drop-off situation.

The setting *Time multiplier* is used for scaling the IDMT operate and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.4.1.6 Application

Since the negative sequence current quantities are not present during normal, balanced load conditions, the negative sequence overcurrent protection elements can be set for faster and more sensitive operation than the normal phase-overcurrent protection for fault conditions occurring between two phases. The negative sequence overcurrent protection also provides a back-up protection functionality for the feeder earth-fault protection in solid and low resistance earthed networks.

The negative sequence overcurrent protection provides the back-up earth-fault protection on the high voltage side of a delta-wye connected power transformer for earth faults taking place on the wye-connected low voltage side. If an earth fault

occurs on the wye-connected side of the power transformer, negative sequence current quantities appear on the delta-connected side of the power transformer.

The most common application for the negative sequence overcurrent protection is probably rotating machines, where negative sequence current quantities indicate unbalanced loading conditions (unsymmetrical voltages). Unbalanced loading normally causes extensive heating of the machine and can result in severe damages even over a relatively short time period.

Multiple time curves and time multiplier settings are also available for coordinating with other devices in the system.

Directional negative-sequence overcurrent protection	DNSPDOC	I2> ->	67Q

[1] Negative sequence current before fault = 0.0, f_n = 50 Hz, results based on statistical distribution of 1000 measurements.
[2] Includes the delay of the signal output contact.
[3] Maximum *Start value* = 2.5 × I_n, *Start value* multiples in range of 1.5...20.

4.4.2.2 Function block

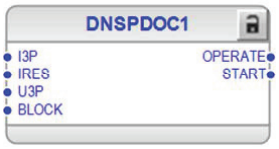

Figure 467: Function block

4.4.2.3 Functionality

The directional negative-sequence overcurrent protection function DNSPDOC is used as directional overcurrent and short-circuit protection.

DNSPDOC starts up when the fundamental value of the operating quantity (negative-sequence or residual current) exceeds the set limit and the directional criterion is fulfilled. The operate time characteristic is according to definite time (DT).

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.4.2.4 Analog channel configuration

DNSPDOC has three analog group inputs which must be properly configured.

Table 743: Analog inputs

Input	Description
I3P	Three-phase currents
IRES [3]	Residual current (measured or calculated) Necessary when *Operating quantity* is "Residual" or "Residual (calc)"
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

Table 744: Special conditions

Condition	Description
U3P connected real measurements	The function requires that at least two voltage channels are connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing

[3] Can be connected to GRPOFF if *Operating quantity* is set to "Negative seq"

blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.4.2.5 Operation principle

The function can be enabled and disabled with the *Operation setting*. The corresponding parameter values are "on" and "off".

The operation of DNSPDOC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

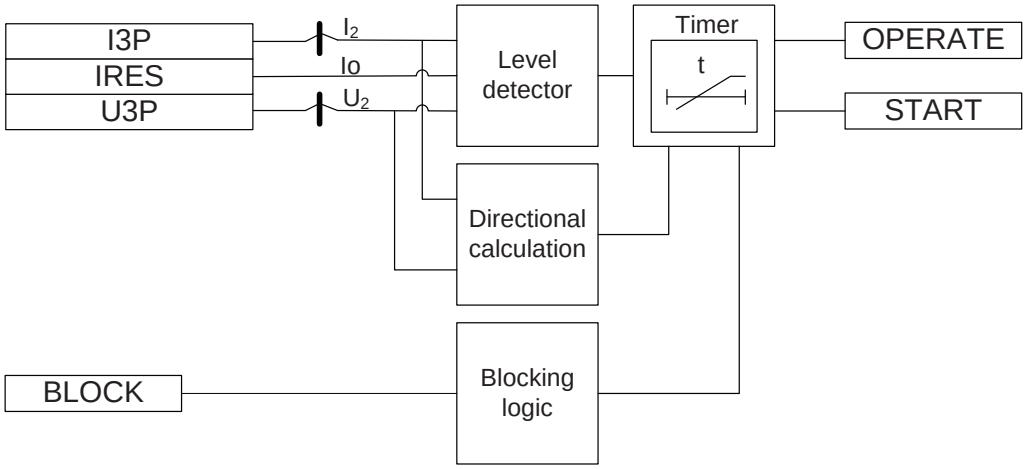

Figure 468: Functional module diagram

Level detector

The operating signal is compared to the set *Start value*. If the operating signal exceeds the set *Start value*, Level detector sends an enabling signal to the Timer module. Timer starts when it is enabled and the directional criterion is fulfilled. A suitable operating quantity can be selected with the *Operating quantity* setting. The options are "Negative seq" or "Residual". The value of operating quantity I_OPER is also available in the Monitored data view.

Irrespective of the operating quantity selected, directional calculation is always determined using the negative-sequence current.

Directional calculation

Directional calculation compares the negative-sequence current phasor with the negative-sequence voltage phasor, that is, the polarizing quantity. The directional operation can be selected with the *Directional mode* setting. The options are "Nondirectional", "Forward" or "Reverse" operation. By setting the value of *Allow Non Dir* to "True", the non-directional operation is allowed when the directional information is invalid.

The *Characteristic angle* setting is used to turn the directional characteristics. The value of *Characteristic angle* should be chosen so that all the faults in the operating direction are seen in the operating zone and all the faults in the opposite direction are seen in the non-operating zone. The value of *Characteristic angle* depends on the network configuration.

Reliable directional calculation requires that both negative-sequence current and negative-sequence voltage quantities exceed certain minimum amplitude levels. The minimum amplitude level for the negative-sequence current is set with the *Min operate current* setting. The minimum amplitude level for the polarizing quantity, that is, the negative-sequence voltage, is set with the *Min operate voltage* setting. If the amplitude level of the operating quantity or polarizing quantity is below the set level, the direction information of the corresponding phase is set to “unknown”. If the negative-sequence voltage before the fault situation is below *Min operate voltage*, the voltage direction cannot be determined.

The value for the *Min operate voltage* setting should be carefully selected since the accuracy in low signal levels is strongly affected by the measuring device accuracy.

Timer

Once activated, Timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated if the operating signal persists.

In a drop-off situation, that is, if a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated. The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, the function operates normally but the OPERATE output is not activated.

4.4.2.6 Directional overcurrent characteristics

The forward and reverse sectors are defined separately. The forward operation area is limited with the *Min forward angle* and *Max forward angle* settings. The reverse operation area is limited with the *Min reverse angle* and *Max reverse angle* settings.

The sector limits are always given as positive degree values.

In the forward operation area, the *Max forward angle* setting gives the counterclockwise sector and the *Min forward angle* setting gives the corresponding clockwise sector, measured from the *Characteristic angle* setting.

In the backward operation area, the *Max reverse angle* setting gives the counterclockwise sector and the *Min reverse angle* setting gives the corresponding

clockwise sector, a measurement from the *Characteristic angle* setting that has been rotated 180 degrees.

Relay characteristic angle (RCA) is set positive if the operating current lags the polarizing quantity and negative if the operating current leads the polarizing quantity.

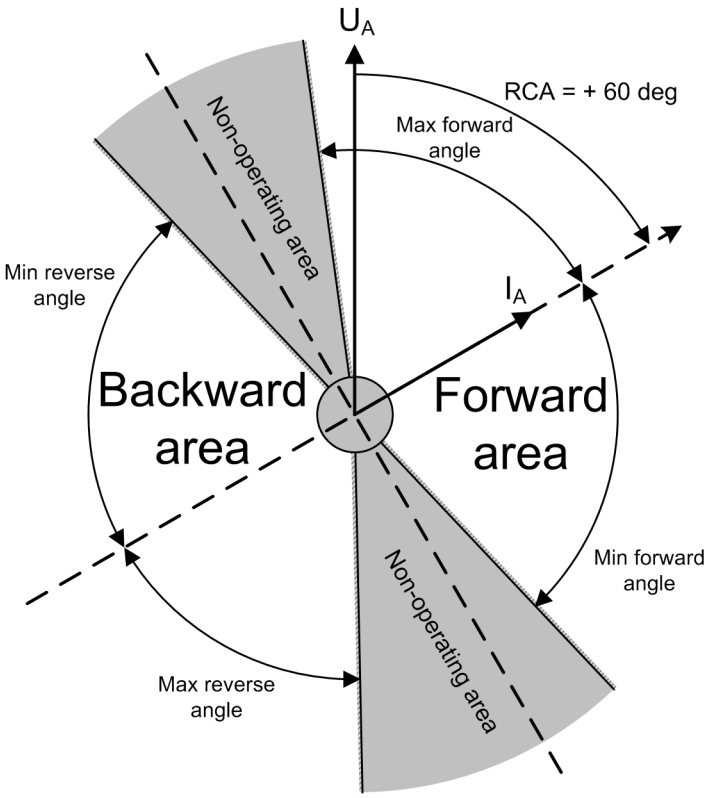

Figure 469: Configurable operating sectors

The angle difference ANGLE between the negative-sequence current and the polarizing quantity is calculated as shown below and is available in the Monitored data view.

$$ANGLE = \phi(-U_2) - \phi(I_2) - \phi_{RCA}$$

(Equation 235)

Based on the ANGLE value, the direction information DIRECTION is evaluated and is made available in the Monitored data view.

Table 745: Momentary direction value for monitored data view

Criterion for direction information	Value for DIRECTION
ANGLE_X is not in any of the defined sectors, or the direction cannot be defined due too low amplitude	0 = unknown
ANGLE_X is in the forward sector	1 = forward
ANGLE_X is in the reverse sector	2 = backward

FAULT_DIR gives the detected direction of the fault during fault situations, that is, when the START output is active.

4.4.2.7 Application

The ability of a protection relay to provide direction information for faults is referred to as its directional security. It is extremely important for the directional protection function to identify the direction of the fault relative to the location of the protection relay. The fault direction can be either downstream (forward fault) or upstream of the protection relay (backward fault).

Different directional elements are used to determine the fault direction. One such element is the negative-sequence voltage. As directional element, the negative-sequence voltage can identify the direction of all unbalance faults. One of the advantages of using negative-sequence elements is that the negative-sequence component is insensitive to zero-sequence mutual coupling. The negative sequence is also used where the source is not strong enough because with such a source the value of the negative sequence near the protection relay has higher magnitude.

[2] Measured with static signal output (SSO).

4.4.3.2 Function block

Figure 470: Function block

4.4.3.3 Functionality

The phase discontinuity protection function PDNSPTOC is used for detecting unbalance situations caused by broken conductors.

The function starts and operates when the unbalance current I_2/I_1 exceeds the set limit. To prevent faulty operation at least one phase current needs to be above the minimum level. PDNSPTOC operates with DT characteristic.

The function contains a blocking functionality. It is possible to block the function output, timer or the function itself.

4.4.3.4 Analog channel configuration

PDNSPTOC has one analog group input which must be properly configured.

Table 754: Analog signals

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.4.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PDNSPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

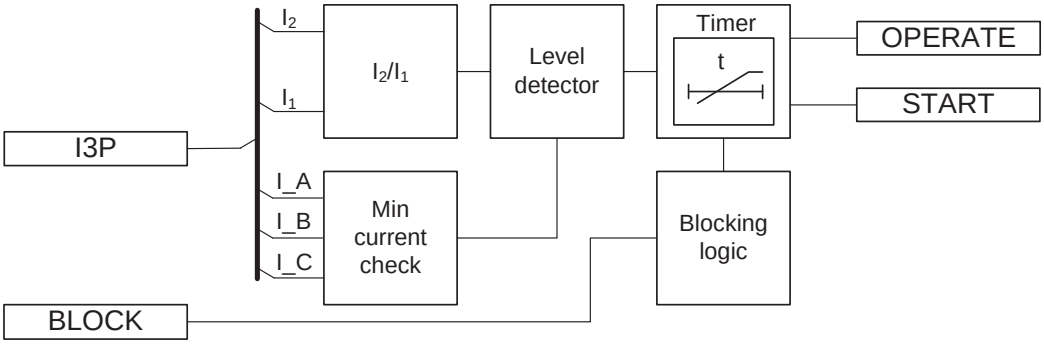

Figure 471: Functional module diagram

I_2/I_1

The I_2/I_1 module calculates the ratio of the negative and positive sequence current. It reports the calculated value to the level detector.

Level detector

The level detector compares the calculated ratio of the negative and positive-sequence currents to the set *Start value*. If the calculated value exceeds the set *Start value* and the min current check module has exceeded the value of *Min phase current*, the level detector reports the exceeding of the value to the timer.

Min current check

The min current check module checks whether the measured phase currents are above the set *Min phase current*. At least one of the phase currents needs to be above the set limit to enable the level detector module.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole

function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.4.3.6 Application

In three-phase distribution and subtransmission network applications the phase discontinuity in one phase can cause an increase of zero-sequence voltage and short overvoltage peaks and also oscillation in the corresponding phase.

PDNSPTOC is a three-phase protection with DT characteristic, designed for detecting broken conductors in distribution and subtransmission networks. The function is applicable for both overhead lines and underground cables.

The operation of PDNSPTOC is based on the ratio of the positive-sequence and negative-sequence currents. This gives a better sensitivity and stability compared to plain negative-sequence current protection since the calculated ratio of positive-sequence and negative-sequence currents is relatively constant during load variations.

The unbalance of the network is detected by monitoring the negative-sequence and positive-sequence current ratio, where the negative-sequence current value is I_2 and I_1 is the positive-sequence current value. The unbalance is calculated with the equation.

$$Iratio = \frac{I_2}{I_1}$$

(Equation 236)

Broken conductor fault situation can occur in phase A in a feeder.

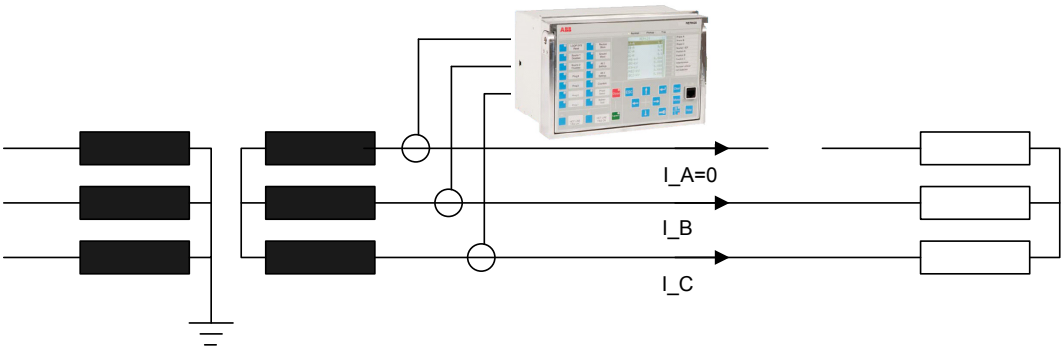

Figure 472: Broken conductor fault situation in phase A in a distribution or subtransmission feeder

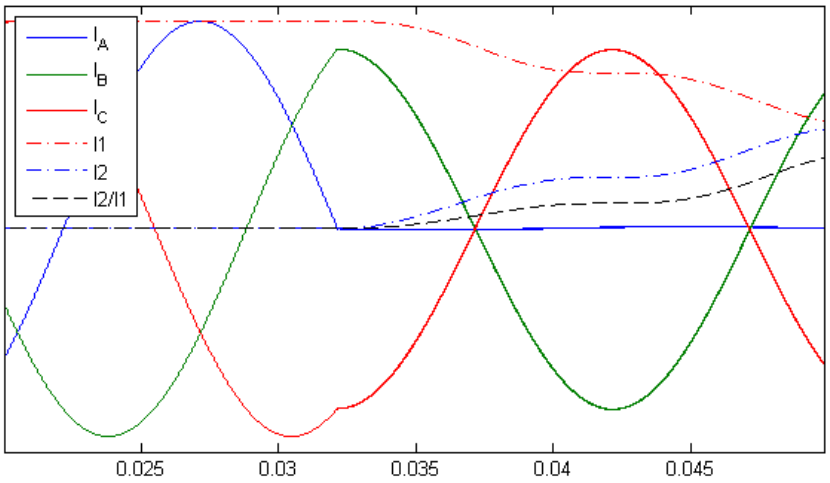

Figure 473: Three-phase current quantities during the broken conductor fault in phase A with the ratio of negative-sequence and positive-sequence currents

Phase reversal protection	PREVPTOC	I2>>	46R

4.4.4.2 Function block

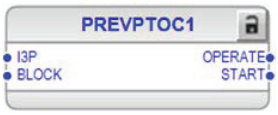

Figure 474: Function block

4.4.4.3 Functionality

The phase reversal protection function PREVPTOC is used to detect the reversed connection of the phases to a three-phase motor by monitoring the negative phase sequence current I_2 of the motor.

PREVPTOC starts and operates when I_2 exceeds the set limit. PREVPTOC operates on definite time (DT) characteristics. PREVPTOC is based on the calculated I_2, and the function detects too high I_2 values during the motor start-up. The excessive I_2 values are caused by incorrectly connected phases, which in turn makes the motor rotate in the opposite direction.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.4.4.4 Analog input configuration

PREVPTOC has one analog group input which must be properly configured.

Table 762: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.4.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PREVPTOC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

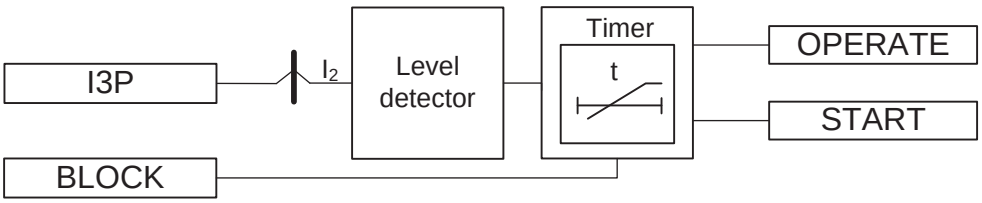

Figure 475: Functional module diagram

Level detector

The level detector compares the negative-sequence current to the set *Start value*. If the I_2 value exceeds the set *Start value*, the level detector sends an enabling signal to the timer module.

Timer

Once activated, the timer activates the `START` output. When the operation timer has reached the set *Operate delay time* value, the `OPERATE` output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value of 200 ms, the operation timer resets and the `START` output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

4.4.4.6 Application

The rotation of a motor in the reverse direction is not a desirable operating condition. When the motor drives fans and pumps, for example, and the rotation direction is reversed due to a wrong phase sequence, the driven process can be disturbed and the flow of the cooling air of the motor can become reversed too. With a motor designed only for a particular rotation direction, the reversed rotation direction can lead to an inefficient cooling of the motor due to the fan design.

In a motor, the value of the negative-sequence component of the phase currents is very negligible when compared to the positive-sequence component of the current during a healthy operating condition of the motor. But when the motor is started with the phase connections in the reverse order, the magnitude of I_2 is very high. So whenever the value of I_2 exceeds the start value, the function detects the reverse rotation direction and provides an operating signal that disconnects the motor from the supply.

4.4.5 Negative-sequence overcurrent protection for machines MNSPTOC (ANSI 46M)

4.4.5.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Negative-sequence overcurrent protection for machines	MNSPTOC	I2>M	46M

4.4.5.2 Function block

Figure 476: Function block

4.4.5.3 Functionality

The negative-sequence overcurrent protection for machines function MNSPTOC protects electric motors from phase unbalance. A small voltage unbalance can produce a large negative-sequence current flow in the motor. For example, a 5 percent voltage unbalance produces a stator negative-sequence current of 30 percent of the full load current, which can severely heat the motor. MNSPTOC detects the large negative-sequence current and disconnects the motor.

The function contains a blocking functionality. It is possible to block the function outputs, timers or the function itself.

[1] Negative-sequence current before = 0.0, f_n = 50 Hz, results based on statistical distribution of 1000 measurements.
[2] Includes the delay of the signal output contact.

4.4.5.4 Analog channel configuration

MNSPTOC has one analog group input which must be properly configured.

Table 769: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.4.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of MNSPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

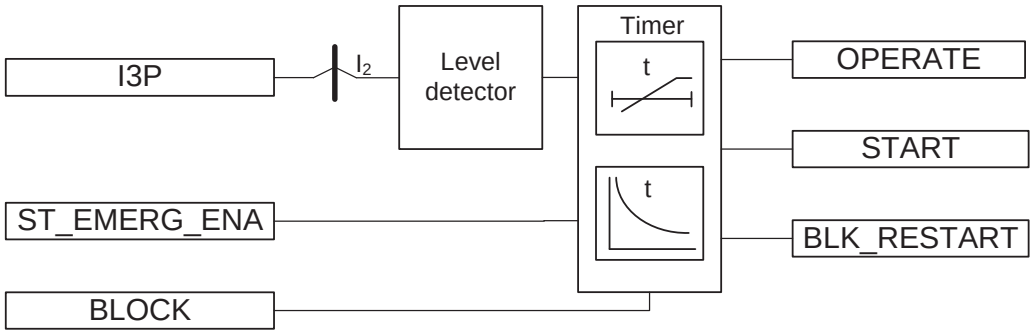

Figure 477: Functional module diagram

Level detector

The calculated negative-sequence current is compared to the *Start value* setting. If the measured value exceeds the *Start value* setting, the function activates the timer module.

Timer

Once activated, the timer activates the `START` output. Depending on the value of the set *Operating curve type*, the time characteristics are according to DT or IDMT. When the operation timer has reached the value set by *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the `OPERATE` output is activated.

In a drop-off situation, that is, when the value of the negative-sequence current drops below the *Start value* setting, the reset timer is activated and the START output resets after the time delay of *Reset delay time* for the DT characteristics. For IDMT, the reset time depends on the curve type selected.

For the IDMT curves, it is possible to define minimum and maximum operate times with the *Minimum operate time* and *Maximum operate time* settings. The *Machine time Mult* setting parameter corresponds to the machine constant, equal to the I_2^2t constant of the machine, as stated by the machine manufacturer. In case there is a mismatch between the used CT and the protected motor's nominal current values, it is possible to fit the IDMT curves for the protected motor using the *Current reference* setting.

The activation of the OPERATE output activates the BLK_RESTART output. The deactivation of the OPERATE output activates the cooling timer. The timer is set to the value entered in the *Cooling time* setting. The BLK_RESTART output is kept active until the cooling timer is exceeded. If the negative-sequence current increases above the set value during this period, the OPERATE output is activated immediately.

T_ENARESTART indicates the duration for which the BLK_RESTART output remains active, that is, it indicates the remaining time of the cooling timer. The value is available in the monitored data view.

When the ST_EMERG_ENA emergency start is set high, the value of the T_ENARESTART is immediately set to "False". This disables BLK_RESTART and in turn makes the restart of the motor possible.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

The T_ENARESTART output indicates the duration for which the BLK_RESTART output remains active, that is, it indicates the remaining time of the cooling timer. The value is available in the monitored data view.

When the ST_EMERG_ENA emergency start is set high, the value of the T_ENARESTART is immediately set to "False". This disables BLK_RESTART and in turn makes the restart of the motor possible.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

4.4.5.6 Timer characteristics

MNSPTOC supports both DT and IDMT characteristics. The DT timer characteristics can be selected with "ANSI Def. Time" or "IEC Def. Time" in the *Operating curve type* setting. The functionality is identical in both cases. When the DT characteristics are selected, the functionality is only affected by the *Operate delay time* and *Reset delay time* settings.

The protection relay provides two user-programmable IDMT characteristics curves, "Inv. curve A" and "Inv. curve B".

Current-based inverse definite minimum time curve (IDMT)

In inverse-time modes, the operate time depends on the momentary value of the current: the higher the current, the shorter the operate time. The operate time

calculation or integration starts immediately when the current exceeds the set *Start value* and the START output is activated.

The OPERATE output of the component is activated when the cumulative sum of the integrator calculating the overcurrent situation exceeds the value set by the inverse time mode. The set value depends on the selected curve type and the setting values used.

The *Minimum operate time* and *Maximum operate time* settings define the minimum operate time and maximum operate time possible for the IDMT mode. For setting these parameters, a careful study of the particular IDMT curves is recommended.

Inv. curve A

The inverse time equation for curve type A is:

$$t[s] = \frac{k}{\left(\frac{I_2}{I_r}\right)^2}$$

(Equation 237)

t[s]	Operate time in seconds
k	Set *Machine time Mult*
I_2	Negative-sequence current
I_r	Set *Rated current*

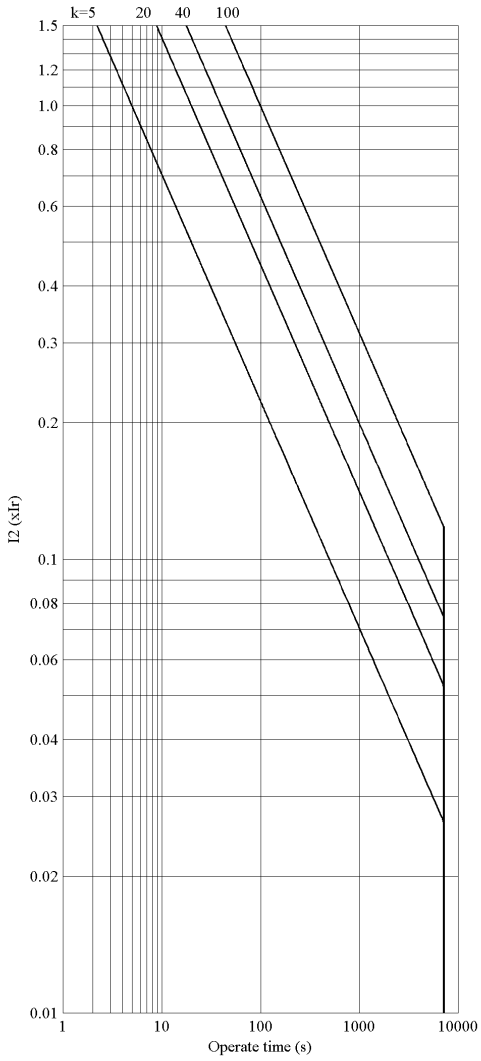

Figure 478: MNSPTOC Inverse Curve A

If the negative sequence current drops below the *Start value* setting, the reset time is defined as:

$$t[s] = a \times \left(\frac{b}{100} \right)$$

(Equation 238)

t[s]	Reset time in seconds
a	set *Cooling time*
b	percentage of start time elapse (START_DUR)

When the reset period is initiated, the time for which START has been active is saved. If the fault reoccurs, that is, the negative-sequence current rises above the

set value during the reset period, the operate calculations are continued using the saved values. If the reset period elapses without a fault being detected, the operate timer is reset and the saved values of start time and integration are cleared.

Inv. curve B

The inverse time equation for curve type B is:

$$t[s] = \frac{k}{\left(\frac{I_2}{I_r}\right)^2 - \left(\frac{I_S}{I_r}\right)^2}$$

(Equation 239)

t[s]	Operate time in seconds
k	*Machine time Mult*
I_2	Negative-sequence current
I_S	Set *Start value*
I_r	Set *Rated current*

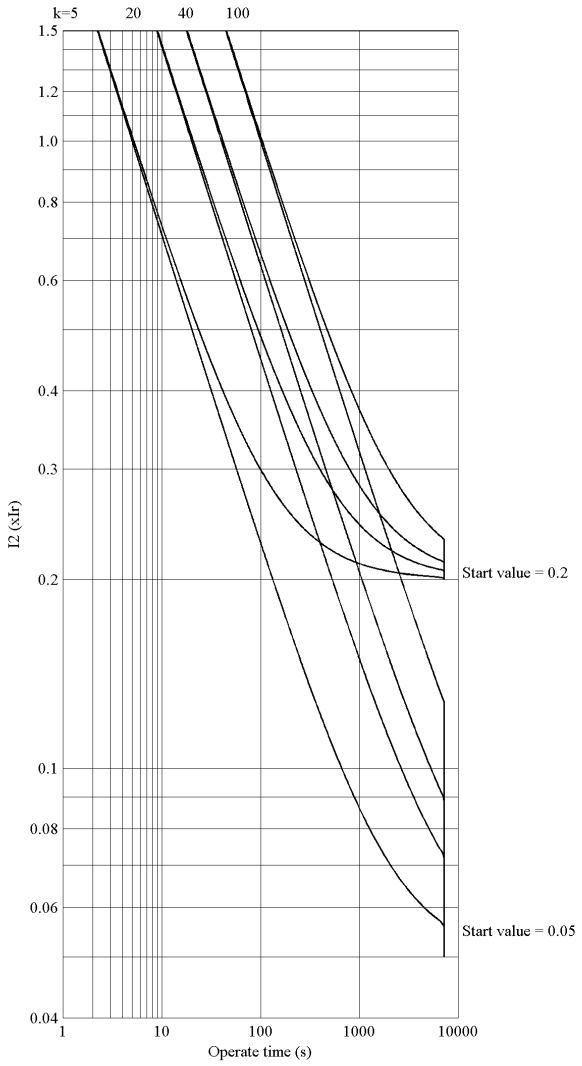

Figure 479: MNSPTOC Inverse Curve B

If the fault disappears, the negative-sequence current drops below the *Start value* setting and the START output is deactivated. The function does not reset instantaneously. Resetting depends on the equation or the *Cooling time* setting.

The timer is reset in three ways:

- When the negative sequence current drops below start value the subtraction in the denominator becomes negative and the cumulative sum starts to decrease. The decrease in the sum indicates the cooling of the machine and the cooling speed depends on the value of the negative-sequence current. If the sum reaches zero without a fault being detected, the accumulation stops and the timer is reset.
- If the reset time set through the *Cooling time* setting elapses without a fault being detected, the timer is reset.
- If ST_EMERG_ENA is activated, the timer is reset.

The reset period thus continues for a time equal to the *Cooling time* setting or until the operate time decreases to zero, whichever is less.

4.4.5.7 Application

In a three-phase motor, the conditions that can lead to unbalance are single phasing, voltage unbalance from the supply and single-phase fault. The negative sequence current damages the motor during the unbalanced voltage condition, and therefore the negative sequence current is monitored to check the unbalance condition.

When the voltages supplied to an operating motor become unbalanced, the positive-sequence current remains substantially unchanged, but the negative-sequence current flows due to the unbalance. For example, if the unbalance is caused by an open circuit in any phase, a negative-sequence current flows and it is equal and opposite to the previous load current in a healthy phase. The combination of positive and negative-sequence currents produces phase currents approximately 1.7 times the previous load in each healthy phase and zero current in the open phase.

The negative-sequence currents flow through the stator windings inducing negative-sequence voltage in the rotor windings. This can result in a high rotor current that damages the rotor winding. The frequency of the induced current is approximately twice the supply frequency. Due to skin effect, the induced current with a frequency double the supply frequency encounters high rotor resistance which leads to excessive heating even with phase currents with value less than the rated current of the motor.

The negative-sequence impedance of induction or a synchronous motor is approximately equal to the locked rotor impedance, which is approximately one-sixth of the normal motor impedance, considering that the motor has a locked-rotor current of six times the rated current. Therefore, even a three percent voltage unbalance can lead to 18 percent stator negative sequence current in windings. The severity of this is indicated by a 30-40 percent increase in the motor temperature due to the extra current.

4.5.1 Three-phase overvoltage protection PHPTOV (ANSI 59)

4.5.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase overvoltage protection	PHPTOV	3U>	59

4.5.1.2 Function block

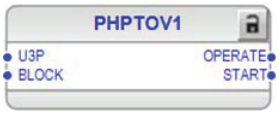

Figure 480: Function block

4.5.1.3 Functionality

The three-phase overvoltage protection function PHPTOV is applied on power system elements, such as generators, transformers, motors and power lines, to protect the system from excessive voltages that could damage the insulation and cause insulation breakdown. The three-phase overvoltage function includes a settable value for the detection of overvoltage either in a single phase, two phases or three phases.

PHPTOV includes both definite time (DT) and inverse definite minimum time (IDMT) characteristics for the delay of the trip.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.5.1.4 Analog channel configuration

PHPTOV has one analog group input which must be properly configured.

Table 778: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 779: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected if *Num of start phases* is set to "1 out of 3". Otherwise, at least two vol-

Condition	Description
	tages must be connected (third one will be derived).

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PHPTOV can be described using a module diagram. All the modules in the diagram are explained in the next sections.

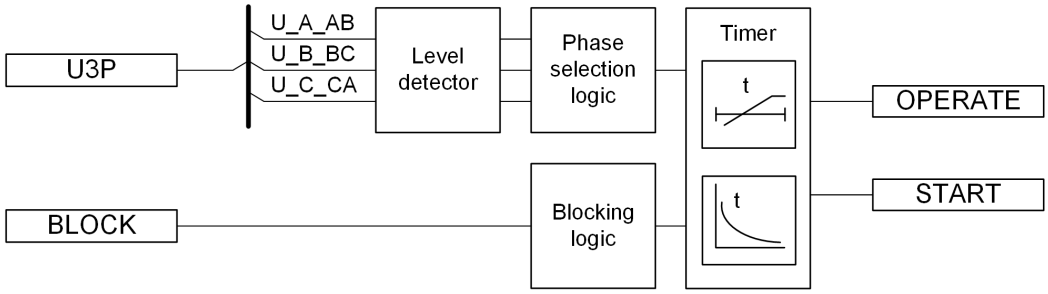

Figure 481: Functional module diagram

Level detector

The fundamental frequency component of the measured three-phase voltages are compared phase-wise to the set value of the *Start value* setting. If the measured value is higher than the set value of the *Start value* setting, the level detector enables the phase selection logic module. The *Relative hysteresis* setting can be used for preventing unnecessary oscillations if the input signal slightly differs from the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return to the hysteresis area.

The *Voltage selection* setting is used for selecting phase-to-earth or phase-to-phase voltages for protection.

For the voltage IDMT operation mode, the used IDMT curve equations contain discontinuity characteristics. The *Curve Sat Relative* setting is used for preventing undesired operation.

For a more detailed description of the IDMT curves and the use of the *Curve Sat Relative* setting, see *Chapter 11.3.1.3 IDMT curve saturation of overvoltage protection* in this manual.

Phase selection logic

If the fault criteria are fulfilled in the level detector, the phase selection logic detects the phase or phases in which the fault level is detected. If the number of faulty

phases match with the set *Num of start phases*, the phase selection logic activates the Timer.

Timer

Once activated, the Timer activates the START output. Depending on the value of the set *Operating curve type*, the time characteristics are selected according to DT or IDMT.

For a detailed description of the voltage IDMT curves, see *Chapter 11.2.1 IDMT curves for overcurrent protection* in this manual.

When the operation timer has reached the value set by *Operate delay time* in the DT mode or the maximum value defined by the IDMT, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operate time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation occurs, that is, a fault suddenly disappears before the operate delay is exceeded, the reset state is activated. The behavior in the drop-off situation depends on the selected operate time characteristics. If the DT characteristics are selected, the reset timer runs until the set *Reset delay time* value is exceeded. If the drop-off situation exceeds the set *Reset delay time*, the Timer is reset and the START output is deactivated.

When the IDMT operate time curve is selected, the functionality of the Timer in the drop-off state depends on the combination of the *Type of reset curve*, *Type of time reset* and *Reset delay time* settings.

Table 780: Reset time functionality when IDMT operation time curve selected

Reset functionality		Setting Type of reset curve	Setting Type of time reset	Setting Reset delay time
Instantaneous reset	Operation timer is “Reset instantaneously” when drop-off occurs	“Immediate”	Setting has no effect	Setting has no effect
Frozen timer	Operation timer is frozen during drop-off	“Def time reset”	“Freeze Op timer”	Operate timer is reset after the set *Reset delay time* has elapsed
Linear decrease	Operation timer value linearly decreases during the drop-off situation	“Def time reset”	“Decrease Op timer”	Operate timer is reset after the set *Reset delay time* has elapsed

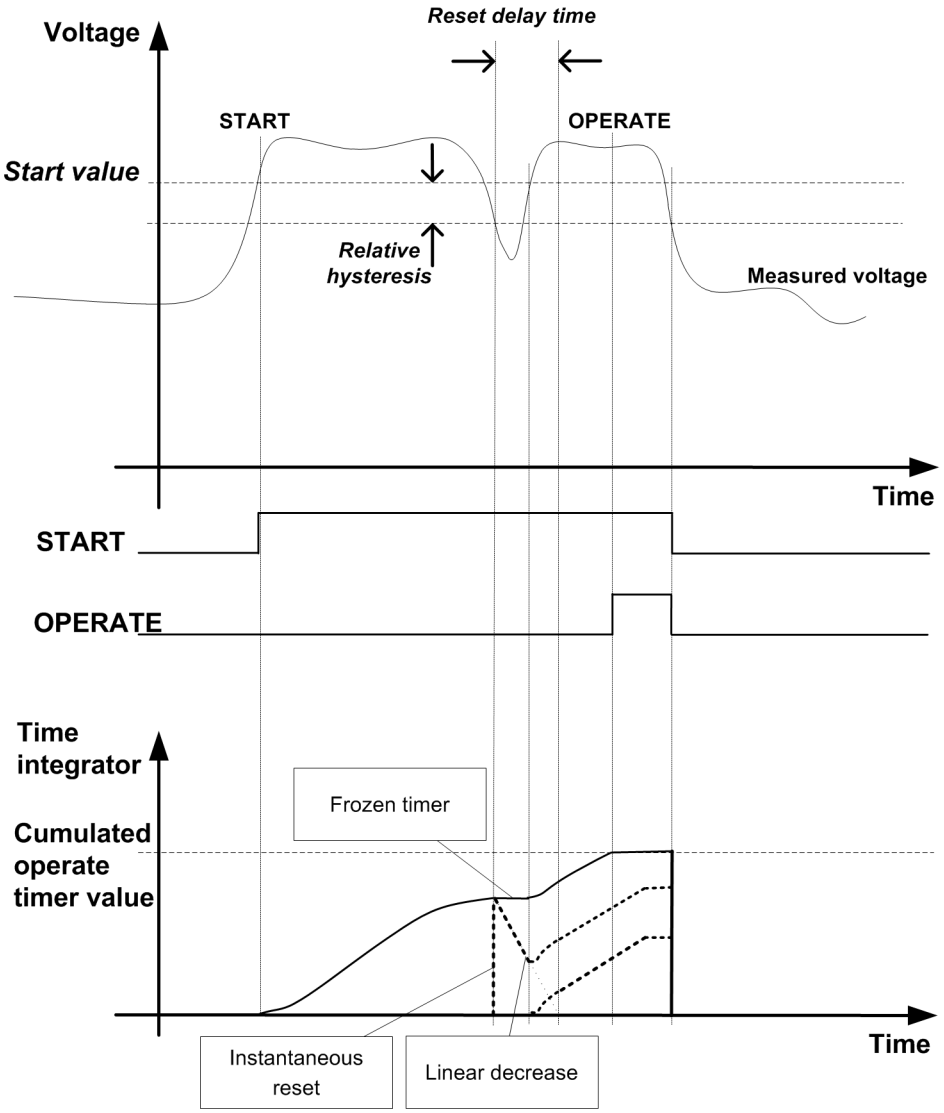

Figure 482: Behavior of different IDMT reset modes. Operate signal is based on settings Type of reset curve = "Def time reset" and Type of time reset= "Freeze Op timer". The effect of other reset modes is also presented

The *Time multiplier* setting is used for scaling the IDMT operate times.

The *Minimum operate time* setting parameter defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.3.1 IDMT curves for overvoltage protection* in this manual.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK input signal activation is preselected with the global *Blocking mode* setting.

The *Blocking mode* setting has three blocking methods. In the "Freeze timer" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the Timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

The “Freeze timers” mode of blocking has no effect during the inverse reset mode.

4.5.1.6 Timer characteristics

The operating curve types supported by PHPTOV are:

Table 781: Timer characteristics supported by IDMT operate curve types

Operating curve type
(5) ANSI Def. Time
(15) IEC Def. Time
(17) Inv. Curve A
(18) Inv. Curve B
(19) Inv. Curve C
(20) Programmable

4.5.1.7 Application

Overvoltage in a network occurs either due to the transient surges on the network or due to prolonged power frequency overvoltages. Surge arresters are used to protect the network against the transient overvoltages, but the relay's protection function is used to protect against power frequency overvoltages.

The power frequency overvoltage may occur in the network due to contingencies such as:

- The defective operation of the automatic voltage regulator when the generator is in isolated operation.
- Operation under manual control with the voltage regulator out of service. A sudden variation of load, in particular the reactive power component, gives rise to a substantial change in voltage because of the inherent large voltage regulation of a typical alternator.
- Sudden loss of load due to the tripping of outgoing feeders, leaving the generator isolated or feeding a very small load. This causes a sudden rise in the terminal voltage due to the trapped field flux and overspeed.

If a load sensitive to overvoltage remains connected, it leads to equipment damage.

It is essential to provide power frequency overvoltage protection, in the form of time delayed element, either IDMT or DT to prevent equipment damage.

Three-phase undervoltage protection	PHPTUV	3U<	27

4.5.2.2 Function block

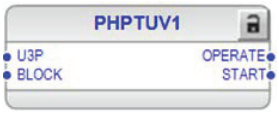

Figure 483: Function block

4.5.2.3 Functionality

The three-phase undervoltage protection function PHPTUV is used to disconnect from the network devices, for example electric motors, which are damaged when subjected to service under low voltage conditions. PHPTUV includes a settable value

[1] *Start value* = 1.0 × U_n, Voltage before fault = 0.9 × U_n, f_n = 50 Hz, overvoltage in one phase-to-phase with nominal frequency injected from random phase angle, results based on statistical distribution of 1000 measurements
[2] Includes the delay of the signal output contact
[3] Maximum *Start value* = 1.20 × U_n, *Start value* multiples in range of 1.10...2.00

for the detection of undervoltage either in a single phase, two phases or three phases.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.5.2.4 Analog channel configuration

PHPTUV has one analog group input which must be properly configured.

Table 790: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 791: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected if *Num of start phases* is set to "1 out of 3" but the other two channels must be fed with high values (considerably above *Start value*). For other values of *Num of start phases*, all three voltage channels must be connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PHPTUV can be described using a module diagram. All the modules in the diagram are explained in the next sections.

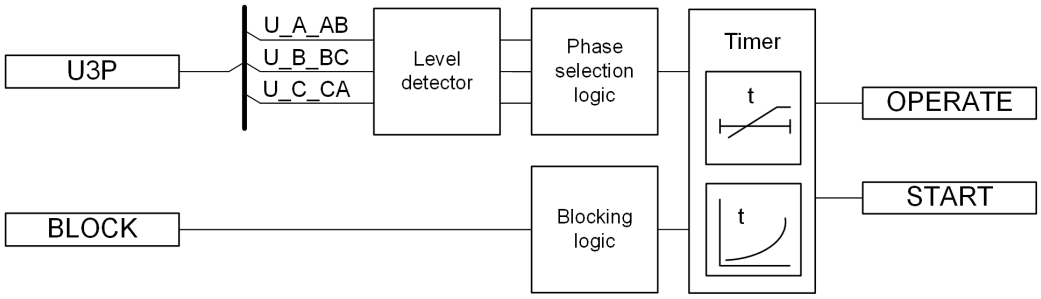

Figure 484: Functional module diagram

Level detector

The fundamental frequency component of the measured three phase voltages are compared phase-wise to the set *Start value*. If the measured value is lower than the set value of the *Start value* setting, the level detector enables the phase selection logic module. The *Relative hysteresis* setting can be used for preventing unnecessary oscillations if the input signal slightly varies above or below the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return back to the hysteresis area.

The *Voltage selection* setting is used for selecting the phase-to-earth or phase-to-phase voltages for protection.

For the voltage IDMT mode of operation, the used IDMT curve equations contain discontinuity characteristics. The *Curve Sat relative* setting is used for preventing unwanted operation.

For more detailed description on IDMT curves and usage of *Curve Sat Relative* setting, see *Chapter 11.3.2 IDMT curves for undervoltage protection* in this manual.

The level detector contains a low-level blocking functionality for cases where one of the measured voltages is below the desired level. This feature is useful when unnecessary starts and operates are wanted to avoid during, for example, an autoreclose sequence. The low-level blocking is activated by default (*Enable block value* is set to "True") and the blocking level can be set with the *Voltage block value* setting.

Phase selection logic

If the fault criteria are fulfilled in the level detector, the phase selection logic detects the phase or phases in which the fault level is detected. If the number of faulty phases match with the set *Num of start phases*, the phase selection logic activates the Timer.

Timer

Once activated, the Timer activates the START output. Depending on the value of the set *Operating curve type*, the time characteristics are selected according to DT or IDMT.

For a detailed description of the voltage IDMT curves, see *Chapter 11.3.2 IDMT curves for undervoltage protection* in this manual.

When the operation timer has reached the value set by *Operate delay time* in the DT mode or the maximum value defined by the IDMT, the OPERATE output is activated.

When the user-programmable IDMT curve is selected, the operate time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C*, *Curve parameter D* and *Curve parameter E*.

If a drop-off situation occurs, that is, a fault suddenly disappears before the operate delay is exceeded, the reset state is activated. The behavior in the drop-off situation depends on the selected operate time characteristics. If the DT characteristics are selected, the reset timer runs until the set *Reset delay time* value is exceeded. If the drop-off situation exceeds the set *Reset delay time*, the Timer is reset and the START output is deactivated.

When the IDMT operate time curve is selected, the functionality of the Timer in the drop-off state depends on the combination of the *Type of reset curve*, *Type of time reset* and *Reset delay time* settings.

Table 792: Reset time functionality when IDMT operation time curve selected

Reset functionality		Setting Type of reset curve	Setting Type of time reset	Setting Reset delay time
Instantaneous reset	Operation timer is “Reset instantaneously” when drop-off occurs	“Immediate”	Setting has no effect	Setting has no effect
Frozen timer	Operation timer is frozen during drop-off	“Def time reset”	“Freeze Op timer”	Operate timer is reset after the set *Reset delay time* has elapsed
Linear decrease	Operation timer value linearly decreases during the drop-off situation	“Def time reset”	“Decrease Op timer”	Operate timer is reset after the set *Reset delay time* has elapsed

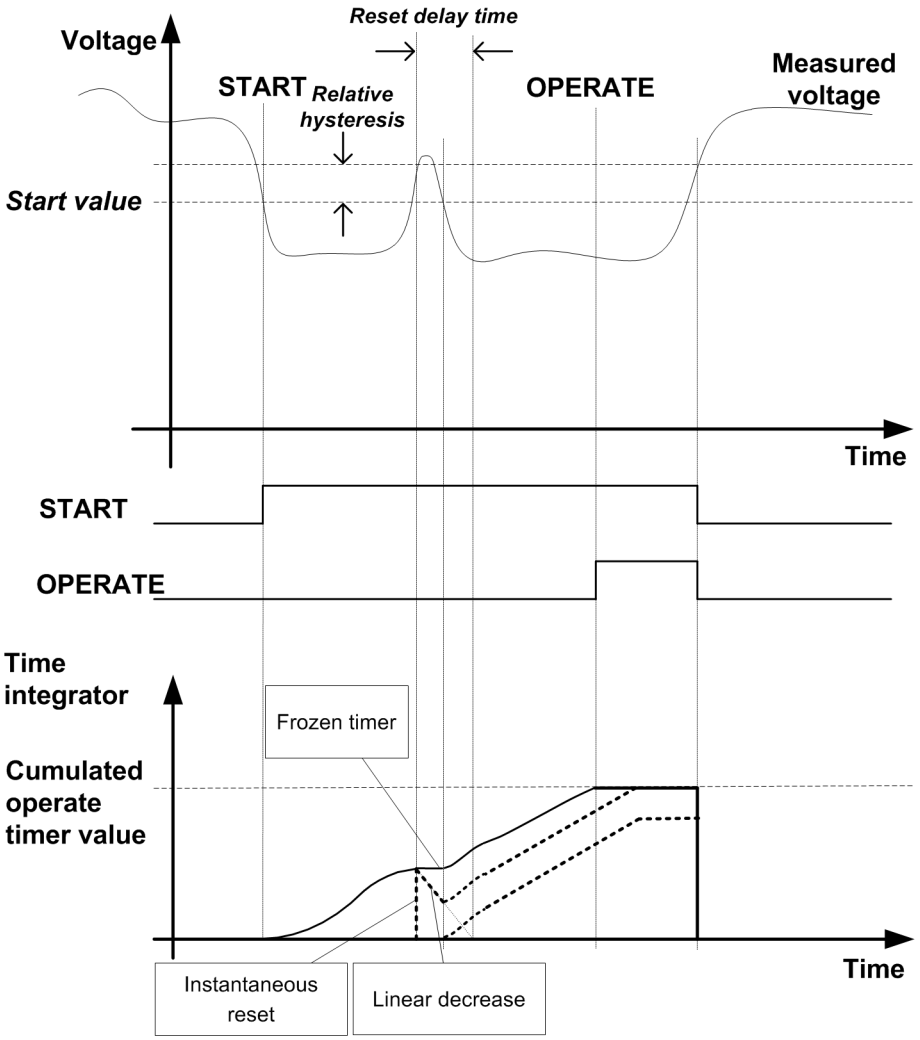

Figure 485: Behavior of different IDMT reset modes. Operate signal is based on settings Type of reset curve = "Def time reset" and Type of time reset= "Freeze Op timer". The effect of other reset modes is also presented

The *Time multiplier* setting is used for scaling the IDMT operate times.

The *Minimum operate time* setting parameter defines the minimum desired operate time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting. For more information, see *Chapter 11.3.2 IDMT curves for undervoltage protection* in this manual.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled

by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK input signal activation is preselected with the global *Blocking mode* setting.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the Timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

The “Freeze timers” mode of blocking has no effect during the “Inverse reset” mode.

4.5.2.6 Timer characteristics

The operating curve types supported by PHPTUV are:

Table 793: Supported IDMT operate curve types

Operating curve type
(5) ANSI Def. Time
(15) IEC Def. Time
(21) Inv. Curve A
(22) Inv. Curve B
(23) Programmable

4.5.2.7 Application

PHPTUV is applied to power system elements, such as generators, transformers, motors and power lines, to detect low voltage conditions. Low voltage conditions are caused by abnormal operation or a fault in the power system. PHPTUV can be used in combination with overcurrent protections. Other applications are the detection of a no-voltage condition, for example before the energization of a high voltage line, or an automatic breaker trip in case of a blackout. PHPTUV is also used to initiate voltage correction measures, such as insertion of shunt capacitor banks, to compensate for a reactive load and thereby to increase the voltage.

PHPTUV can be used to disconnect from the network devices, such as electric motors, which are damaged when subjected to service under low voltage conditions. PHPTUV deals with low voltage conditions at power system frequency. Low voltage conditions can be caused by:

- Malfunctioning of a voltage regulator or incorrect settings under manual control (symmetrical voltage decrease)
- Overload (symmetrical voltage decrease)
- Short circuits, often as phase-to-earth faults (unsymmetrical voltage increase).

PHPTUV prevents sensitive equipment from running under conditions that could cause overheating and thus shorten their life time expectancy. In many cases, PHPTUV is a useful function in circuits for local or remote automation processes in the power system.

4.5.3 Residual overvoltage protection ROVPTOV (ANSI 59G/59N)

4.5.3.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Residual overvoltage protection	ROVPTOV	Uo>	59G/59N

[1] *Start value* = 0.97 × U_n, voltage level before fault = 1 × U_n, f_n = 50 Hz, undervoltage in one phase-to-phase voltage injected from random phase angle, results based on statistical distribution of 1000 measurements, includes the delay (≈0ms) of the static signal output (SSO) contact

[2] Start time is accelerated when set *Operate delay time* < 60ms. The shorter the set delay, the shorter the start time. Here measurements done for *Operate delay time* = 20ms

[3] Valid when set *Operate delay time* ≥ 60ms or inverse time curve selected

[4] Minimum *Start value* = 0.50, *Start value* multiples in range of 0.90...0.20

4.5.3.2 Function block

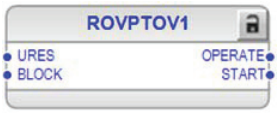

Figure 486: Function block

4.5.3.3 Functionality

The residual overvoltage protection function ROVPTOV is used in distribution networks where the residual overvoltage can reach non-acceptable levels in, for example, high impedance earthing.

The function starts when the residual voltage exceeds the set limit. ROVPTOV operates with the definite time (DT) characteristic.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.5.3.4 Analog channel configuration

ROVPTOV has one analog group input which must be properly configured.

Table 803: Analog inputs

Input	Description
URES	Residual voltage (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 804: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected to calculate residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of ROVPTOV can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

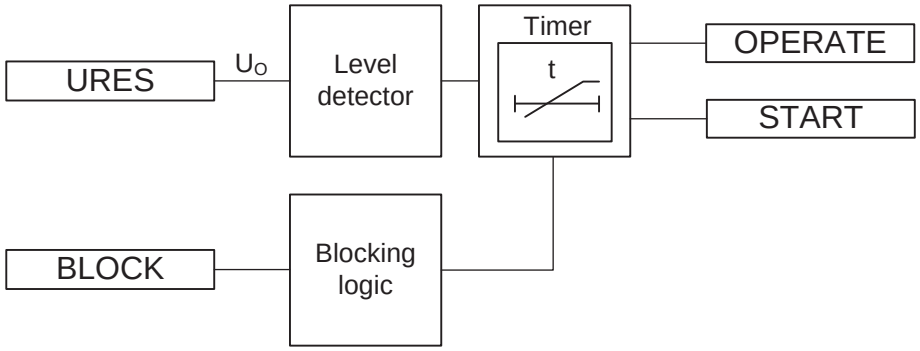

Figure 487: Functional module diagram

Level detector

The residual voltage is compared to the set *Start value*. If the value exceeds the set *Start value*, the level detector sends an enable signal to the timer.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If the fault disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.5.3.6 Application

ROVPTOV is designed to be used for earth-fault protection in isolated neutral, resistance earthed or reactance earthed systems. In compensated networks, starting of the function can be used to control the switching device of the neutral resistor. The function can also be used for the back-up protection of feeders for busbar protection when a more dedicated busbar protection would not be justified.

In compensated and isolated neutral systems, the system neutral voltage, that is, the residual voltage, increases in case of any fault connected to earth. Depending on the type of the fault and the fault resistance, the residual voltage reaches different values. The highest residual voltage, equal to the phase-to-earth voltage, is achieved for a single-phase earth fault. The residual voltage increases approximately the same amount in the whole system and does not provide any guidance in finding the faulty component. Therefore, this function is often used as a backup protection or as a release signal for the feeder earth-fault protection.

The protection can also be used for the earth-fault protection of generators and motors and for the unbalance protection of capacitor banks.

The residual voltage can be calculated internally based on the measurement of the three-phase voltage. This voltage can also be measured by a single-phase voltage transformer, located between a transformer star point and earth, or by using an open-delta connection of three single-phase voltage transformers.

4.5.4 Positive-sequence overvoltage protection PSPTOV (ANSI 59PS)

4.5.4.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Positive-sequence overvoltage protection	PSPTOV	U1>	59PS

4.5.4.2 Function block

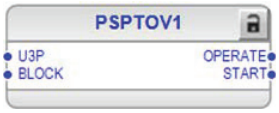

Figure 488: Function block

4.5.4.3 Functionality

The positive-sequence overvoltage protection function PSPTOV is used as an alternative to the ordinary three-phase overvoltage protection. PSPTOV is used for supervision and for detection of abnormal conditions, and, together with the other protection functions, increases the security of the protection system.

The function starts when the positive-sequence voltage exceeds the set limit. PSPTOV operates on definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.5.4.4 Analog channel configuration

PSPTOV has one analog group input which must be properly configured.

Table 812: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 813: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PSPTOV can be described with a module diagram. All the modules in the diagram are explained in the next sections.

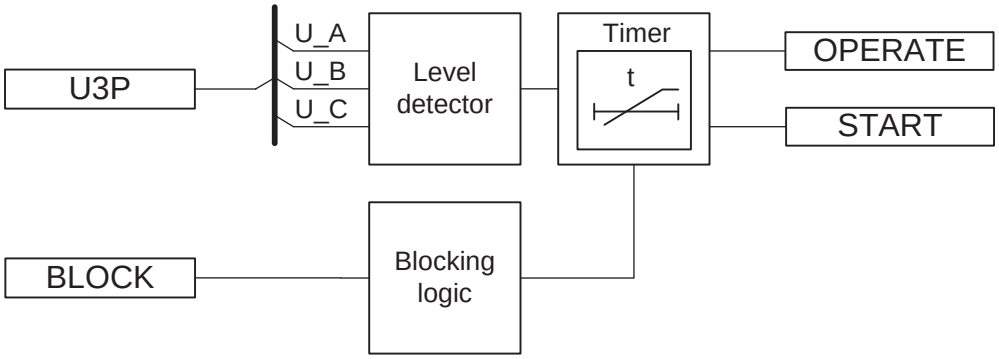

Figure 489: Functional module diagram

Level detector

The calculated positive-sequence voltage is compared to the set *Start value* setting. If the value exceeds the set *Start value*, the level detector enables the timer. The *Relative hysteresis* setting can be used for preventing unnecessary oscillations if the input signal slightly varies from the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return to the hysteresis area.

Timer

Once activated, Timer activates the `START` output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the `OPERATE` output is activated if the overvoltage condition persists. If the positive-sequence voltage normalizes before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the `START` output is deactivated.

Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

Blocking logic

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates all outputs and resets internal timers.

4.5.4.6 Application

A sudden power loss, tap changer regulating failures and open line ends on long lines are abnormal conditions which cause overvoltage in a power system. PSPTOV is applied to power system elements, such as generators, transformers, motors and power lines, to detect overvoltage conditions.

PSPTOV can be used in combination with low-current signals or a directional reactive overpower function to identify the distribution line with an open remote end. PSPTOV can also be used to initiate voltage correction measures, such as insertion of shunt reactors or switching out capacitor banks, to control the voltage.

Overvoltage faced by the power transformer can lead to an overexcitation problem. Overexcitation normally occurs when the voltage-to-frequency ratio increases much above the design value resulting into transformer operation under a nonlinear region. A transformer can be in such an overvoltage situation during a sudden loss of load due to underfrequency load shedding. Overexcitation results in an increase of the exciting current which leads to core heating and thus to transformer damage. PSPTOV along with the underfrequency protection can be used for the protection of the transformer during overexcitation.

Some common reasons leading to positive-sequence overvoltages are:

- Broken conductor falling to a crossing overhead line, transformer flash overfault from high-voltage winding to low-voltage winding
- Malfunctioning of a voltage regulator or wrong settings under manual control (symmetrical voltage increase)
- Low load compared to the reactive power generation (symmetrical voltage increase)

PSPTOV prevents sensitive equipment from running under overvoltage conditions which cause equipment overheating or stress on insulation material.

4.5.5 Negative-sequence overvoltage protection NSPTOV (ANSI 59NS)

4.5.5.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Negative-sequence overvoltage protection	NSPTOV	U2>	59NS

4.5.5.2 Function block

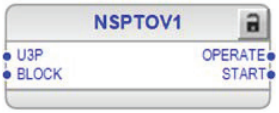

Figure 490: Function block

4.5.5.3 Functionality

The negative-sequence overvoltage protection function NSPTOV is used to detect negative sequence overvoltage conditions. NSPTOV is used for the protection of machines.

The function starts when the negative sequence voltage exceeds the set limit. NSPTOV operates with the definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

[1] Positive-sequence voltage before fault = 0.0 × U_n, f_n = 50 Hz, positive-sequence overvoltage of nominal frequency injected from random phase angle
[2] Measured with static signal output (SSO)

4.5.5.4 Analog channel configuration

NSPTOV has one analog group input which must be properly configured.

Table 821: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 822: Special conditions

Condition	Description
U3P connected to real measurements	The function requires that any two voltage channels are connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of NSPTOV can be described using a module diagram. All the modules in the diagram are explained in the next sections.

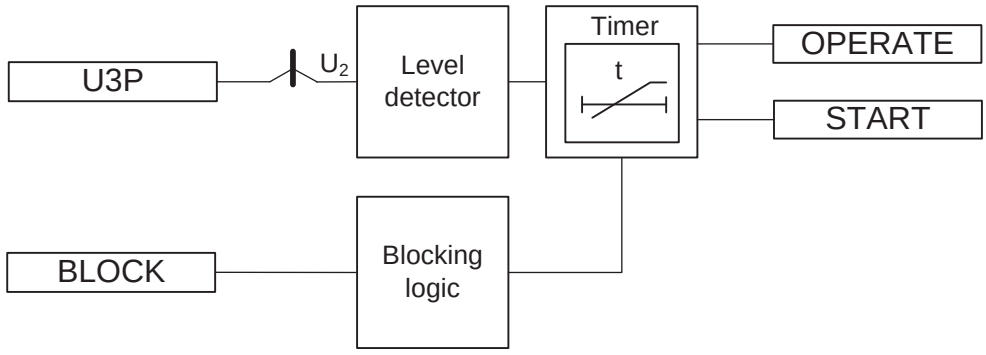

Figure 491: Functional module diagram

Level detector

The calculated negative-sequence voltage is compared to the set *Start value* setting. If the value exceeds the set *Start value*, the level detector enables the timer.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated if the overvoltage condition persists. If the negative-sequence voltage normalizes before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.5.5.6 Application

A continuous or temporary voltage unbalance can appear in the network for various reasons. The voltage unbalance mainly occurs due to broken conductors or asymmetrical loads and is characterized by the appearance of a negative-sequence component of the voltage. In rotating machines, the voltage unbalance results in a current unbalance, which heats the rotors of the machines. The rotating machines, therefore, do not tolerate a continuous negative-sequence voltage higher than typically 1-2 percent x U_n.

The negative-sequence component current I_2, drawn by an asynchronous or a synchronous machine, is linearly proportional to the negative-sequence component voltage U_2. When U_2 is P% of U_n, I_2 is typically about 5 x P% x I_n.

The negative-sequence overcurrent NSPTOC blocks are used to accomplish a selective protection against the voltage and current unbalance for each machine separately. Alternatively, the protection can be implemented with the NSPTOV function, monitoring the voltage unbalance of the busbar.

If the machines have an unbalance protection of their own, the NSPTOV operation can be applied as a backup protection or it can be used as an alarm. The latter can be applied when it is not required to trip loads tolerating voltage unbalance better than the rotating machines.

If there is a considerable degree of voltage unbalance in the network, the rotating machines should not be connected to the network at all. This logic can be implemented by inhibiting the closure of the circuit breaker if the NSPTOV operation has started. This scheme also prevents connecting the machine to the network if the phase sequence of the network is not correct.

An appropriate value for the setting parameter *Voltage start value* is approximately 3 percent of U_n. A suitable value for the setting parameter *Operate delay time* depends on the application. If the NSPTOV operation is used as backup protection, the operate time should be set in accordance with the operate time of NSPTOC used as main protection. If the NSPTOV operation is used as main protection, the operate time should be approximately one second.

[2] Includes the delay of the signal output contact

4.5.6.2 Function block

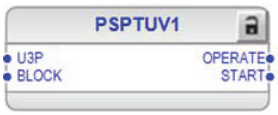

Figure 492: Function block

4.5.6.3 Functionality

The positive-sequence undervoltage protection function PSPTUV is used to detect positive-sequence undervoltage conditions. PSPTUV is used for the protection of small power generation plants. The function helps in isolating an embedded plant from a fault line when the fault current fed by the plant is too low to start an overcurrent function but high enough to maintain the arc. Fast isolation of all the fault current sources is necessary for a successful autoreclosure from the network-end circuit breaker.

The function starts when the positive-sequence voltage drops below the set limit. PSPTUV operates with the definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.5.6.4 Analog channel configuration

PSPTUV has one analog group input which must be properly configured.

Table 830: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 831: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.6.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PSPTUV can be described using a module diagram. All the modules in the diagram are explained in the next sections.

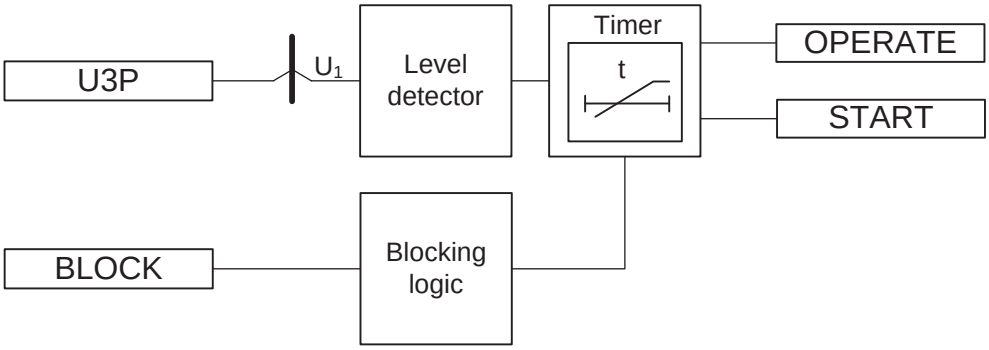

Figure 493: Functional module diagram. U1 is used for representing positive phase sequence voltage.

Level detector

The calculated positive-sequence voltage is compared to the set *Start value* setting. If the value drops below the set *Start value*, the level detector enables the timer. The *Relative hysteresis* setting can be used for preventing unnecessary oscillations if the input signal slightly varies from the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return to the hysteresis area.

The level detector contains a low-level blocking functionality for cases where the positive-sequence voltage is below the desired level. This feature is useful when unnecessary starts and operates are wanted to avoid during, for example, an autoreclose sequence. The low-level blocking is activated by default (*Enable block value* is set to “Enabled”) and the blocking level can be set with the *Voltage block value* setting.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated if the undervoltage condition persists. If the positive-sequence voltage normalizes before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can

be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.5.6.6 Application

PSPTUV can be applied for protecting a power station used for embedded generation when network faults like short circuits or phase-to-earth faults in a transmission or a distribution line cause a potentially dangerous situations for the power station. A network fault can be dangerous for the power station for various reasons. The operation of the protection can cause an islanding condition, also called a loss-of-mains condition, in which a part of the network, that is, an island fed by the power station, is isolated from the rest of the network. There is then a risk of an autoreclosure taking place when the voltages of different parts of the network do not synchronize, which is a straining incident for the power station. Another risk is that the generator can lose synchronism during the network fault. A sufficiently fast trip of the utility circuit breaker of the power station can avoid these risks.

The lower the three-phase symmetrical voltage of the network is, the higher is the probability that the generator loses the synchronism. The positive-sequence voltage is also available during asymmetrical faults. It is a more appropriate criterion for detecting the risk of loss of synchronism than, for example, the lowest phase-to-phase voltage.

Analyzing the loss of synchronism of a generator is rather complicated and requires a model of the generator with its prime mover and controllers. The generator can be able to operate synchronously even if the voltage drops by a few tens of percent for some hundreds of milliseconds. The setting of PSPTUV is thus determined by the need to protect the power station from the risks of the islanding conditions since that requires a higher setting value.

The loss of synchronism of a generator means that the generator is unable to operate as a generator with the network frequency but enters into an unstable condition in which it operates by turns as a generator and a motor. Such a condition stresses the generator thermally and mechanically. This kind of loss of synchronism should not be mixed with the one between an island and the utility network. In the islanding situation, the condition of the generator itself is normal but the phase angle and the frequency of the phase-to-phase voltage can be different from the corresponding voltage in the rest of the network. The island can have a frequency of its own relatively fast when fed by a small power station with a low inertia.

PSPTUV complements other loss-of-grid protection principles based on the frequency and voltage operation.

Motor stalling and failure to start can lead to a continuous undervoltage. The positive-sequence undervoltage is used as a backup protection against the motor stall condition.

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Overexcitation protection	OEPVPH	U/f>	24

[1] *Start value* = 1.0 × U_n, positive-sequence voltage before fault = 1.1 × U_n, f_n = 50 Hz, positive sequence undervoltage with nominal frequency injected from random phase angle, results based on statistical distribution of 1000 measurements

[2] Includes the delay of the signal output contact

4.5.7.2 Function block

Figure 494: Function block

4.5.7.3 Functionality

The overexcitation protection function OEPVPH is used to protect generators and power transformers against an excessive flux density and saturation of the magnetic core.

The function calculates the U/f ratio (volts/hertz) proportional to the excitation level of the generator or transformer and compares this value to the setting limit. The function starts when the excitation level exceeds the set limit and operates when the set operating time has elapsed. The operating time characteristic can be selected to be either definite time (DT) or overexcitation inverse definite minimum time (overexcitation type IDMT).

This function contains a blocking functionality. It is possible to block the function outputs, reset timer or the function itself.

4.5.7.4 Analog channel configuration

OEPVPH has two analog group inputs which must be properly configured.

Table 840: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 841: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with at least one voltage channel connected (A, B or C according to *Phase selection* “1”, “2” or “3”) if *Voltage selection* is set to "phase-to-earth".
	The function can work with any two voltage channels connected (AB, BC or CA according

Table continues on the next page

Condition	Description
	to *Phase selection* “1”, “2” or “3”) if *Voltage selection* is set to "phase-to-phase".
	The function requires that all three voltage channels are connected if *Voltage selection* is set to "pos sequence".

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.7.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of OEPVPH can be described using a module diagram. All the modules in the diagram are explained in the next sections.

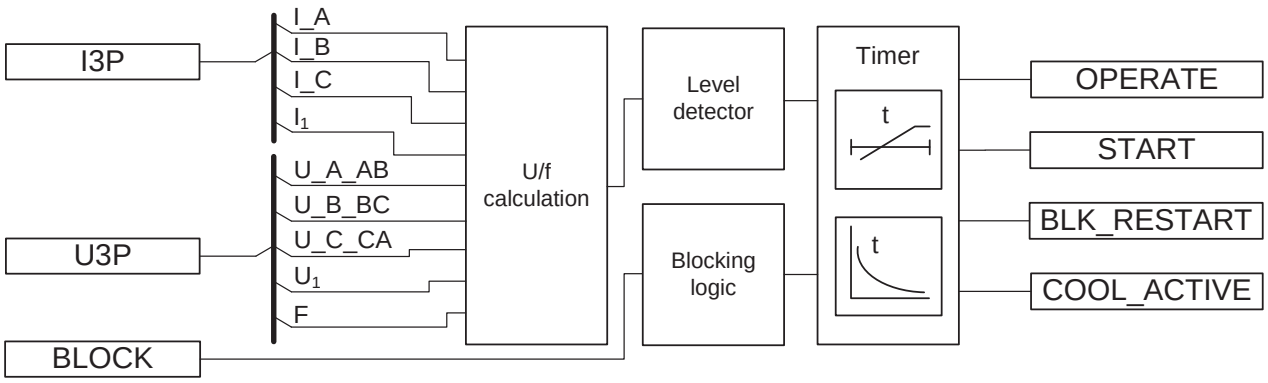

Figure 495: Functional module diagram

U/f calculation

This module calculates the U/f ratio, that is, the excitation level from the internal induced voltage (E) and frequency. The actual measured voltage (U_m) deviates from the internal induced voltage (E), a value the equipment has to withstand. This voltage compensation is based on the load current (I_L) and the leakage reactance (X_{leak}) of the equipment. The leakage reactance of the transformer or generator is set through the *Leakage React* setting in percentage of the Z base.

The internal induced voltage (E) is calculated from the measured voltage. The settings *Voltage selection* and *Phase supervision* determine which voltages and currents are to be used. If the *Voltage selection* setting is set to "phase-to-earth" or "phase-to-phase", the *Phase supervision* setting is used for determining which phases or phase-to-phase voltages ("A or AB", "B or BC" and "C or CA") and currents are to be used for the calculation of the induced voltage.

Table 842: Voltages and currents used for induced voltage (emf) E calculation

Voltage selection setting	Phase supervision setting	Calculation of internal induced voltage (emf) E [1]
phase-to-earth	A or AB	$\overline{E} = \sqrt{3} \cdot \left(\overline{U_A} + \overline{I_A} \cdot (j \cdot X_{leak}) \right)$ (Equation 240)
phase-to-earth	B or BC	$\overline{E} = \sqrt{3} \cdot \left(\overline{U_B} + \overline{I_B} \cdot (j \cdot X_{leak}) \right)$ (Equation 241)
phase-to-earth	C or CA	$\overline{E} = \sqrt{3} \cdot \left(\overline{U_C} + \overline{I_C} \cdot (j \cdot X_{leak}) \right)$ (Equation 242)
phase-to-phase	A or AB	$\overline{E} = \overline{U_{AB}} + \left((\overline{I_A} - \overline{I_B}) \cdot (j \cdot X_{leak}) \right)$ (Equation 243)
phase-to-phase	B or BC	$\overline{E} = \overline{U_{BC}} + \left((\overline{I_B} - \overline{I_C}) \cdot (j \cdot X_{leak}) \right)$ (Equation 244)
phase-to-phase	C or CA	$\overline{E} = \overline{U_{CA}} + \left((\overline{I_C} - \overline{I_A}) \cdot (j \cdot X_{leak}) \right)$ (Equation 245)
Pos sequence	N/A	$\overline{E} = \sqrt{3} \cdot \left(\overline{U_1} + \overline{I_1} \cdot (j \cdot X_{leak}) \right)$ (Equation 246)

If all three phase or phase-to-phase voltages and phase currents are fed to the protection relay, the positive-sequence alternative is recommended.

If the leakage reactance of the protected equipment is unknown or if the measured voltage (U_m) is to be used in the excitation level calculation, then by setting the leakage reactance value to zero the calculated induced voltage (E) is equal to the measured voltage.

The calculated U/f ratio is scaled to a value based on the nominal U_n/f_n ratio. However, the highest allowed continuous voltage (in % U_n) can be defined by setting the parameter *Voltage Max Cont* to change the basis of the voltage. The measured voltage is compared to the new base value to obtain the excitation level.

[1] Voltages, currents and the leakage reactance X_{leak} in the calculations are given in volts, amps and ohms.

The excitation level (M) can be calculated:

$$M = \frac{\frac{E}{f_m}}{\frac{U_n}{f_n} \cdot \frac{Volt\ Max\ continuous}{100}}$$

(Equation 247)

M	excitation level (U/f ratio or volts/hertz) in pu
E	internal induced voltage (emf)
f_m	measured frequency
U_n	nominal phase-to-phase voltage
f_n	nominal frequency

If the input frequency (f_m) is less than 20 percent of the nominal frequency (f_n), the calculation of the excitation level is disabled and forced to zero value. This means that the function is blocked from starting and operating during a low-frequency condition.

The calculated excitation level (U/f ratio or volts/hertz) VOLTPERHZ is available in the Monitored data view.

Level detector

Level detector compares the calculated excitation level to the *Start value* setting. If the excitation level exceeds the set limit, the module sends an enabling signal to start Timer.

Timer

Once activated, Timer activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value set by *Operate delay time* in the DT mode or the value defined by the inverse time curve, the OPERATE output is activated.

In a drop-off situation, that is, when the excitation level drops below *Start value* before the function operates, the reset timer is activated and the START output resets after the time delay of *Reset delay time* for the DT characteristics. For the IDMT curves, the reset operation is as described in *Chapter 4.5.7.6 Timer characteristics* .

For the IDMT curves, it is possible to define the maximum and minimum operating times via the *Minimum operate time* and *Maximum operate time* settings. The *Maximum operate time* setting is used to prevent infinite start situations at low degrees of overexcitation. The *Time multiplier* setting is used for scaling the IDMT operate times.

The activation of the OPERATE output activates the BLK_RESTART output.

For the DT characteristics, the deactivation of the OPERATE output activates the cooling timer. The timer is set to the value entered in the *Cooling time* setting. The BLK_RESTART and COOL_ACTIVE outputs are kept active until the cooling timer is reset. If the excitation increases above the set value during this period, the OPERATE output is activated immediately. For IDMT, the deactivation of BLK_RESTART and COOL_ACTIVE depends on the curve type selected.

The T_ENARESTART output indicates in seconds the duration for which the BLK_RESTART output still remains active. The value is available in the Monitored data view.

Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.5.7.6 Timer characteristics

OEPVPH supports both DT and IDMT characteristics. The DT timer characteristics can be selected as "ANSI Def. Time" or "IEC Def. Time" in the *Operating curve type* setting. The functionality is identical in both cases. When the DT characteristics are selected, the functionality is only affected by the *Operate delay time* and *Reset delay time* settings.

OEPVPH also supports four overexcitation IDMT characteristic curves: "OvExt IDMT Crv1", "OvExt IDMT Crv2", "OvExt IDMT Crv3" and "OvExt IDMT Crv4".

Overexcitation inverse definite minimum time curve (IDMT)

In the inverse time modes, the operate time depends on the momentary value of the excitation: the higher the excitation level, the shorter the operate time. The operate time calculation or integration starts immediately when the excitation level exceeds the set *Start value* and the START output is activated.

The OPERATE output is activated when the cumulative sum of the integrator calculating the overexcitation situation exceeds the value set by the inverse time mode. The set value depends on the selected curve type and the setting values used.

The *Minimum operate time* and *Maximum operate time* settings define the minimum operate time and maximum operate time possible for the IDMT mode. For setting these parameters, a careful study of the particular IDMT curves is recommended.

The operation time of the function block can vary much between different operating curve types even if other setting parameters for the curves were not changed.

Once activated, the Timer activates the START output for the IDMT curves. If the excitation level drops below the *Start value* setting before the function operates, the reset timer is activated and the START output resets immediately. If START

reoccurs during the reset time, the operation calculation is made based on the effects of the period when START was previously active. This is intended to allow an operating condition to occur in less time to account for the heating effects from the previous active start period.

When START becomes active, the reset time is based on the following equation.

$$reset\ time = \left(\frac{START_DUR}{100} \right) \cdot Cooling\ time$$

(Equation 248)

For the IDMT curves, when START is deactivated, the integral value calculated during START is continuously decremented by a constant that causes its value to become zero when the reset time elapses during the reset period. If a fault reoccurs, the integration continues from the current integral value and the start time is adjusted, as shown in *Figure 496*. The start time becomes the value at the time when the fault dropped off minus the amount of reset time that occurred. If the reset period elapses without a fault being detected, the saved values of the start time and integration are cleared.

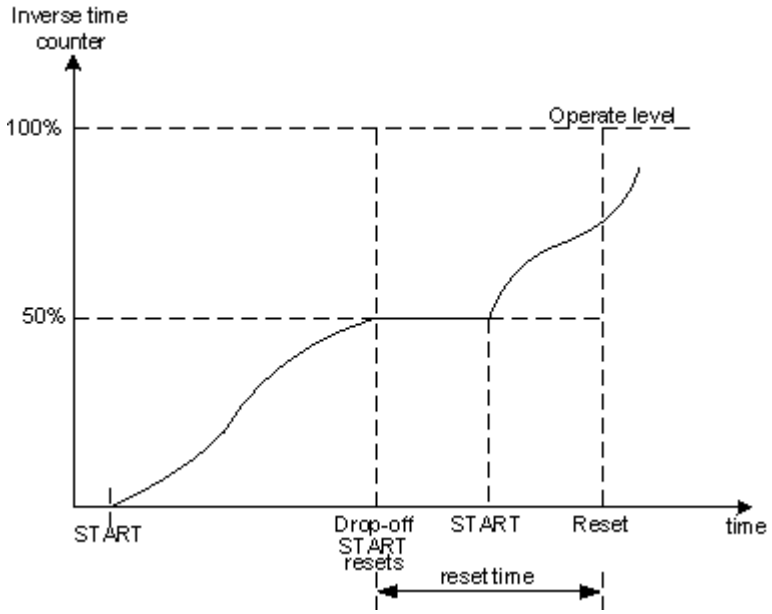

Figure 496: An example of a delayed reset in the inverse time characteristics. When the start becomes active during the reset period, the operate time counter continues from the level corresponding to the drop-off (reset time = 0.50 · Cooling time)

Overexcitation IDMT curves 1, 2 and 3

The base equation for the IDMT curves "OvExt IDMT Crv1", "OvExt IDMT Crv2" and "OvExt IDMT Crv3" is:

$$t(s) = 60 \cdot e^{\left(\frac{ak+b-100M}{c} \right)}$$

(Equation 249)

t(s)	Operate time in seconds
M	Excitation level (U/f ratio or volts/hertz) in pu
k	*Time multiplier* setting

The constant "60" in *Equation 249* converts time from minutes to seconds.

Table 843: Parameters a, b and c for different IDMT curves

***Operating curve type* setting**	**a**	**b**	**c**
OvExt IDMT Crv1	2.5	115.00	4.886
OvExt IDMT Crv2	2.5	113.50	3.040
OvExt IDMT Crv3	2.5	108.75	2.443

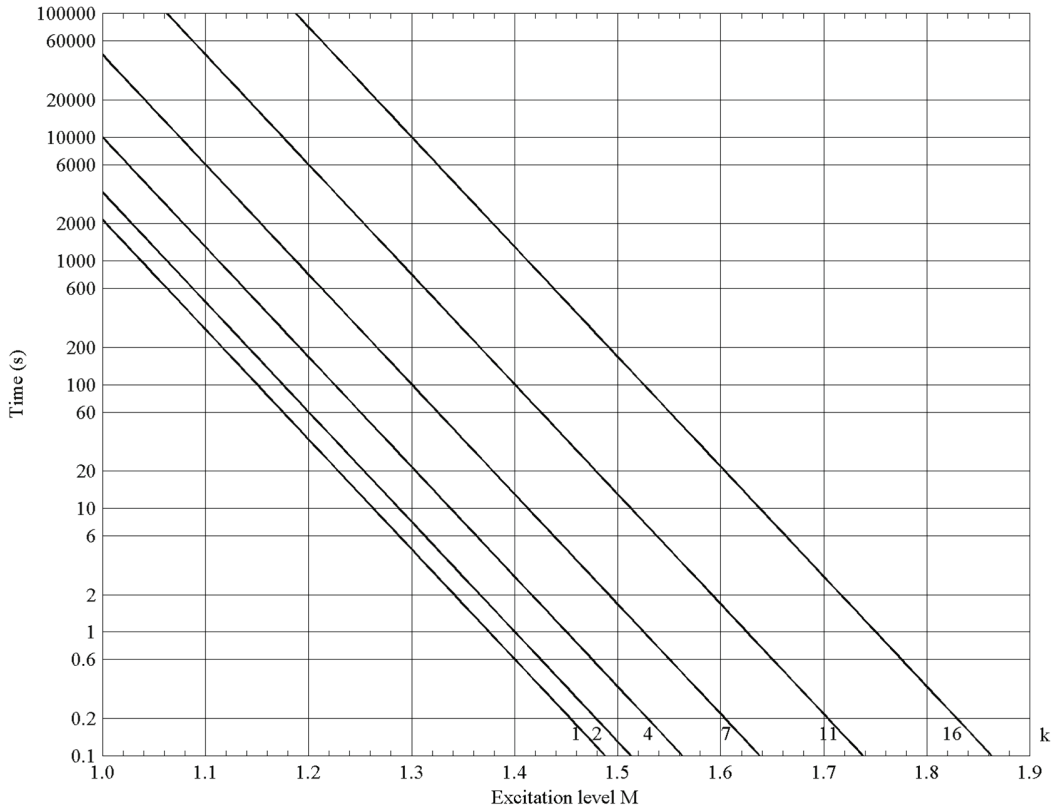

Figure 497: Operating time curves for the overexcitation IDMT curve ("OvExt IDMT Crv1") for parameters a = 2.5, b = 115.0 and c = 4.886

Overexcitation IDMT curve 4

The base equation for the IDMT curve "OvExt IDMT Crv4" is:

$$t(s) = d + \frac{0.18k}{(M-1)^2}$$

(Equation 250)

t(s)	Operate time in seconds
d	*Constant delay* setting in milliseconds
M	Excitation value (U/f ratio or volts/hertz) in pu
k	*Time multiplier* setting

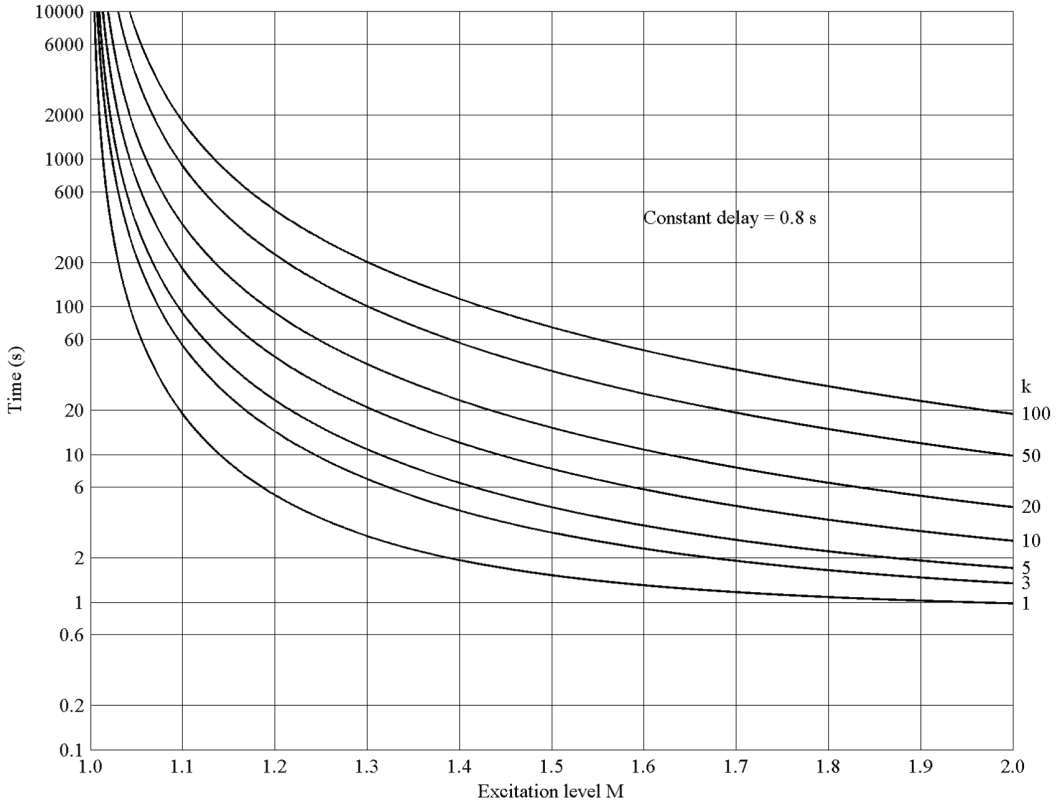

Figure 498: Operating time curves for the overexcitation IDMT curve 4 ("OvExt IDMT Crv4") for different values of the Time multiplier setting when the Constant delay is 800 milliseconds

The activation of the OPERATE output activates the BLK_RESTART output.

If the excitation level increases above the set value when BLK_RESTART is active, the OPERATE output is activated immediately.

If the excitation level increases above the set value when BLK_RESTART is not active but COOL_ACTIVE is active, the OPERATE output is not activated instantly. In this case, the remaining part of the cooling timer affects the calculation of the operate timer as shown in *Figure 499*. This compensates for the heating effect and makes the overall operate time shorter.

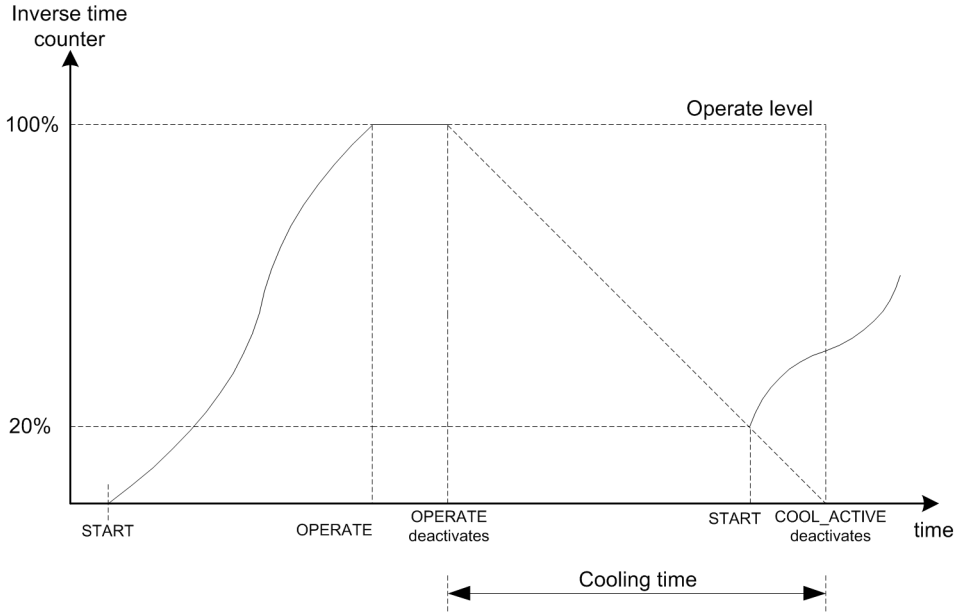

Figure 499: Example of an inverse time counter operation if START occurs when BLK_RESTART is inactive while COOL_ACTIVE is active.

4.5.7.7 Application

If the laminated core of a power transformer or generator is subjected to a magnetic flux density beyond its designed limits, the leakage flux increases. This results in a heavy hysteresis and eddy current losses in the non-laminated parts. These losses can cause excessive heating and severe damage to the insulation and adjacent parts in a relatively short time.

Overvoltage, underfrequency or a combination of the two, results in an excessive flux density level. Since the flux density is directly proportional to the voltage and inversely proportional to the frequency, the overexcitation protection calculates the relative V/Hz ratio instead of measuring the flux density directly. The nominal level (nominal voltage at nominal frequency) is usually considered as the 100 percent level, which can be exceeded slightly based on the design.

The greatest risk for overexcitation exists in a thermal power station when the generator-transformer unit is disconnected from the rest of the network or in the network islands where high voltages or low frequencies can occur.

Overexcitation can occur during the start-up and shutdown of the generator if the field current is not properly adjusted. The loss-of-load or load shedding can also result in overexcitation if the voltage control and frequency governor do not function properly. The low frequency in a system isolated from the main network can result in overexcitation if the voltage-regulating system maintains a normal voltage.

Overexcitation protection for the transformer is generally provided by the generator overexcitation protection, which uses the VTs connected to the generator terminals. The curves that define the generator and transformer V/Hz limits must be coordinated properly to protect both equipment.

If the generator can be operated with a leading power factor, the high-side voltage of the transformer can have a higher pu V/Hz than the generator V/Hz. This needs

to be considered in a proper overexcitation protection of the transformer. Also, measurement for the voltage must not be taken from any winding where OLTC is located.

It is assumed that overexcitation is a symmetrical phenomenon caused by events such as loss-of-load. A high phase-to-earth voltage does not mean overexcitation. For example, in an unearthed power system, a single phase-to-earth fault means high voltages of the healthy two phases to earth but no overexcitation on any winding. The phase-to-phase voltages remain essentially unchanged. An important voltage to be considered for the overexcitation is the voltage between the two ends of each winding.

Example calculations for overexcitation protection

Example 1

Nominal values of the machine

Nominal phase-to-phase voltage (U_n)	11000 V
Nominal phase current (I_n)	7455 A
Nominal frequency (f_n)	50 Hz
Leakage reactance (X_{leak})	20% or 0.2 pu

Measured voltage and load currents of the machine

Phase A-to-phase B voltage (U_{AB})	11500∠0° V
Phase A current (I_A)	5600∠-63.57° A
Phase B current (I_B)	5600∠176.42° A
Measured frequency (f_m)	49.98 Hz
The setting *Voltage Max Cont*	100%
The setting *Voltage selection*	phase-to-phase
The setting *Phase supervision*	A or AB

The pu leakage reactance X_{leakPU} is converted to ohms.

$$X_{leak\Omega} = X_{leakPU} \cdot \frac{U_n}{I_n \cdot \sqrt{3}} = 0.2 \cdot \frac{11000}{7455 \cdot \sqrt{3}} = 0.170378\ Ohms$$

(Equation 251)

The internal induced voltage E of the machine is calculated.

$$\overline{E} = \overline{U_{AB}} + (\overline{I_A} - \overline{I_B}) \cdot (jX_{leak})$$

(Equation 252)

E = 11500∠0°+ (5600∠-63.57°- 5600∠176.42°) · (0.170378∠90°) = 12490 V

The excitation level M of the machine is calculated.

$$Excitation\ level\ M = \frac{\frac{12490}{49.98}}{\frac{11000}{50} \cdot 1.00} = 1.1359$$

(Equation 253)

Example 2

The situation and the data are according to Example 1. In this case, the manufacturer of the machine allows the continuous operation at 105 percent of the nominal voltage at the rated load and this value to be used as the base for overexcitation.

Usually, the U/f characteristics are specified so that the ratio is 1.00 at the nominal voltage and nominal frequency. Therefore, the value 100 percent for the setting *Voltage Max Cont* is recommended.

If the *Voltage Max Cont* setting is 105 percent, the excitation level M of the machine is calculated with the equation.

$$Excitation\ level\ M = \frac{\frac{12490}{49.98}}{\frac{11000}{50} \cdot 1.05} = 1.0818$$

(Equation 254)

Example 3

In this case, the function operation is according to IDMT. The *Operating curve type* setting is selected as "OvExt IDMT Crv2". The corresponding example settings for the IDMT curve operation are given as: *Start value* = 110%, *Voltage Max Cont* = 100%, *Time multiplier* = 4, *Maximum operate time* = 1000 s, *Minimum operate time* = 1 s and *Cooling time* = 200 s.

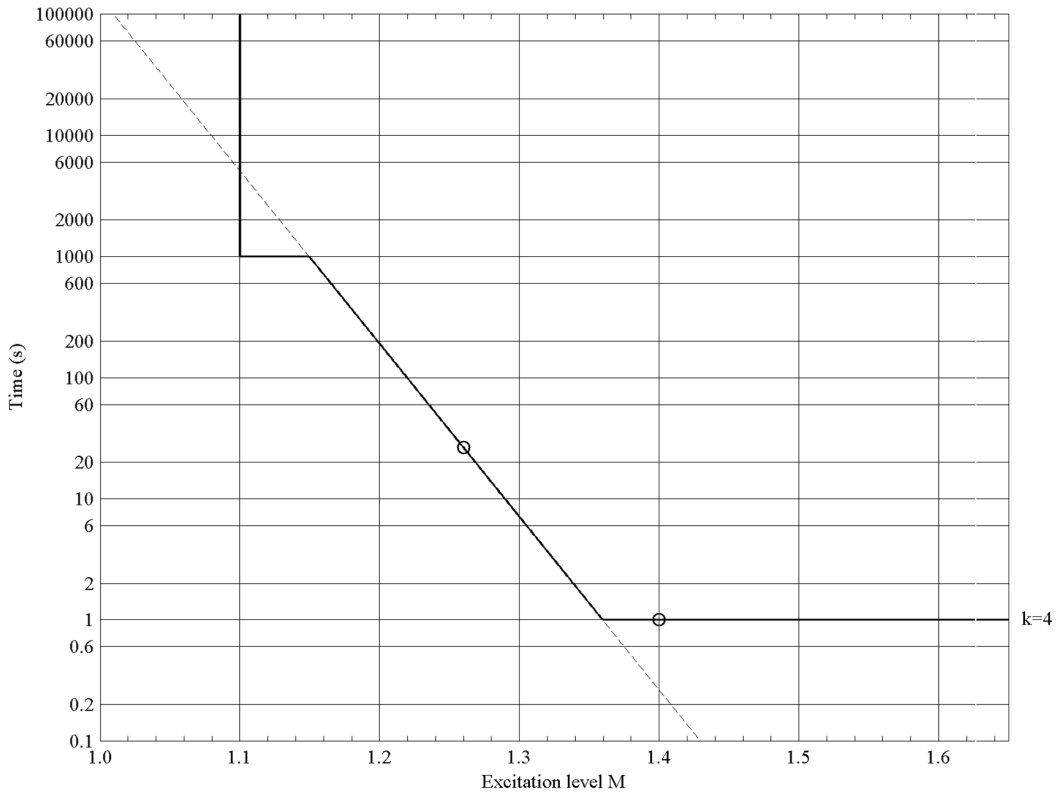

Figure 500: Operating curve of "OvExt IDMT Crv2" based on the settings specified in example 3. The two dots marked on the curve are referred to in the text.

If the excitation level stays at 1.26, the operation occurs after 26.364 s as per the marked dot in *Figure 500*. For the excitation level of 1.4, the second dot in *Figure 500*, the curve "OvExt IDMT Crv2" gives 0.2636 s as per *Equation 249*, but the *Minimum operate time* setting limits the operate time to 1.0 s.

The *Maximum operate time* setting limits the operate time to 1000 s if the excitation level stays between 1.1 and 1.16.

In general, however, the excitation level seldom remains constant. Therefore, the exact operate times in any inverse time mode are difficult to predict.

Example 4

In this case, the function operation is according to IDMT. The *Operating curve type* setting is selected as "OvExt IDMT Crv4". The corresponding example settings for the IDMT curve operation are given as: *Start value* = 110%, *Voltage Max Cont* = 100%, *Time multiplier* = 5, *Maximum operate time* = 3600 s, *Constant delay* = 0.8 s and *Cooling time* = 100 s.

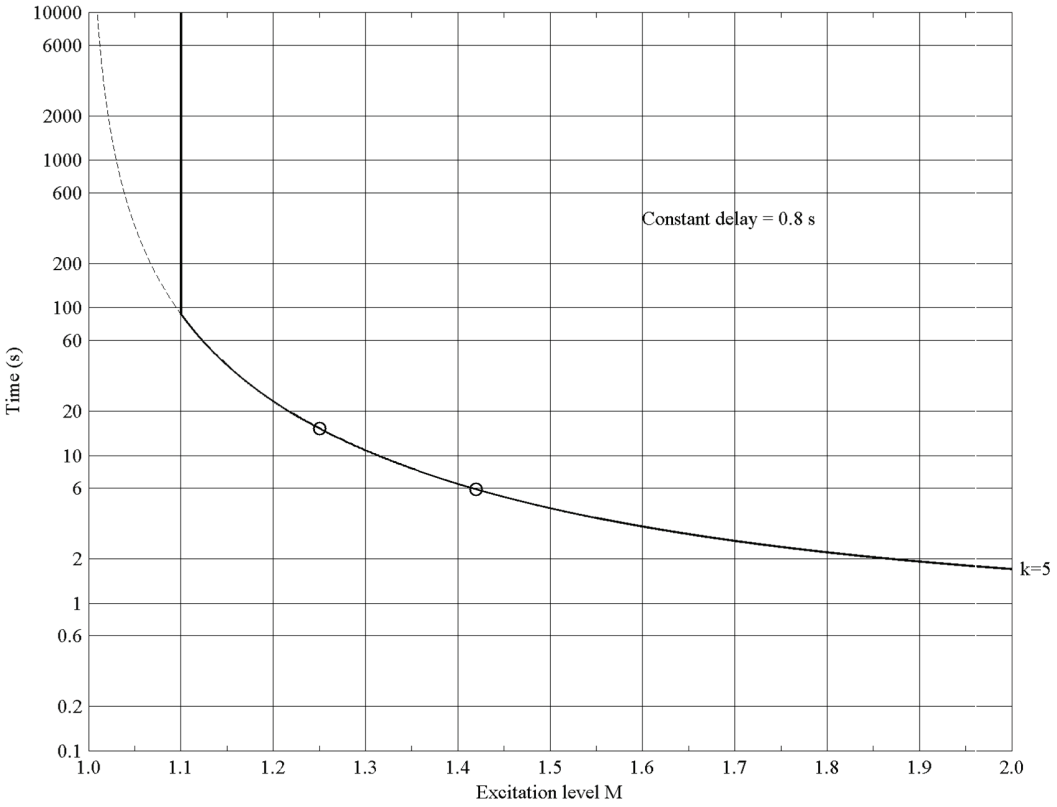

Figure 501: Operating curve of "OvExt IDMT Crv4" based on the specified settings. The two dots marked on the curve are referred to in the text.

If the excitation level stays at 1.25, the operation occurs after 15.20 s. At the excitation level of 1.42, the time to operation would be 5.90 s as per the two dots in *Figure 501*. In this case, the setting *Maximum operate time* 3600 s does not limit the maximum operate time because the operate time at *Start value* = 110% (1.1 pu) is approximately 75 s.

Operate time accuracy in inverse-time mode	±5.0% of the theoretical value or ±50 ms

4.5.8 Low-voltage ride-through protection LVRTPTUV (ANSI 27RT)

4.5.8.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Low-voltage ride-through protection	LVRTPTUV	U<RT	27RT

4.5.8.2 Function block

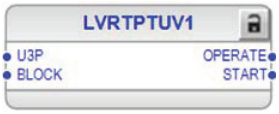

Figure 502: Function block

4.5.8.3 Functionality

The low-voltage ride-through protection function LVRTPTUV is principally a three-phase undervoltage protection. It differs from the traditional three-phase undervoltage protection PHPTUV by allowing the grid operators to define its own Low-Voltage Ride-Through (LVRT) curve for generators, as defined by local or national grid codes. The LVRT curve can be defined accurately according to the requirements by setting the appropriate time-voltage coordinates.

This function contains a blocking functionality. LVRTPTUV can be blocked with the `BLOCK` input. Blocking resets timers and outputs.

4.5.8.4 Analog channel configuration

LVRTPTUV has one analog group input which must be properly configured.

Table 851: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 852: Special conditions

Condition	Description
U3P connected to real measurements	The function requires that at least two voltage channels are connected as the the third channel can then be derived. However, it is recommended that all three voltage channels are connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.8.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of LVRTPTUV is described using a module diagram. All modules in the diagram are explained in the next sections.

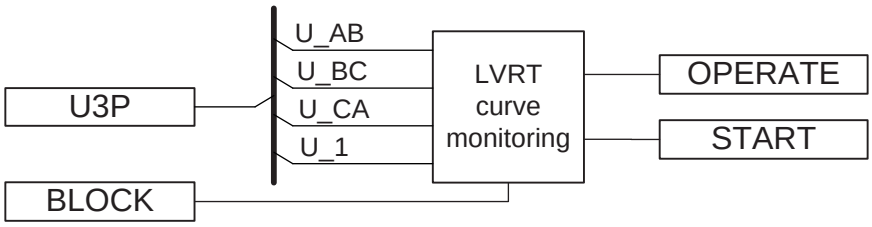

Figure 503: Functional module diagram

LVRT curve monitoring

LVRT curve monitoring starts with detection of undervoltage. Undervoltage detection depends on *Voltage selection* setting. All selectable options are based on fundamental frequency components.

Function uses phase-to-earth voltages when *Voltage selection* is set to “Highest Ph-to-E” or “Lowest Ph-to-E” and phase-to-phase voltages when *Voltage selection* is set to “Highest Ph-to-Ph” or “Lowest Ph-to-Ph”.

When the *Voltage selection* setting is set to “Highest Ph-to-E”, “Lowest Ph-to-E”, “Highest Ph-to-Ph” or “Lowest Ph-to-Ph”, the measured three-phase voltages are compared phase-wise to the set *Voltage start value*. If the measured value is lower than the set *Voltage start value* setting in number of phases equal to that set *Num of start phases*, the `START` output is activated.

The setting options available for *Num of start phases* are “Exactly 1 of 3”, "Exactly 2 of 3", and “Exactly 3 of 3”, which are different from conventional setting options available in other functions. For example, *Num of start phases* is set to "Exactly 2 of 3", any two voltages should drop below *Voltage start value* within one cycle network for the `START` output to activate. Even if more than two voltages drop below *Voltage start value*, `START` output is not activated.

When the *Voltage selection* setting is “Positive Seq”, the positive-sequence component is compared with the set *Voltage start value*. If it is lower than the set *Voltage start value*, the START output is activated.

Once START is activated, the function monitors the behavior of the voltage defined by *Voltage selection setting* with the defined LVRT curve. When defined voltage enters the operating area, the OPERATE output is activated instantaneously. The pulse length of OPERATE is fixed to 100 ms. START also deactivates along with OPERATE.

If a drop-off situation occurs, that is, voltage restores above *Voltage start value*, before OPERATE is activated, the function does not reset until maximum recovery time under consideration has elapsed, that is, START output remains active.

LVRT curve is defined using time-voltage settings coordinates. The settings available are *Recovery time 1*... *Recovery time 10* and *Voltage level 1*... *Voltage level 10*. The number of coordinates required to define a LVRT curve is set by *Active coordinate* settings.

When *Recovery time 1* is set to non-zero value, it results into horizontal characteristics from point of fault till *Recovery time 1.*

Two examples of LVRT curve are defined in *Figure 504* and *Figure 505* with corresponding settings in *Table 853*.

It is necessary to set the coordinate points correctly in order to avoid maloperation. For example, setting for *Recovery time 2* should be greater than *Recovery time 1*. *Recovery time 1*... *Recovery time 10* are the respective time setting from the point of fault.

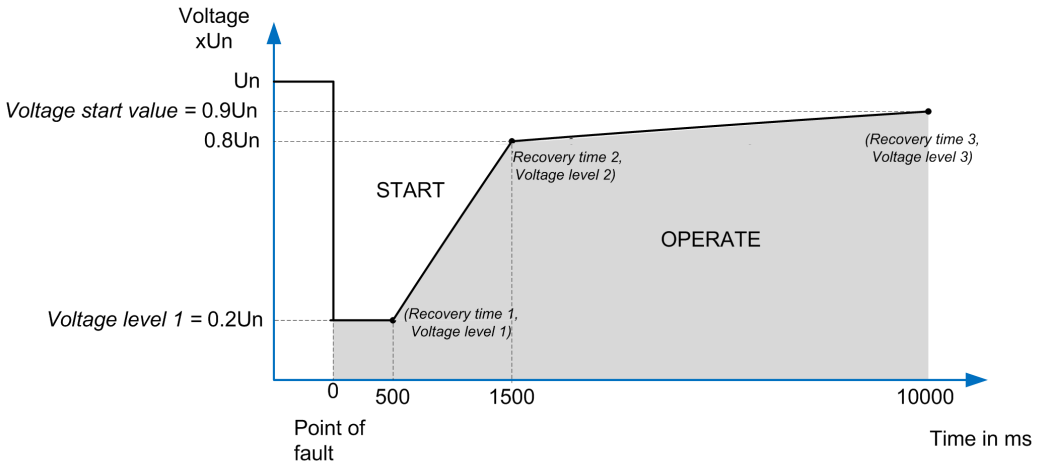

Figure 504: Low voltage ride through example curve A

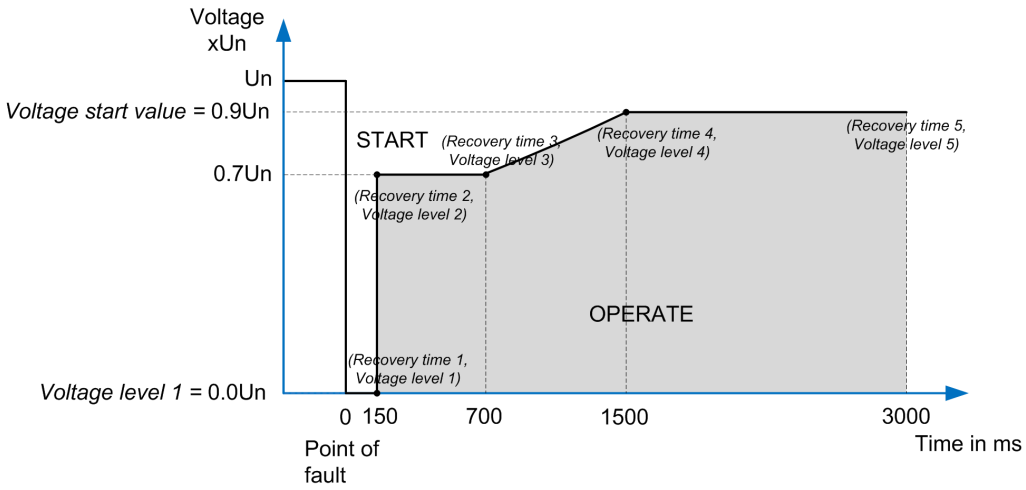

Figure 505: Low voltage ride through example curve B

Table 853: Settings for example A and B

Settings	Curve A	Curve B
Voltage start value	0.9 · Un	0.9 · Un
Active coordinates	3	5
Voltage level 1	0.2 · Un	0 · Un
Recovery time 1	500 ms	150 ms
Voltage level 2	0.8 · Un	0.7 · Un
Recovery time 2	1500 ms	150 ms
Voltage level 3	0.9 · Un	0.7 · Un
Recovery time 3	10000 ms	700 ms
Voltage level 4	-	0.9 · Un
Recovery time 4	-	1500 ms
Voltage level 5	-	0.9 · Un
Recovery time 5	-	3000 ms

It is necessary that the last active *Voltage level X* setting is set greater than or equal to *Voltage start value*. Settings are not accepted if the last active *Voltage level X* setting is not set greater than or equal to *Voltage start value*.

Figure 506 describes an example of operation of LVRTPTUV protection function set to operate with *Num of start phases* set to “Exactly 2 of 3” and *Voltage selection* as “Lowest Ph-to-Ph” voltage.

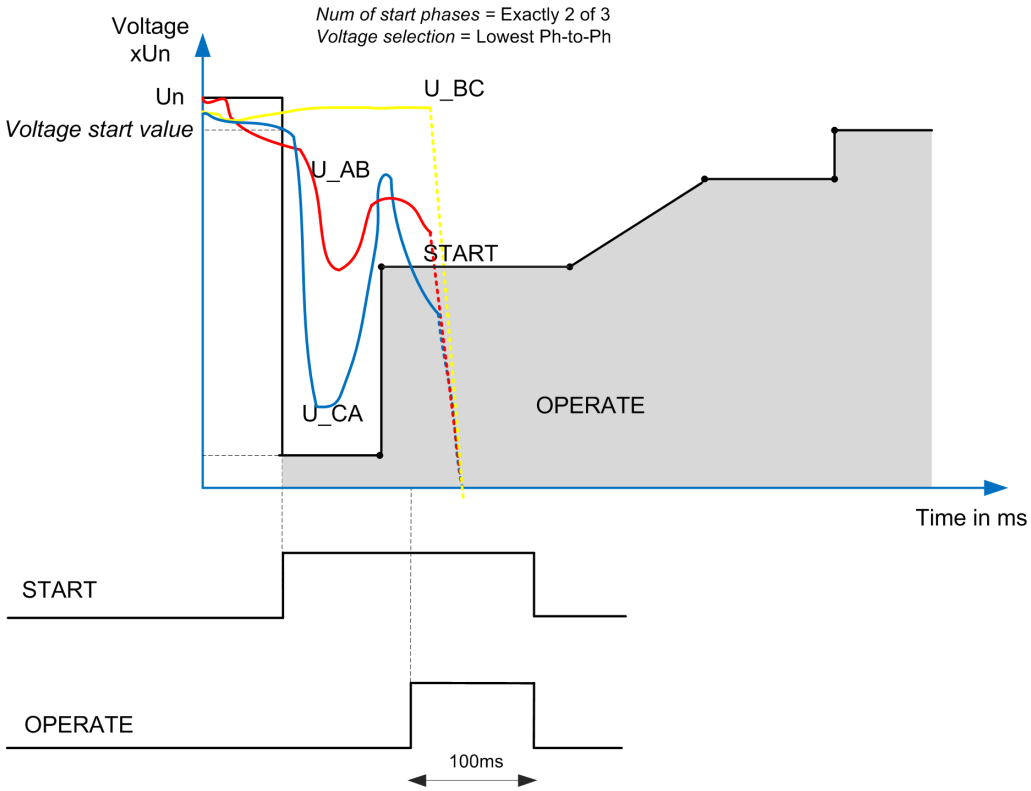

Figure 506: Typical example of operation of LVRTPTUV function

Activation of the BLOCK input resets the timers and deactivates the function outputs.

4.5.8.6 Application

Distributed generation, mainly wind and solar farms, are rapidly increasing due to liberalized markets (deregulation) and the global trend to use more renewable sources of energy. These farms are directly connected to grids, and due to their large size may influence the behavior of the grid. These farms are now required to comply with stringent grid connection requirement, which was previously mandatory only for high capacity power plants. These requirements include helping grid in maintaining system stability, reactive power support, transient recovery and voltage-frequency regulation. These requirements make it necessary for the wind and solar farms to remain in operation in the event of network disturbances.

Many grid codes now demand that the distributed generation connected to HV grids must withstand voltage dips to a certain percentage of nominal voltage (down to 0% in some cases) and for a specific duration. Such requirements are known as Low-Voltage Ride-Through (LVRT) or Fault-Ride-Through (FRT) and are described by a voltage versus time characteristics.

Typical LVRT behavior of a distributed generation can be divided into three areas according to the variation in voltage over time.

- At the time of system faults, the magnitude of the voltage may dip to *Voltage level 1* for time defined by *Recovery time 1*. The generating unit has to remain connected to the network during such condition. This boundary defines area A.

- Area B defines the linear growth recovery voltage level from *Voltage level 1* to *Voltage level 2* in a time period from *Recovery time 1* to *Recovery time 2*.
- Area C is the zone where voltage stabilizes. *Voltage level 3* is defined to same value as *Voltage level 2*. The system should remain above this voltage in a time period from *Recovery time 2* to *Recovery time 3*.

The system restores to a normal state and function resets when the voltage is equal or greater than *Voltage level 4* after *Recovery time 4* time period.

When the voltage at the point of common coupling is above the LVRT curve, the generation unit must remain connected, and must be disconnected only if the voltage takes values below the curve.

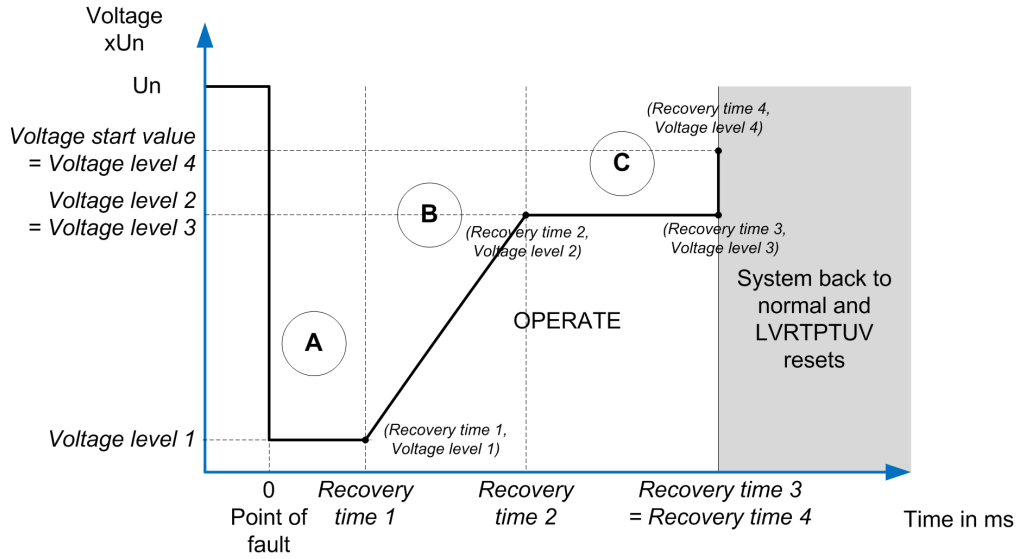

Figure 507: A typical required ride-through voltage capability of generating unit

The LVRT requirement depends on the power system characteristics and the protection employed, varying significantly from each other. The requirement also differs from country to country. LVRTPTUV function incorporates four types of LVRT curves which satisfy most of the power system needs. Grid operators can fine-tune the LVRT curve by setting the parameters as per their requirement, making the use simpler in comparison with different conventional undervoltage protection with different operate time setting and logics.

4.5.8.7 Signals

LVRTPTUV Input signals

4.5.9 Voltage vector shift protection VVSPPAM (ANSI 78VS)

4.5.9.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Voltage vector shift protection	VVSPPAM	VS	78VS

4.5.9.2 Function block

Figure 508: Function block

4.5.9.3 Functionality

The voltage vector shift protection function VVSPPAM, also known as vector surge or delta phi function, measures continuously the duration of a voltage cycle. At the instance of islanding, the duration of measured voltage cycle becomes shorter or longer than the previous one, that is, the measured voltage cycle shifts with time. This shifting of voltage is measured in terms of phase angle. VVSPPAM issues an instantaneous trip when the shift in voltage vector exceeds the set value.

VVSPPAM can be blocked with `BLOCK` input. Blocking resets timers and outputs.

4.5.9.4 Analog channel configuration

VVSPPAM has one analog group input which must be properly configured.

Table 860: Analog inputs

Input	Description
U3P	Three-phase voltages

[1] Tested for *Number of Start phases* = 1 out of 3, results based on statistical distribution of 1000 measurements
[2] Includes the delay of the signal output contact

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 861: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.9.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”.

The operation of VVSPPAM can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

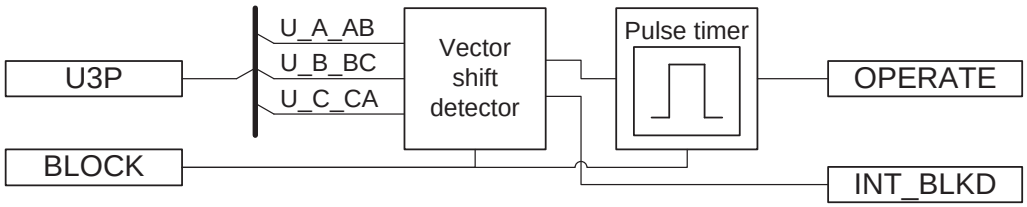

Figure 509: Functional module diagram

Vector shift detector

This module measures the duration of each cycle of the voltage signal phase. The duration of the present cycle is compared to the previous cycle, considered as reference. When the mains is lost, a sudden change is seen in the cycle length, if loading of the generator changes suddenly and power mismatch or unbalance (generation vs. load) in the islanded part of the network is large enough. The cycle shifts with time, that is, the frequency may not change but a vector shift is seen in phase as shown in *Figure 510*.

This step is measured in degrees for each voltage signal defined by the *Phase supervision* setting. The *Phase supervision* setting determines which voltage is used for detecting vector shift. The available *Phase supervision* options are “All” and “Pos sequence”. If the calculated value of Δδ exceeds the set *Start value* setting for all the defined phases, the module sends an enabling signal to start the Pulse timer.

The *Voltage selection* setting is used to select whether the available voltage signal is phase-to-earth or phase-to-phase voltage.

The recommended and the default value for *Phase supervision* is “Pos sequence”.

If the magnitude of the voltage level of any of the monitored voltage signal, defined by the *Phase supervision* setting, drops below *Under Volt Blk value* or exceeds *Over Volt Blk value*, the calculation of vector shift is disabled and the INT_BLKD output is activated.

The function is blocked and LOWAMPL_BLKD is activated, if the measured frequency deviates ±5% from the nominal value.

The magnitude of calculated vector shift for three phase-to-earth or phase-to-phase voltages, USHIFT_A_AB, USHIFT_B_BC and USHIFT_C_CA or positive sequence voltage U1SHIFT, which resulted in the activation of last OPERATE output, are available in the Monitored data view.

The activation of BLOCK input deactivates the INT_BLKD output.

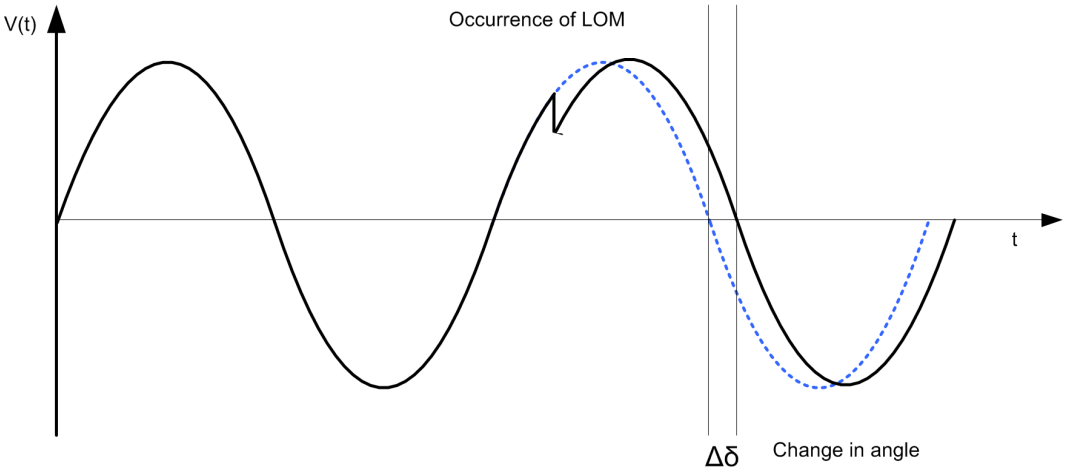

Figure 510: Vector shift during Loss of Mains

Pulse timer

Once the Pulse timer is activated, it activates the OPERATE output. The pulse length of OPERATE is fixed to 100 ms.

The activation of the BLOCK input deactivates the OPERATE binary output and resets the timer.

4.5.9.6 Application

Use of distributed generation (DG) units is increasing due to liberalized markets (deregulation) and the global trend to use more renewable sources of energy. They generate power in the range of 10 kW...10 MW and most of them are interconnected to the distribution network. They can supply power into the network as well as to the local loads. It is not common to connect generators directly to the distribution networks and thus the distributed generation can cause some challenges for the protection of distribution networks. From the protection point of view, one of the most challenging issue is islanding.

Islanding is defined as a condition in which a distributed generation unit continues to supply power to a certain part of the distribution network when power from the

larger utility main grid is no longer available after the opening of a circuit-breaker. Islanding is also referred as Loss of Mains (LOM) or Loss of Grid (LOG). When LOM occurs, neither the voltage or the frequency is controlled by the utility supply. These distributed generators are not equipped with voltage and frequency control; therefore, the voltage magnitude of an islanded network may not be kept within the desired limits which causes undefined voltage magnitudes during islanding situations and frequency instability. Uncontrolled frequency represents a high risk for drives and other machines. Islanding can occur as a consequence of a fault in the network, due to circuit breaker maloperation or due to circuit breaker opening during maintenance. If the distributed generator continues its operation after the utility supply is disconnected, faults do not clear under certain conditions as the arc is charged by the distributed generators. Moreover, the distributed generators are incompatible with the current reclosing practices. During the reclosing sequence dead time, the generators in the network tend to drift out of synchronism with the grid and reconnecting them without synchronizing may damage the generators introducing high currents and voltages in the neighboring network.

To avoid these technical challenges, protection is needed to disconnect the distributed generation once it is electrically isolated from the main grid supply. Various techniques are used for detecting Loss of Mains. However, the present function focuses on voltage vector shift.

The vector shift detection guarantees fast and reliable detection of mains failure in almost all operational conditions when a distributed generation unit is running in parallel with the mains supply, but in certain cases this may fail.

If the active and reactive power generated by the distributed generation units is nearly balanced (for example, if the power mismatch or unbalance is less than 5...10%) with the active and reactive power consumed by loads, a large enough voltage phase shift may not occur which can be detected by the vector shift algorithm. This means that the vector shift algorithm has a small non-detection-zone (NDZ) which is also dependent on the type of generators, loads, network and start or operate value of the vector shift algorithm. Other network events like capacitor switching, switching of very heavy loads in weak networks or connection of parallel transformer at HV/MV substation, in which the voltage magnitude is not changed considerably (unlike in faults) can potentially cause maloperation of vector shift algorithm, if very sensitive settings are used.

The vector shift detection also protects synchronous generators from damaging due to islanding or loss-of-mains. To detect loss-of-mains with vector shift function, the generator should aim to export or import at least 5...10% of the generated power to the grid, in order to guarantee detectable change in loading after islanding or loss-of-mains.

Multicriteria Loss of Mains

Apart from vector shift, there are other passive techniques which are used for detecting Loss of Mains. Some of these passive techniques are over/under voltage, over/under frequency, rate of change of frequency, voltage unbalance, rate of change of power and so on. These passive methods use voltage and frequency to identify Loss of Mains. The performance of these methods depends on the power mismatch between local generation and load. The advantage of all these methods is that, they are simple and cost effective, but each method has a non detectable zone. To overcome this problem, it is recommended to combine different criteria for detecting Loss of Mains.

Two or more protection functions run in parallel to detect Loss of Mains. When all criteria are fulfilled to indicate Loss of Mains, an alarm or a trip can be generated.

Vector shift and rate of change of frequency are two parallel criteria typically used for detection of Loss of Mains.

Chosen protection criteria can be included in the Application Configuration tool to create multicriteria loss of mains alarm or trip.

4.5.10.2 Function block

Figure 511: Function block

4.5.10.3 Functionality

The three-phase overvoltage variation protection function PHVPTOV monitors the quality of the voltages. The function evaluates the power quality in the voltage by calculating the average RMS value of the voltage over a set period. The function includes a settable limit for the detection of overvoltage in a single phase, two phases or three phases.

The function starts when the average RMS value of the voltage exceeds the set limit. PHVPTOV operates with the definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.5.10.4 Analog channel configuration

PHVPTOV has one analog group input which must be properly configured.

Table 870: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 871: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected if *Num of start phases* is set to "1 out of 3". Otherwise, all three voltage channels must be connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.5.10.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of PHVPTOV can be described with a module diagram. All the modules in the diagram are explained in the next sections.

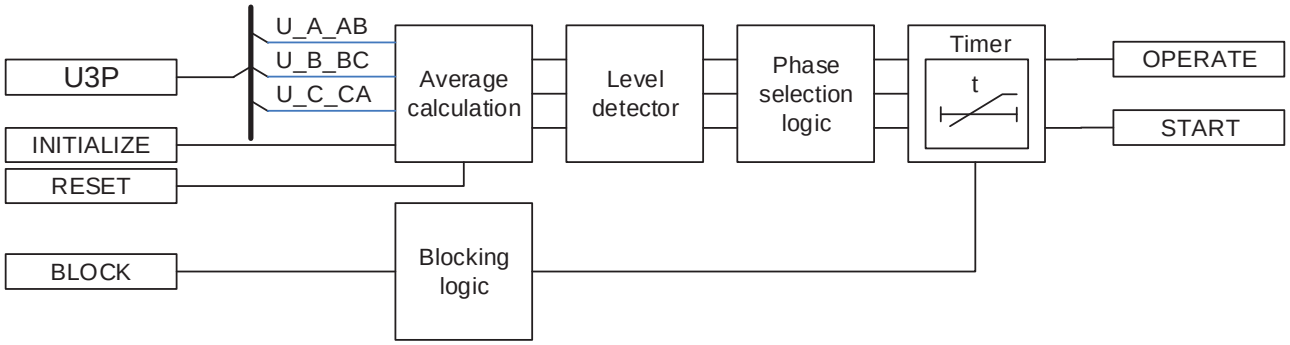

Figure 512: Functional module diagram

Average calculation

The module calculates the average voltage magnitude variation for each of the three input phase voltages. The calculation is done in three successive aggregations.

- 10/12-cycle voltage input samples are aggregated to calculate the 10/12-cycle RMS voltage.
- 10/12-cycle RMS voltages are aggregated over a time period of $T_{refresh}$ to get the refresh value.
- Refresh values are aggregated over a time period $T_{average}$ to get the average RMS voltage magnitude.

The *Voltage selection* setting is used for selecting phase-to-earth or phase-to-phase voltages for protection.

Calculation of 10/12-cycle RMS voltage

The 10/12-cycle RMS voltage is calculated for each of the three input voltages by applying the standard RMS formula using the voltage samples over a range of 0.2 s. Depending on the *Voltage selection* setting, voltage samples are either phase-to-earth or phase-to-phase voltage samples.

Calculation of RMS refresh voltage

The RMS refresh voltage is calculated by aggregating the $U_{10cycles}$ / $U_{12cycles}$ RMS voltage over a time period of $T_{refresh}$. The time period $T_{refresh}$ depends on the setting *Time interval*.

$$T_{refresh} = Roundup\left(\frac{Time\ interval\ in\ seconds}{200}\right)$$

(Equation 255)

The function Roundup rounds up the result to the next higher time multiple of 0.2 s because the result of the division is not a multiple of 0.2 s in case of an odd *Time interval* setting (1, 3, 5…120 mins).

$$U_{Refresh} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} U_{10/12cycles}^{2}(i)}$$

(Equation 256)

N Number of values to be aggregated as defined by *Equation 257*

$$N = \left(\frac{T_{refresh}}{0.2}\right)$$

(Equation 257)

Calculation of RMS average voltage

The RMS average voltage is calculated by aggregating the RMS $U_{refresh}$ voltage over a time period equal to the *Time interval*.

$$U_{Average} = \sqrt{\frac{1}{M}\sum_{i=1}^{M} U_{Refresh}^{2}(i)}$$

(Equation 258)

M Number of values to be aggregated as defined by *Equation 259*

$$M = Round\left(\frac{Time\ interval\ in\ seconds}{T_{Refresh}}\right)$$

(Equation 259)

At the initialization of the function, the average voltage is calculated considering initial values as zero. On the IEC 61850 mapped data, the quality of the calculated average voltage value is indicated as “Questionable” until the first complete time interval passes. The calculated average voltage measurement for the set *Time interval* for all three phase-to-earth and phase-to-phase voltages U_MEAN_A, U_MEAN_B, U_MEAN_C, U_MEAN_AB, U_MEAN_BC and U_MEAN_CA is available in the Monitored data view.

The calculated average voltage can be reset by the RESET binary input. The calculated average voltage can also be reset using PHVPTOV1 Reset mean on the Clear menu.

When the INITIALIZE input is activated, the average voltage measurement value is initialized with the 10/12-cycle RMS voltage. The average voltage measurement value can also be initialized using PHVPTOV1 Ini mean on the Clear menu.

Level detector

The calculated average voltage for all three voltages is compared phase-wise to the set *Start value* setting. If the calculated voltage value is higher than the set value of the *Start value* setting, Level detector enables the Phase selection logic module. The *Relative hysteresis* setting can be used for preventing unnecessary oscillations if the input signal slightly differs from the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return to the hysteresis area.

Phase selection logic

If the fault criteria are fulfilled in the level detector, the phase selection logic detects the phase or phases in which the fault level is detected. If the number of faulty phases matches with the set *Num of start phases*, the phase selection logic activates the Timer module.

Timer

Once activated, the timer activates the START output. The operate delay time is not settable directly but it depends on the *Operate delay Mult* setting and refresh timer $T_{refresh}$. The operate delay time is calculated as:

$$Operate\ delay\ time\ in\ s = Operate\ delay\ Mult \cdot T_{refresh}$$

(Equation 260)

When the operation timer has reached the value equal to *Operate delay time*, the OPERATE output is activated if the overvoltage condition persists. If the average voltage value normalizes before the module operates, the reset timer is activated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the monitored data view.

When the relay has tripped due to variation overvoltage protection, check that operation is safe before closing the breaker. Clear the average voltage value by using *PHVPTOV1 Reset mean* on the **Clear** menu to prevent immediate retripping of breaker by PHVPTOV.

Considering the slow dynamic of the measurement, the protection may remain in the START status for a long time. If the measured voltage returns to a value lower than *Start value*, the function does not immediately reset. The function resets when the calculated average RMS value drops below *Start value*.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the “Block all” mode, the whole

function is blocked and the timers are reset. In the “Block OPERATE output” mode, the function operates normally but the OPERATE output is not activated.

4.5.10.6 Application

Overvoltage in a network occurs either due to the transient surges on the network or due to power frequency overvoltages. Surge arresters are used to protect the network against the transient overvoltages; power frequency overvoltage of magnitude greater than 15...20% of nominal voltage is normally handled by traditional overvoltage protection. However, slow voltage variations are usually quantified by calculating the RMS value of the voltage. To assess the RMS voltage, measurements are taken over a relatively long period of time to avoid any instantaneous effect caused by switching transients or faults.

It is important to monitor such slow voltage variation which can cause sub-optimal operation of the equipment. EN 50160 quantifies slow voltage variation using 10 min mean RMS value. CEI EN 50160 standard indicates that the RMS value of the voltage calculated over a period of 10 min should not exceed 110% of the nominal voltage; if the voltage exceeds this level, the generator must be disconnected from the network within 3 s. PHVPTOV provides overvoltage protection by calculating the RMS value over a period of 10 min.

A sudden change in the magnitude of the supply voltage is not immediately detected by the RMS calculation; hence this is mainly used as an indication of voltage quality supplied by the utility.

Frequency protection	FRPFRQ	f>/f<,df/dt	81

4.6.1.2 Function block

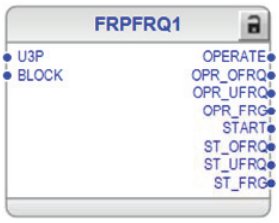

Figure 513: Function block

4.6.1.3 Functionality

The frequency protection function FRPFRQ is used to protect network components against abnormal frequency conditions.

The function provides basic overfrequency, underfrequency and frequency rate-of-change protection. Additionally, it is possible to use combined criteria to achieve even more sophisticated protection schemes for the system.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.6.1.4 Analog channel configuration

FRPFRQ has one analog group input which must be properly configured.

Table 879: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 880: Special conditions

Condition	Description
U3P connected to real measurements	The function requires that at least one phase or phase-to-phase voltage channel is connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.6.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of FRPFRQ can be described using a module diagram. All the modules in the diagram are explained in the next sections.

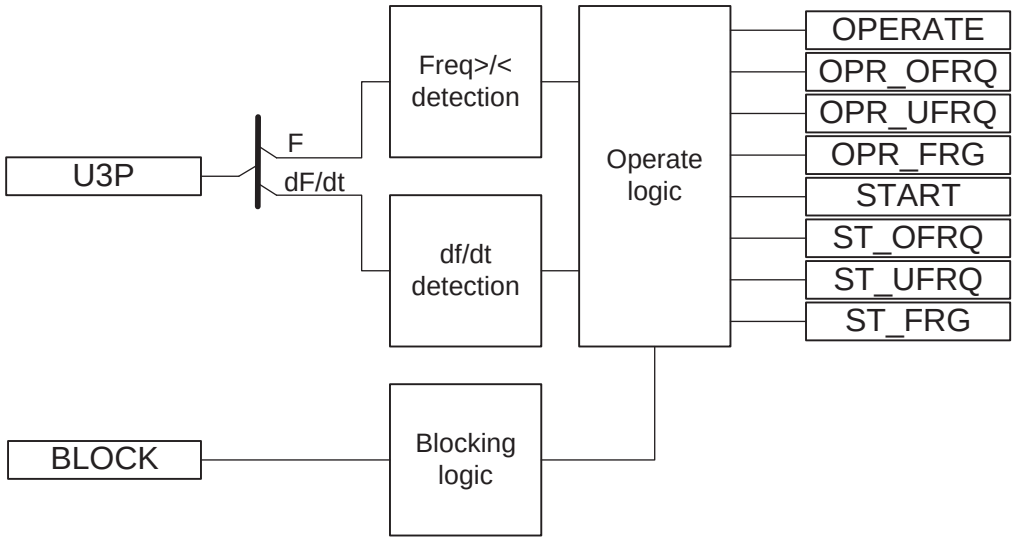

Figure 514: Functional module diagram

Freq>/< detection

The frequency detection module includes an overfrequency or underfrequency detection based on the *Operation mode* setting.

In the “Freq>” mode, the measured frequency is compared to the set *Start value Freq>*. If the measured value exceeds the set value of the *Start value Freq>* setting, the module reports the exceeding of the value to the operate logic module.

In the “Freq<” mode, the measured frequency is compared to the set *Start value Freq<*. If the measured value is lower than the set value of the *Start value Freq<* setting, the module reports the value to the operate logic module.

df/dt detection

The frequency gradient detection module includes a detection for a positive or negative rate-of-change (gradient) of frequency based on the set *Start value df/dt* value. The negative rate-of-change protection is selected when the set value is negative. The positive rate-of-change protection is selected when the set value is positive. When the frequency gradient protection is selected and the gradient exceeds the set *Start value df/dt* value, the module reports the exceeding of the value to the operate logic module.

The protection relay does not accept a value between -0.002...+0.002 for the *Start value df/dt* setting.

Operate logic

This module is used for combining different protection criteria based on the frequency and the frequency gradient measurement to achieve a more sophisticated behavior of the function. The criteria are selected with the *Operation mode* setting.

Table 881: Operation modes for operation logic

Operation mode	Description
Freq<	The function operates independently as the underfrequency ("Freq<") protection function. When the measured frequency is below the set value of the *Start value Freq<* setting, the module activates the START and STR_UFRQ outputs. The time characteristic is according to DT. When the operation timer has reached the value set by the *Operate Tm Freq* setting, the OPERATE and OPR_UFRQ outputs are activated. If the frequency restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm Freq* setting, the operate timer resets and the START and STR_UFRQ outputs are deactivated.
Freq>	The function operates independently as the overfrequency ("Freq>") protection function. When the measured frequency exceeds the set value of the *Start value Freq>* setting, the module activates the START and STR_OFRQ outputs. The time characteristic is according to DT. When the operation timer has reached the value set by the *Operate Tm Freq* setting, the OPERATE and OPR_OFRQ outputs are activated.

Table continues on the next page

Operation mode	**Description**
	If the frequency restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm Freq* setting, the operate timer resets and the START and STR_OFRQ outputs are deactivated.
df/dt	The function operates independently as the frequency gradient ("df/dt"), rate-of-change, protection function. When the frequency gradient exceeds the set value of the *Start value df/dt* setting, the module activates the START and STR_FRG outputs. The time characteristic is according to DT. When the operation timer has reached the value set by the *Operate Tm df/dt* setting, the OPERATE and OPR_FRG outputs are activated. If the frequency gradient restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm df/dt* setting, the operate timer resets and the START and STR_FRG outputs are deactivated.
Freq< + df/dt	A consecutive operation is enabled between the protection methods. When the measured frequency is below the set value of the *Start value Freq<* setting, the frequency gradient protection is enabled. After the frequency has dropped below the set value, the frequency gradient is compared to the set value of the *Start value df/dt* setting. When the frequency gradient exceeds the set value, the module activates the START and STR_FRG outputs. The time characteristic is according to DT. When the operation timer has reached the value set by the *Operate Tm df/dt* setting, the OPERATE and OPR_FRG outputs are activated. If the frequency gradient restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm df/dt* setting, the operate timer resets and the START and STR_FRG outputs are deactivated. The OPR_UFRQ output is not active when this operation mode is used.
Freq> + df/dt	A consecutive operation is enabled between the protection methods. When the measured frequency exceeds the set value of the *Start value Freq>* setting, the frequency gradient protection is enabled. After the frequency exceeds the set value, the frequency gradient is compared to the set value of the *Start value df/dt* setting. When the frequency gradient exceeds the set value, the module activates the START and STR_FRG outputs. The time characteristic is according to DT. When the operation timer has reached the value set by the *Operate Tm df/dt* setting, the OPERATE and OPR_FRG outputs are activated. If the frequency gradient restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm df/dt* setting, the operate timer resets and the START and STR_FRG outputs are deactivated. The OPR_OFRQ output is not active when this operation mode is used.

Table continues on the next page

Operation mode	Description
Freq< OR df/dt	A parallel operation between the protection methods is enabled. The START output is activated when either of the measured values of the protection module exceeds its set value. Detailed information about the active module is available at the STR_UFRQ and STR_FRG outputs. The shortest operate delay time from the set *Operate Tm Freq* or *Operate Tm df/dt* is dominant regarding the OPERATE output. The time characteristic is according to DT. The characteristic that activates the OPERATE output can be seen from the OPR_UFRQ or OPR_FRG output. If the frequency gradient restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm df/dt* setting, the operate timer resets and the STR_FRG output is deactivated. If the frequency restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm Freq* setting, the operate timer resets and the STR_UFRQ output is deactivated.
Freq> OR df/dt	A parallel operation between the protection methods is enabled. The START output is activated when either of the measured values of the protection module exceeds its set value. A detailed information from the active module is available at the STR_OFRQ and STR_FRG outputs. The shortest operate delay time from the set *Operate Tm Freq* or *Operate Tm df/dt* is dominant regarding the OPERATE output. The time characteristic is according to DT. The characteristic that activates the OPERATE output can be seen from the OPR_OFRQ or OPR_FRG output. If the frequency gradient restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm df/dt* setting, the operate timer resets and the STR_FRG output is deactivated. If the frequency restores before the module operates, the reset timer is activated. If the timer reaches the value set by the *Reset delay Tm Freq* setting, the operate timer resets and the STR_UFRQ output is deactivated.

The module calculates the start duration value which indicates the percentage ratio of the start situation and set operate time (DT). The start duration is available according to the selected value of the *Operation mode* setting.

Table 882: Start duration value

Operation mode in use	Available start duration value
Freq<	ST_DUR_UFRQ
Freq>	ST_DUR_OFRQ
df/dt	ST_DUR_FRG

The combined start duration START_DUR indicates the maximum percentage ratio of the active protection modes. The values are available via the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.6.1.6 Application

The frequency protection function uses the positive phase-sequence voltage to measure the frequency reliably and accurately.

The system frequency stability is one of the main principles in the distribution and transmission network maintenance. To protect all frequency-sensitive electrical apparatus in the network, the departure from the allowed band for a safe operation should be inhibited.

The overfrequency protection is applicable in all situations where high levels of the fundamental frequency of a power system voltage must be reliably detected. The high fundamental frequency in a power system indicates an unbalance between production and consumption. In this case, the available generation is too large compared to the power demanded by the load connected to the power grid. This can occur due to a sudden loss of a significant amount of load or due to failures in the turbine governor system. If the situation continues and escalates, the power system loses its stability.

The underfrequency is applicable in all situations where a reliable detection of a low fundamental power system voltage frequency is needed. The low fundamental frequency in a power system indicates that the generated power is too low to meet the demands of the load connected to the power grid.

The underfrequency can occur as a result of the overload of generators operating in an isolated system. It can also occur as a result of a serious fault in the power system due to the deficit of generation when compared to the load. This can happen due to a fault in the grid system on the transmission lines that link two parts of the system. As a result, the system splits into two with one part having the excess load and the other part the corresponding deficit.

The frequency gradient is applicable in all the situations where the change of the fundamental power system voltage frequency should be detected reliably. The frequency gradient can be used for both increasing and decreasing the frequencies. This function provides an output signal suitable for load shedding, generator shedding, generator boosting, set point change in sub-transmission DC systems and gas turbine startup. The frequency gradient is often used in combination with a low frequency signal, especially in smaller power systems where the loss of a large generator requires quick remedial actions to secure the power system integrity. In such situations, the load shedding actions are required at a rather high frequency level. However, in combination with a large negative frequency gradient, the underfrequency protection can be used at a high setting.

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Load-shedding and restoration	LSHDPFRQ	UFLS/R	81LSH

4.6.2.2 Function block

Figure 515: Function block

4.6.2.3 Functionality

The load-shedding and restoration function LSHDPFRQ is capable of performing load-shedding based on underfrequency and the rate of change of the frequency. The load that is shed during the frequency disturbance can be restored once the frequency has stabilized to the normal level.

[1] Applies to sudden frequency change of ≤0.2 Hz or to frequency slope of ≤ 5 Hz/s. When frequency change is outside of these limits, start may be delayed by additional 100 ms to prevent false starts when connecting / disconnecting heavy loads.

The measured system frequency is compared to the set value to detect the underfrequency condition. The measured rate of change of frequency (df/dt) is compared to the set value to detect a high frequency reduction rate. The combination of the detected underfrequency and the high df/dt is used for the activation of the load-shedding. There is a definite time delay between the detection of the underfrequency and high df/dt and the activation of LSHDPFRQ. This time delay can be set and it is used to prevent unwanted load-shedding actions when the system frequency recovers to the normal level.

Throughout this document, “high df/dt” is used to mean “a high rate of change of the frequency in negative direction.”

Once the frequency has stabilized, LSHDPFRQ can restore the load that is shed during the frequency disturbance. The restoration is possible manually or automatically.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.6.2.4 Analog channel configuration

LSHDPFRQ has one analog group input which must be properly configured.

Table 891: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 892: Special conditions

Condition	Description
U3P connected to real measurements	The function requires that at least one phase or phase-to-phase voltage channel is connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.6.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of LSHDPFRQ can be described using a module diagram. All the modules are explained in the next sections.

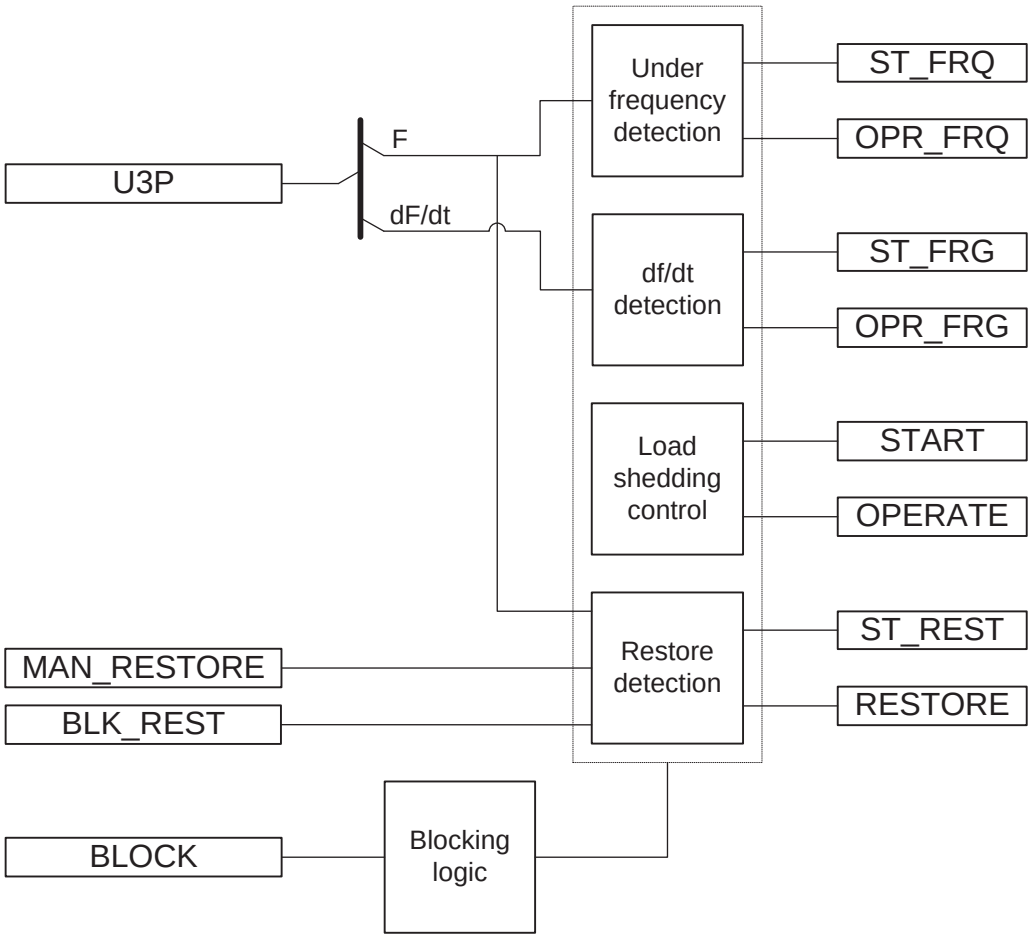

Figure 516: Functional module diagram

Underfrequency detection

The underfrequency detection measures the input frequency calculated from the voltage signal. An underfrequency is detected when the measured frequency drops below the set value of the *Start value Freq* setting.

The underfrequency detection module includes a timer with the definite time (DT) characteristics. Upon detection of underfrequency, operation timer activates the `ST_FRQ` output. When the underfrequency timer has reached the value set by *Operate Tm Freq*, the `OPR_FRQ` output is activated if the underfrequency condition still persists. If the frequency becomes normal before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the timer resets and the `ST_FRQ` output is deactivated.

df/dt detection

The df/dt detection measures the input frequency calculated from the voltage signal and calculates its gradient. A high df/dt condition is detected by comparing the gradient to the *Start value df/dt* setting. The df/dt detection is activated when the frequency gradient decreases at a faster rate than the set value of *Start value df/dt*.

The df/dt detection module includes a timer with the DT characteristics. Upon detection of df/dt, operation timer activates the ST_FRG output. When the timer has reached the value set by *Operate Tm df/dt*, the OPR_FRG output is activated if the df/dt condition still persists. If df/dt becomes normal before the module operates, the reset timer is activated. If the reset timer reaches the value of the *Reset delay time* setting, the timer resets and the ST_FRG output is deactivated.

Load-shedding control

The way of load-shedding, that is, whether to operate based on underfrequency or high df/dt or both, is defined with the *Load shed mode* user setting. The valid operation modes for the *Load shed mode* settings are "Freq<", "Freq< AND df/dt" and "Freq< OR df/dt".

Once the selected operation mode conditions are satisfied, the START and OPERATE output signals are activated.

When the START output is active, the percentage of the elapsed delay time can be monitored through START_DUR which is available as monitored data.

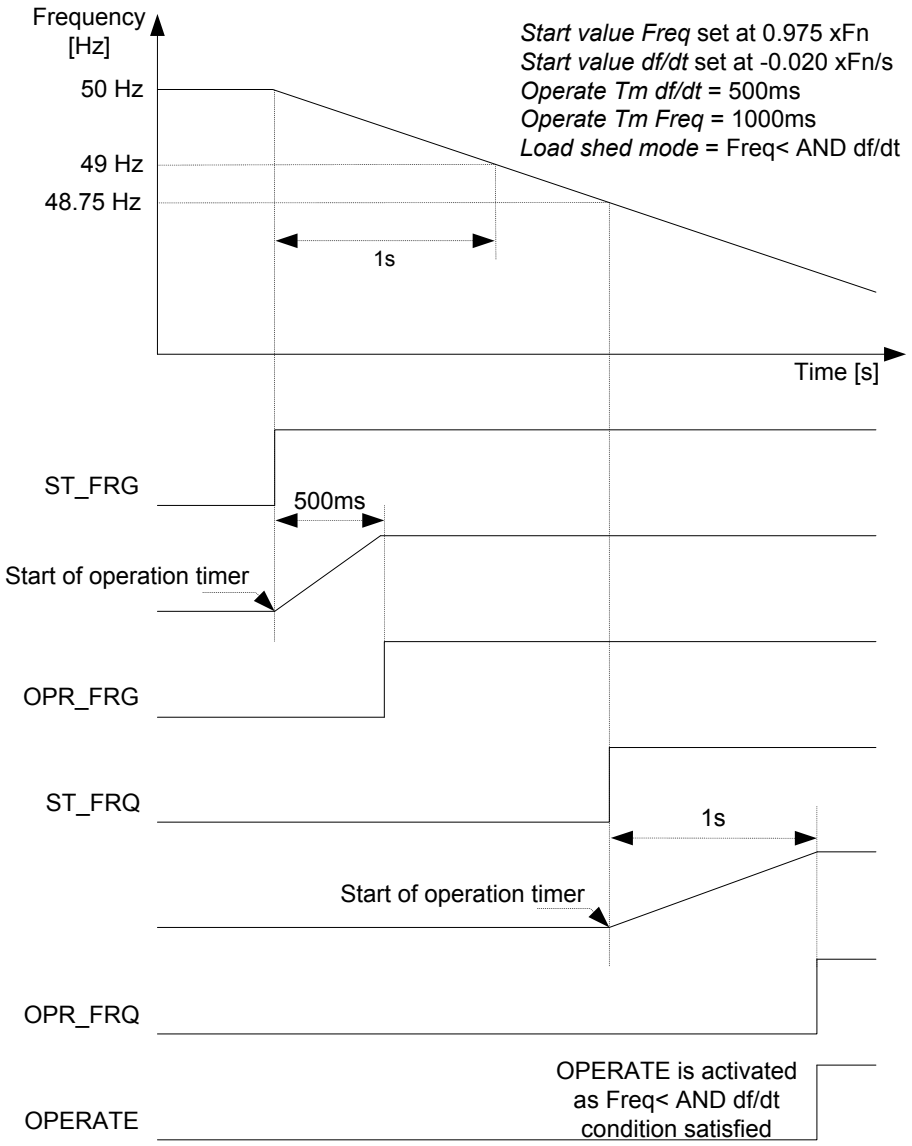

Figure 517: Load-shedding operation in the "Freq< AND df/dt>" mode when both Freq< and df/dt conditions are satisfied (Rated frequency=50 Hz)

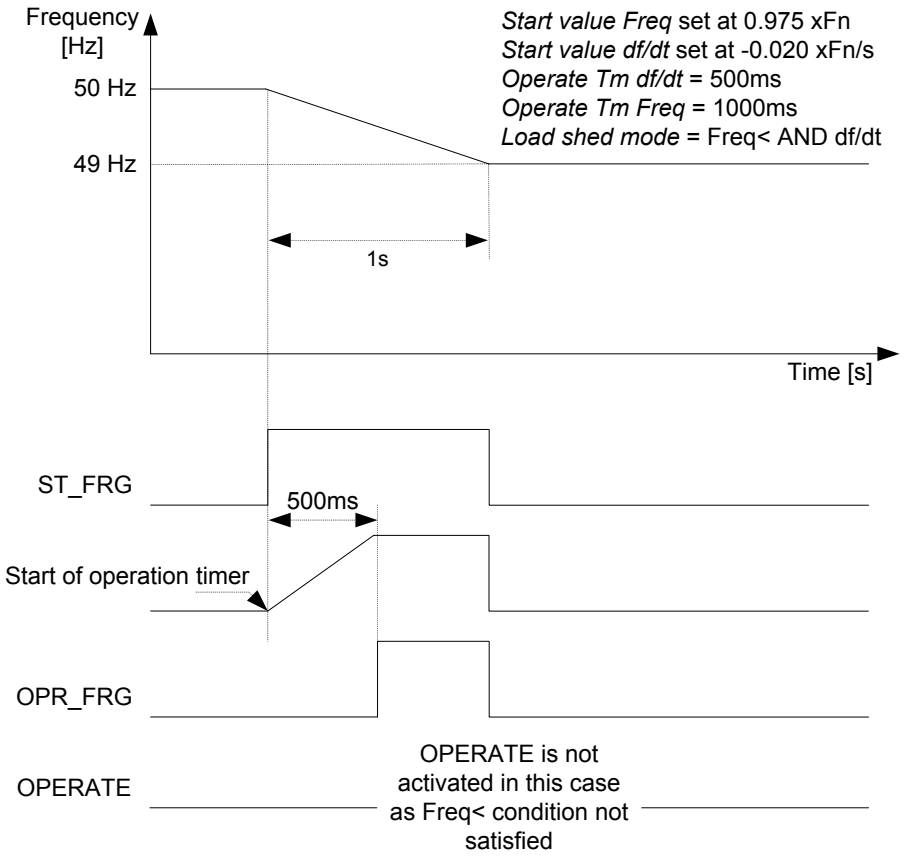

Figure 518: Load-shedding operation in the "Freq< AND df/dt>" mode when only the df/dt condition is satisfied (Rated frequency=50 Hz)

Restore detection

If after the activation of the OPERATE output the frequency recovers to a level above the *Restore start Val* setting, the RESTORE signal output is activated. The RESTORE output remains active for 100 ms. The *Restore mode* setting is used to select the restoring mode to be "Disabled", "Auto" or "Manual".

Restoring mode	Description
Disabled	Load restoration is disabled.
Auto	In the "Auto" mode, input frequency is continuously compared to the *Restore start Val* setting. The restore detection module includes a timer with the DT characteristics. Upon detection of restoring, the operation timer activates the ST_REST output. When the timer has reached the value of the *Restore delay time* setting, the RESTORE output is activated if the restoring condition still persists. If the frequency drops below the *Restore start Val* before the RESTORE output is activated, the reset timer is activated. If the reset timer reaches the value of the *Reset delay time* setting, the timer resets and the ST_REST start output is deactivated.
Manual	In the "Manual" mode, a manual restoration is possible through the MAN_RESTORE input or via communication. The ST_REST output is activated if the MAN_RESTORE command is available and the frequen-

Restoring mode	Description
	cy has exceeded the *Restore start Val* setting. The manual restoration includes a timer with the DT characteristics. When the timer has reached the set value of the *Restore delay time* setting, the RESTORE output is activated if the restoring condition still persists. If the frequency drops below the *Restore start Val* setting before the RESTORE output is activated, the reset timer is activated. If the reset timer reaches the value of the *Reset delay time* setting, the timer resets and the ST_REST start output is deactivated.

A condition can arise where the restoring operation needs to be canceled. Activating the BLK_REST input for the "Auto" or "Manual" modes cancels the restoring operation. In the "Manual" restoring mode, the cancellation happens even if MAN_RESTORE is present.

Once the RESTORE output command is cancelled, the reactivation of RESTORE is possible only after the reactivation of the OPERATE output, that is, when the next load-shedding operation is detected.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** that selects the blocking mode. The BLOCK input can be controlled with a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK input signal activation is preselected with the *Blocking mode* global setting.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE, OPR_FRQ and OPR_FRG outputs are not activated.

4.6.2.6 Application

An AC power system operates at a defined rated frequency. The nominal frequency in most systems in the world is 50 Hz or 60 Hz. The system operation is such that the operating frequency remains approximately at the nominal frequency value by a small margin. The safe margin of operation is usually less than ±0.5 Hz. The system frequency stability is one of the main concerns in the transmission and distribution network operation and control. To protect the frequency-sensitive electrical equipment in the network, departure from the allowed band for safe operation should be inhibited.

Any increase in the connected load requires an increase in the real power generation to maintain the system frequency. Frequency variations form whenever there are system conditions that result in an unbalance between the generation and load. The rate of change of the frequency represents the magnitude of the difference between the load and generation. A reduction in frequency and a negative rate of change of the frequency are observed when the load is greater than the generation, and an increase in the frequency along with a positive rate of change of the frequency are observed if the generation is greater than the load. The rate of change of the frequency is used for a faster decision of load-shedding. In an

underfrequency situation, the load-shedding trips out the unimportant loads to stabilize the network. Thus, loads are normally prioritized so that the less important loads are shed before the important loads.

During the operation of some of the protective schemes or other system emergencies, the power system is divided into small islands. There is always a load - generation imbalance in such islands that leads to a deviation in the operating frequency from the nominal frequency. This off-nominal frequency operation is harmful to power system components like turbines and motors. Therefore, such situation must be prevented from continuing. The frequency-based load-shedding scheme should be applied to restore the operation of the system to normal frequency. This is achieved by quickly creating the load - generation balance by disconnecting the load.

As the formation of the system islands is not always predefined, several load-shedding relays are required to be deployed at various places near the load centers. A quick shedding of a large amount of load from one place can cause a significant disturbance in the system. The load-shedding scheme can be made most effective if the shedding of load feeders is distributed and discrete, that is, the loads are shed at various locations and in distinct steps until the system frequency reaches the acceptable limits.

Due to the action of load-shedding schemes, the system recovers from the disturbance and the operating frequency value recovers towards the nominal frequency. The load that was shed during the disturbance can be restored. The load-restoring operation should be done stepwise in such a way that it does not lead the system back to the emergency condition. This is done through an operator intervention or in case of remote location through an automatic load restoration function. The load restoration function also detects the system frequency and restores the load if the system frequency remains above the value of the set restoration frequency for a predefined duration.

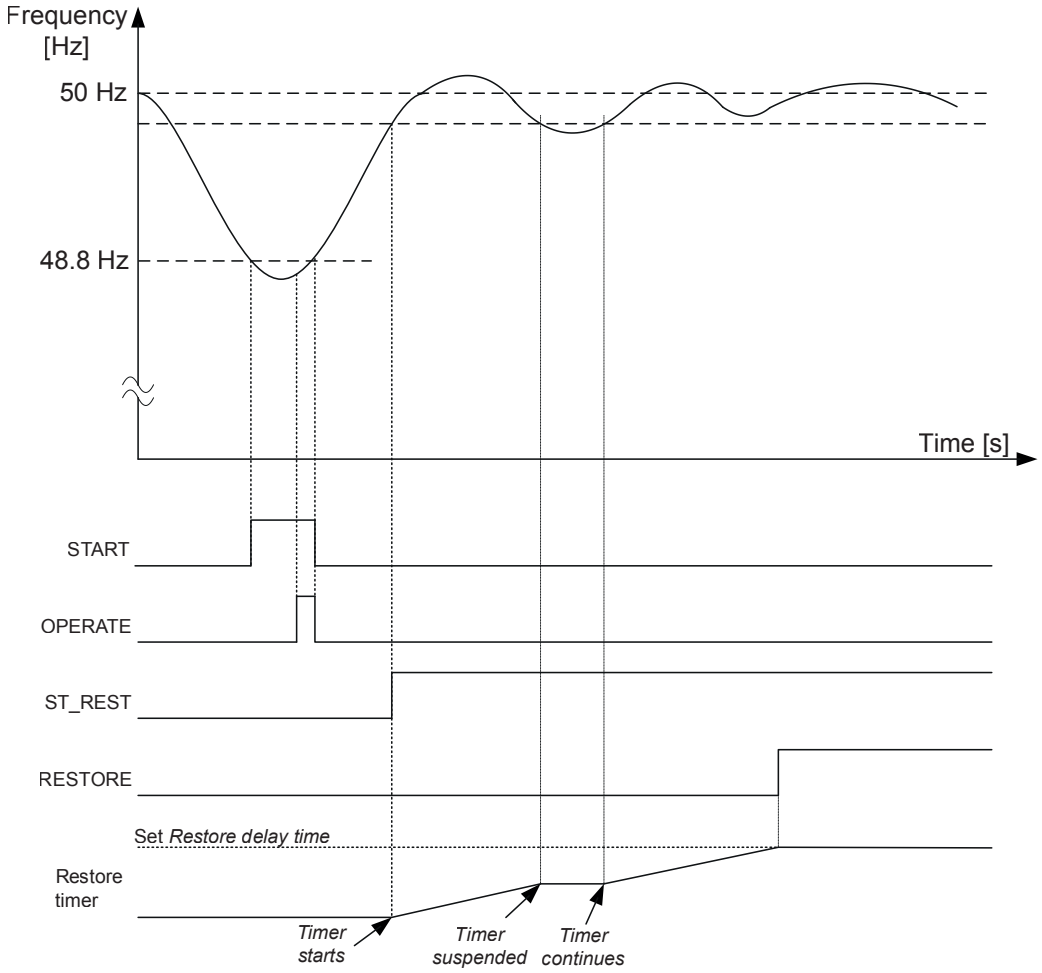

Figure 519: Operation of the load-shedding function

Power system protection by load-shedding

The decision on the amount of load that is required to be shed is taken through the measurement of frequency and the rate of change of frequency (df/dt). At a single location, many steps of load-shedding can be defined based on different criteria of the frequency and df/dt. Typically, the load-shedding is performed in six or four steps with each shedding increasing the portion of load from five to twenty-five percent of full load within a few seconds. After every shedding, the system frequency is read back and further shedding actions are taken only if necessary. In order to take the effect of any transient, a sufficient time delay should be set.

The value of the setting has to be well below the lowest occurring normal frequency and well above the lowest acceptable frequency of the system. The setting level, the number of steps and the distance between two steps (in time or in frequency) depend on the characteristics of the power system under consideration. The size of the largest loss of generation compared to the size of the power system is a critical parameter. In large systems, the load-shedding can be set at a high frequency level and the time delay is normally not critical. In small systems, the frequency start level has to be set at a low value and the time delay must be short.

If a moderate system operates at 50 Hz, an underfrequency should be set for different steps from 49.2 Hz to 47.5 Hz in steps of 0.3 – 0.4 Hz. The operating time

for the underfrequency can be set from a few seconds to a few fractions of a second stepwise from a higher frequency value to a lower frequency value.

Table 893: Setting for a five-step underfrequency operation

Load-shedding steps	Start value Freq setting	Operate Tm Freq setting
1	0.984 · Fn (49.2 Hz)	45000 ms
2	0.978 · Fn (48.9 Hz)	30000 ms
3	0.968 · Fn (48.4 Hz)	15000 ms
4	0.958 · Fn (47.9 Hz)	5000ms
5	0.950 · Fn (47.5 Hz)	500 ms

The rate of change of frequency function is not instantaneous since the function needs time to supply a stable value. It is recommended to have a time delay long enough to take care of the signal noise.

Small industrial systems can experience the rate of change of frequency as high as 5 Hz/s due to a single event. Even large power systems can form small islands with a large imbalance between the load and generation when severe faults or combinations of faults are cleared. Up to 3 Hz/s has been experienced when a small island becomes isolated from a large system. For normal severe disturbances in large power systems, the rate of change of the frequency is much less, often just a fraction of 1.0 Hz/s.

Similarly, the setting for df/dt can be from 0.1 Hz/s to 1.2 Hz/s in steps of 0.1 Hz/s to 0.3 Hz/s for large distributed power networks, with the operating time varying from a few seconds to a few fractions of a second. Here, the operating time should be kept in minimum for the higher df/dt setting.

Table 894: Setting for a five-step df/dt< operation

Load-shedding steps	Start value df/dt setting	Operate Tm df/dt setting
1	-0.005 · Fn /s (-0.25 Hz/s)	8000 ms
2	-0.010 · Fn /s (-0.50 Hz/s)	2000 ms
3	-0.015 · Fn /s (-0.75 Hz/s)	1000 ms
4	-0.020 · Fn /s (-1.00 Hz/s)	500 ms
5	-0.025 · Fn /s (-1.25 Hz/s)	250 ms

Once the frequency has stabilized, the shed load can be restored. The restoring operation should be done stepwise, taking care that it does not lead the system back to the emergency condition.

Table 895: Setting for a five-step restoring operation

Load-shedding steps	Restore start Val setting	Restore delay time setting
1	0.990 · Fn (49.5 Hz)	200000 ms
2	0.990 · Fn (49.5 Hz)	160000 ms
3	0.990 · Fn (49.5 Hz)	100000 ms

Table continues on the next page

Load-shedding steps	Restore start Val setting	Restore delay time setting
4	0.990 · Fn (49.5 Hz)	50000 ms
5	0.990 · Fn (49.5 Hz)	10000 ms

4.7 Impedance protection

4.7.1 Distance protection DSTPDIS (ANSI 21P, 21N)

4.7.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Distance protection	DSTPDIS	Z<	21P, 21N

4.7.1.2 Function block

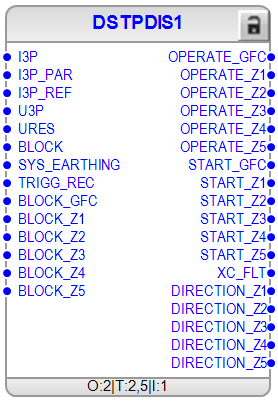

Figure 520: Function block

4.7.1.3 Functionality

The distance protection function DSTPDIS provides a full-scheme distance protection function for distribution networks where three-phase tripping is allowed for all kinds of faults.

DSTPDIS has five flexible, configurable impedance zones for protection (Z1...Z5).

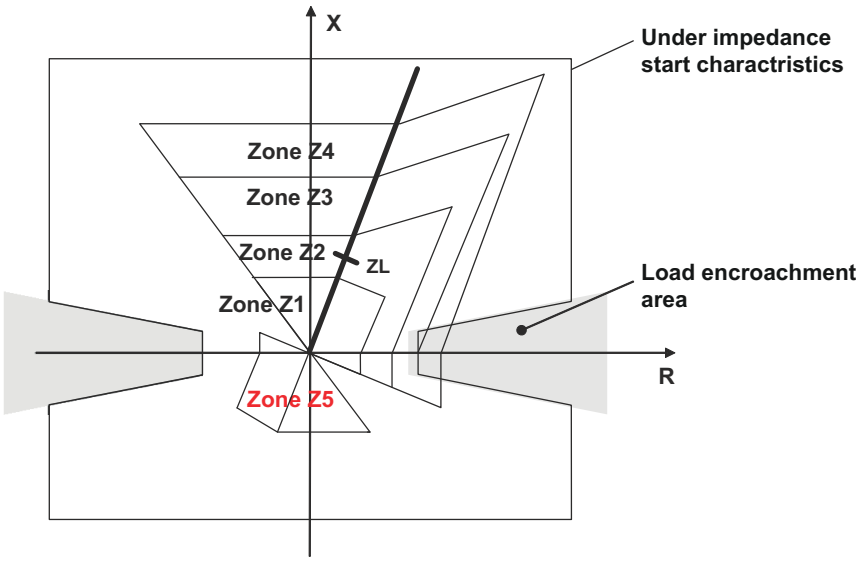

Figure 521: Zones of DSTPDIS function (example 1)

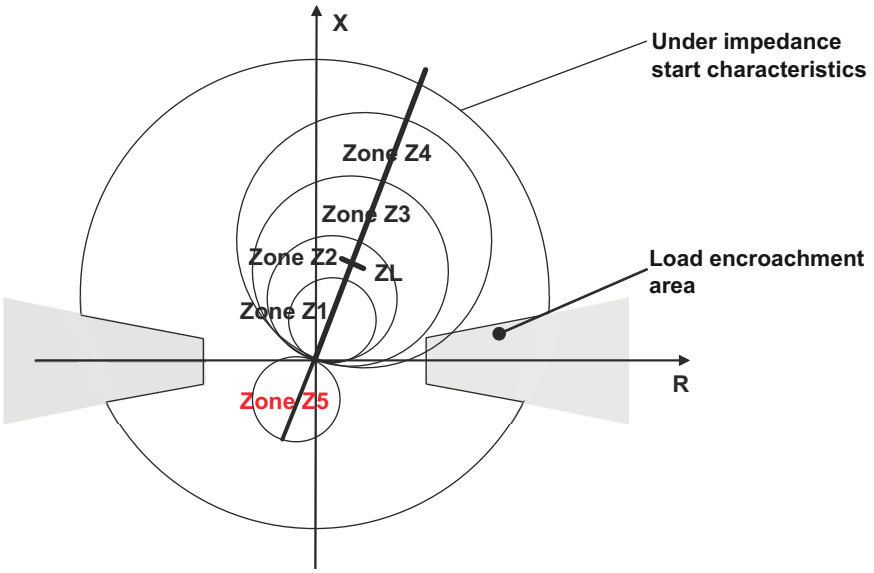

Figure 522: Zones of DSTPDIS function (example 2)

The supported zone characteristic shapes are quadrilateral, mho (circular) or bullet (quadrilateral and mho characteristics combined). Mho can be combined with directional lines to secure directionality and to enable increased fault resistance coverage with an offset mho circle.

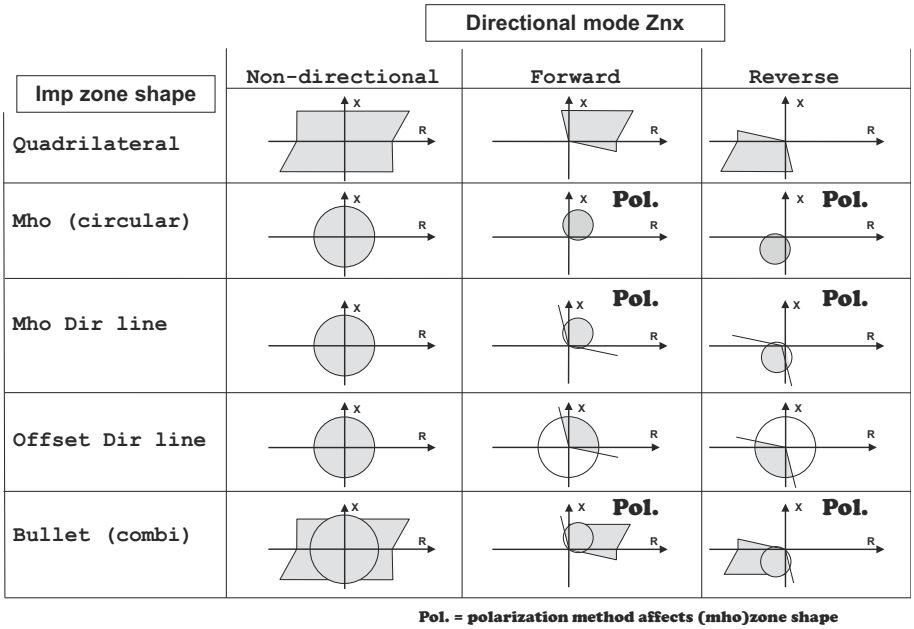

Figure 523: Possible combinations of Directional mode Znx and Zone characteristics settings. Pol. here means that the shape of the characteristic is affected by the selected polarization method of mho circle (Pol quantity zone = "Cross pol", "Pos. seq. volt.", "Self pol")

The directional lines are polarized with the set polarizing quantity of all impedance measuring elements. In addition, the memory voltage that is based on positive-sequence voltage substitute for the measured voltage with any impedance measurement element polarization if the corresponding voltage drops too low.

DSTPDIS has separate and independent measurement elements for each fault loop in the distance protection zone. In addition to the full scheme design, the separate measuring elements are used for general fault detection and faulted phase selection.

DSTPDIS supports both fault detection dependent control of zone timers and zone-dedicated phasewise timer control for maximum application flexibility.

The impedance measurement is always done the same way regardless of the zone shape. The operation is based on the impedance mapping approach where the fault loop impedance is first calculated and then compared to the zone boundaries. If impedance is recognized within the operation zone, the corresponding operate output is activated after the operate time has elapsed.

The impedance measurement is based on full-cycle DFT filtered current and voltage phasors.

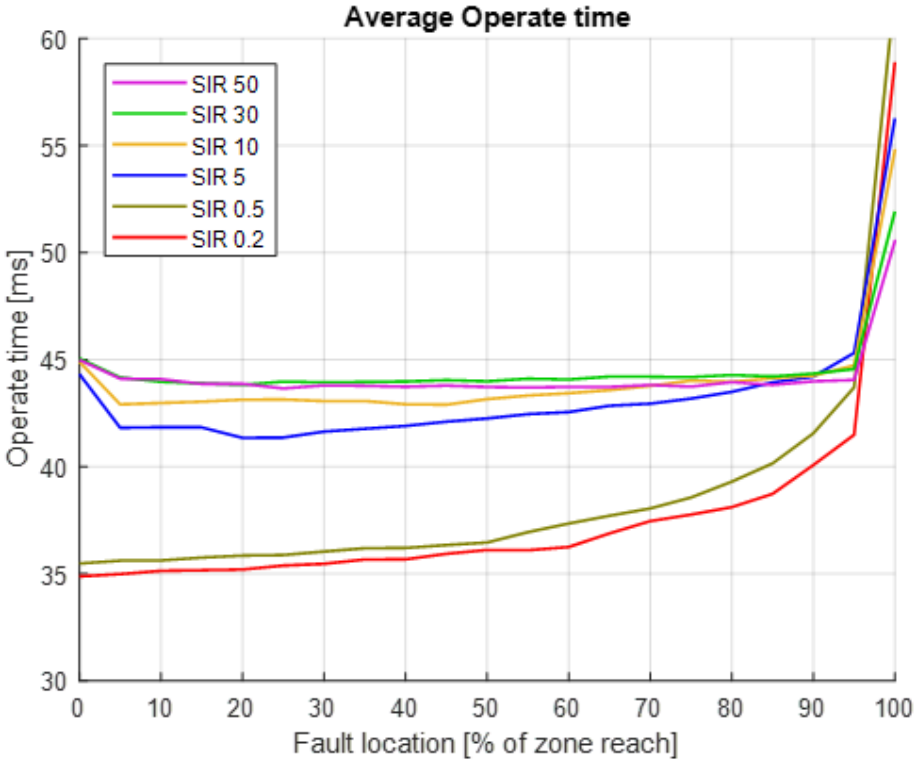

Figure 524: Average operate time of DSTPDIS according to IEC 60255-121 network models Short line and Long line (50 Hz)

SIR curves are plotted from the data which includes variation of fault location (0…100% of zone reach, 5% step), fault type (LN, LL, LLN, LLL) and fault inception angle (0, 30, 60, 90 degrees). Each combination has been repeated ten times giving the total number of 26880 shots. The operate times include the delay of relay output contacts. The SIR curves presented in *Figure 524* were obtained using the static power outputs (SPOs) and with *Zone timer mode* = "common".

4.7.1.4 Analog channel configuration

DSTPDIS has five analog group inputs which must be properly configured.

Table 904: Analog inputs

Input	Description
I3P	Three-phase currents
I3P_PAR [1]	Three-phase currents Necessary when *Par line Comp zone x* is set to True
I3P_REF [2]	Three-phase currents

Table continues on the next page

[1] Can be connected to GRPOFF if *Par line Comp zone x* is set to False.
[2] Can be connected to GRPOFF if *EF detection Mod GFC* is not set to "Io AND IoRef"

Input	Description
	Necessary when *EF detection Mod GFC* is set to "Io AND IoRef"
U3P	Three-phase voltages
URES [3]	Residual voltage (measured) Necessary when *EF detection Mod GFC* is set to "Io OR Uo" or "Io AND Uo". Necessary also if only main voltages are available but *Phase voltage Meas* is set to "Accurate".

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

Table 905: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.7.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The function consists of sub-functions which are described in the next sections.

[3] Can be connected to GRPOFF if *EF detection Mod GFC* is set to "Io" or "Io AND IoRef" or *Phase voltage Meas* is set to "Ph-to-ph without Uo"

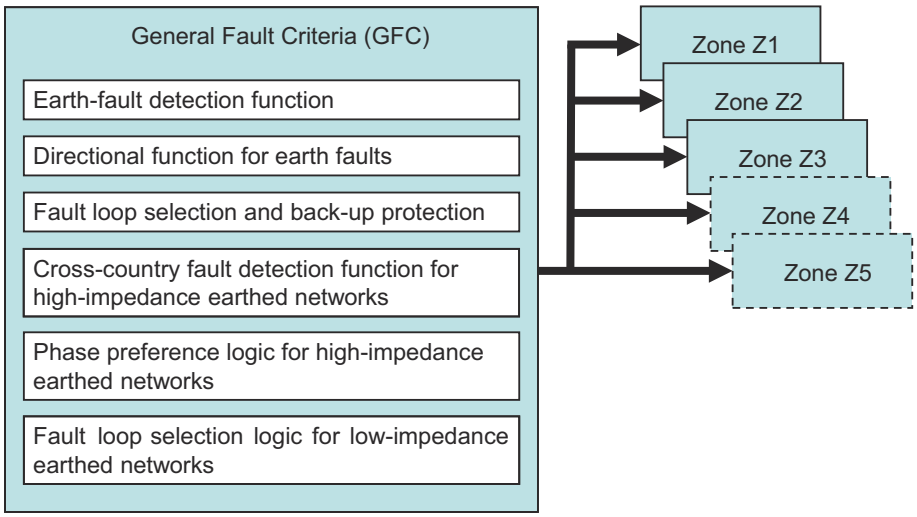

Figure 525: Main functionality of DSTPDIS

All outputs and the operation of all sub-functions can be blocked with the BLOCK binary input signal. In addition, it resets the timers.

Blocking

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE_Z1...5 output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE_Z1...5 output is not activated.

In addition, the function has zone-specific blocking signals BLOCK_Z1...5. The signal resets zone timers disabling the corresponding start and operate output activation.

BLOCK_GFC deactivates START_GFC and OPERATE_GFC. It also resets GFC operate time (set by *Operate delay GFC*). Blocking does not prevent GFC operation.

Earth-fault detection function

The recognition of an earth fault is an important part in identifying the correct fault type. This information is used in faulted loop (phase) selection to release the correct impedance-measuring elements. The earth-fault recognition is always required to release the phase-to-earth impedance-measuring elements.

The earth-fault detection is indicated with the EARTH_FLT monitored data. The earth-fault detection criterion can be defined with the *EF detection Mod GFC* setting. The fundamental criterion is based on the residual current. The residual voltage and reference neutral current, measured from the transformer neutral point, can be used for the earth-fault detection criteria.

Table 906: Selection of earth-fault detection criteria

Setting	Enumerator name
EF detection Mod GFC	• Io • Io OR Uo • Io AND Uo • Io AND IoRef

If the residual current Io is derived from the phase currents either by the summation connection of CTs, that is, the Holmgreen connection, or by internally summing the phase currents, there is a risk of a false earth-fault detection due to apparent residual current from the current transformer errors. This risk can be eliminated using a stabilized residual current measurement. The stabilization is enabled by setting the *EF Cur stabilization* setting to "True". The stabilization increases the residual current *Gnd Op current GFC* threshold setting when the maximum phase current exceeds the nominal current. The increase is defined with the *Stab slope 1 GFC* setting. The apparent residual current may exist during short circuits and in inrush current situations if the CTs saturate partially. The earth-fault detection function takes the CT saturation into account with additional stabilization settings *Gnd Op current 2 GFC, A Ph Stab value GFC* and *Stab slope 2 GFC*.

Setting *EF Cur stabilization* to "False" disables the stabilization of the residual current measurement and should be used only when the residual current is measured with a cable current transformer. The residual current threshold setting for earth-fault detection is *Gnd Op current GFC*. If the residual current is measured from a transformer neural point, *Gnd Op A Ref GFC* is used. This is valid when the setting *EF detection Mod GFC* is "Io AND IoRef".

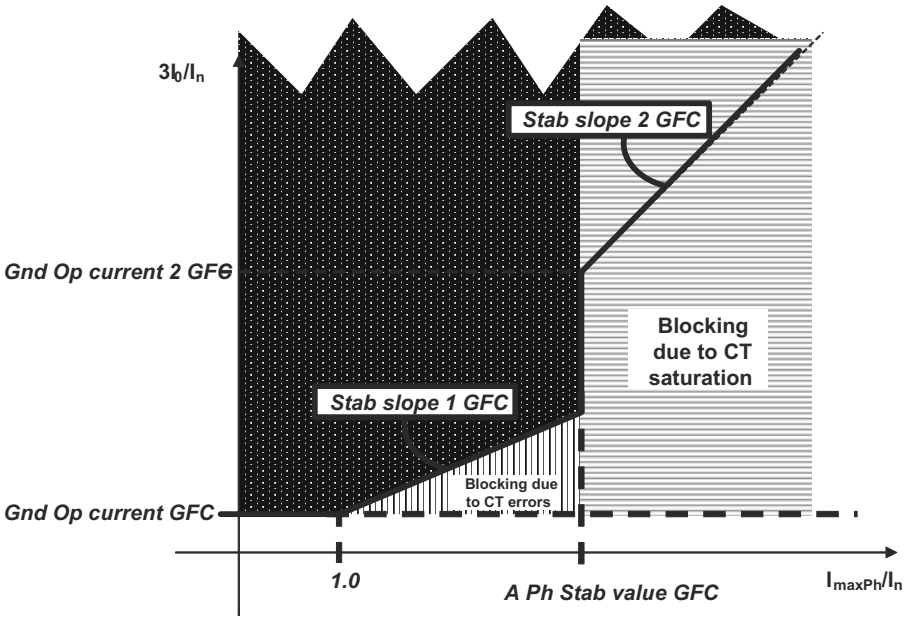

Figure 526: Stabilized residual current measurement for earth-fault detection

The residual voltage can also be used as a complementary criterion for earth-fault detection. This is valid when the setting *EF detection Mod GFC* is "Io OR Uo" or *EF detection Mod GFC* is "Io AND Uo". The threshold setting for the residual voltage is *Gnd Str voltage GFC*.

Directional function for earth faults

In low-impedance earthed networks, when the *System grounding GFC* setting is set to "Low impedance", the earth-fault detection function can be optionally supervised by a directional function which can be enabled with the *Dir mode EF GFC* setting. If *Dir mode EF GFC* is set to "Forward" or "Reverse", the earth-fault direction is also detected. The calculated direction for the earth fault is indicated in the DIR_E_FLT monitored data ("unknown", "forward", "backward" (reverse), "both"). Direction criteria do not directly affect earth-fault detection, but the earth-fault direction information is used for zone starting, when only those directional zones that are set to the indicated earth-fault direction can be started.

The operation characteristic of the directional function is defined by three settings: *Chr angle GFC*, *Min phase angle GFC* and *Max phase angle GFC*.

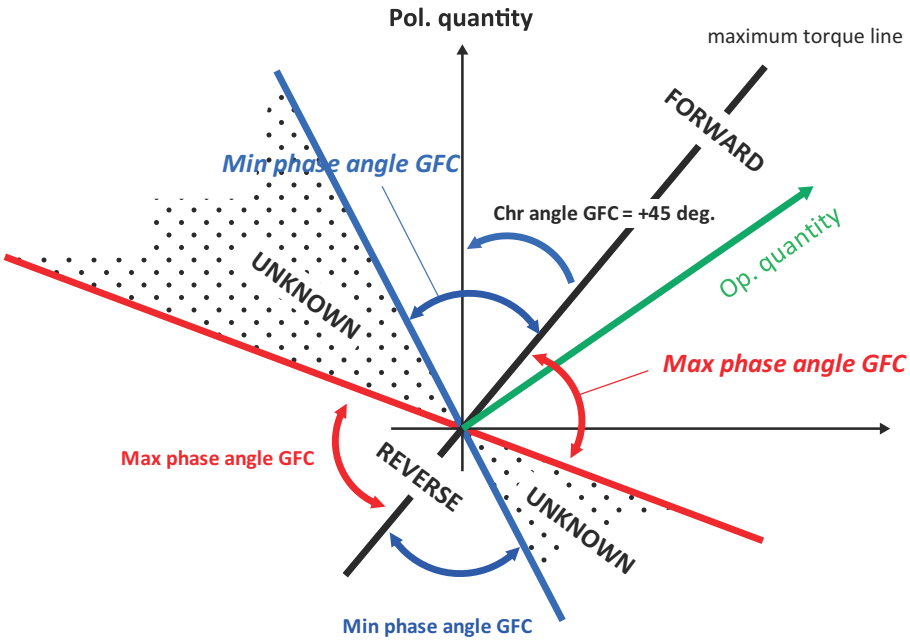

Figure 527: Characteristic of the directional function for earth faults

The *Chr angle GFC* setting, also known as relay characteristic angle or basic angle, is used to turn the directional characteristic. It has a positive value when the operating quantity lags the polarizing quantity and a negative value when the operating quantity leads the polarizing quantity. For low-impedance earthed networks, *Chr angle GFC* equals the angle of the fault loop impedance and is typically positive.

The *Min phase angle GFC* and *Max phase angle GFC* settings define the width of the operating sector. These settings are mirror-symmetric to the origin for reverse (backward).

The directional function for earth faults must operate at fault current values below the magnitude of the load currents. The use of sequence quantities is preferred for polarizing quantity as phase quantities are affected by the load currents. Four possibilities are available and defined by the *Pol quantity GFC* setting.

Table 907: Polarizing quantities for optional directional function for earth faults in low-impedance earthed networks

Pol quantity GFC	Polarizing quantity	Operating quantity	Description
Zero seq. volt.	$-U_0$	I_0	Zero-sequence voltage polarization
Neg. seq. volt.	$-U_2$	I_2	Negative-sequence voltage polarization
Zero seq. cur.	I_{oref}	I_0	Zero-sequence current polarization
Zro vol. OR cur.	$-U_0$ OR I_{0ref}	I_0	Dual polarization

The polarizing quantity is $-U_0$ and the operating quantity is I_0 in case of zero-sequence voltage polarization.

The polarizing quantity is $-U_2$ and the operating quantity is I_2 in case of negative-sequence polarization.

In case of zero-sequence current polarization "Zero seq. cur.", the zero-sequence current I_0 of the protected line is the operating quantity while another reference zero-sequence current I_{0ref} is the polarizing quantity. I_{0ref}, for example, could be the current from the neutral of a power transformer. In case of zero-sequence current polarization, the relay characteristic angle *Chr angle GFC* is internally fixed and is equal to zero degrees. The zero-sequence current direction must remain unchanged during all network configurations and faults. Therefore, all transformer configurations or constructions are not suitable for polarization.

In case of dual polarization "Zro vol. OR cur.", the zero-sequence voltage polarization and zero-sequence current polarization elements are logically OR:ed. Typically, when I_0 is high, U_0 is low, and when I_0 is low, U_0 is high. Hence the protection can benefit from both elements as the two polarization methods complement each other. If the zero-sequence current polarization source is switched off for service, the flexibility is increased as the zero-sequence voltage polarization can be used.

Faulted loop phase selection

A reliable identification of a fault and faulted phases is needed to guarantee a selective operation of the distance protection. This information is used to release correct measuring elements of the protection zones.

In DSTPDIS, the faulted phase selection can be done in various ways and defined with the *Phase Sel mode GFC* setting.

Table 908: Supported methods for phase selection

Setting	Enumerator value
Phase Sel mode GFC	• Overcurrent • Vol Dep Overcur • Under impedance • OC AND Und impedance

- The “Overcurrent” method is the basic method for identifying the faulted phases. It can be used in applications where the fault current magnitude exceeds the load current despite the changes in the network configuration and fault type.

- The “Vol Dep Overcur” method combines overcurrent and undervoltage conditions. An undervoltage condition allows lower current threshold settings and increases the sensitivity of the fault detection.
- The “Under impedance” method uses fault loop impedance for identifying the faulted phases. The underimpedance characteristic can be either quadrilateral or circular in shape. The sensitivity of the fault detection is defined by an independent setting in resistive and reactive reaches. The underimpedance method is supervised by a load encroachment logic which ensures that the load impedance does not interfere with the faulted phase selection.

The ”OC AND Und impedance” method combines “Overcurrent” and “Under impedance” methods so that both criteria have to be fulfilled.

All phase selection methods require that all three phase currents are measured and all three phase-to-earth voltages are available. If only phase-to-phase voltages are available (*Phase voltage Meas* = “Ph-to-ph without Uo”), only phase-to-phase measuring loops can be released for measurement. The release of phase-to-earth fault measuring elements is then blocked, RELEASE_PE = “No fault”.

The operation of the faulted phase selection function is highly dependent on the earth-fault detection function. The phase preference or faulted loop selection logic can be set to filter the faulted phases to be released for measurement in the protection zones.

The general indication of a fault is given in the binary output START_GFC. The faulted phase information can be found from the integer monitored data signal STARTS_GFC.

Table 909: Enumeration values for integer monitored data signal STARTS_GFC

Enumeration name	Value
No fault	-5
AG Fault	1
BG Fault	2
CG Fault	3
AB Fault	4
BC Fault	5
CA Fault	6
ABC Fault	7

The fault loops released for measurement are indicated with the integer monitored data signals RELEASE_PE and RELEASE_PP. These signals may be filtered by the phase preference of the faulted loop selection logic.

Table 910: Enumeration values for integer monitored data signal RELEASE_PE

Enumeration name	Value
No fault	-5
AG Fault	1
BG Fault	2
CG Fault	3
AB Fault	4

Table continues on the next page

Enumeration name	Value

CA Fault	6
ABC Fault	7

Table 911: Enumeration values for integer monitored data signal RELEASE_PP

Enumeration name	Value
No fault	-5
AB Fault	4
BC Fault	5
CA Fault	6
ABC Fault	7

The phase selection function can be set to issue an operate signal as the faulted phase selection uses independent measuring elements from the distance protection zones. This can be applied as a back-up protection for the measurement zones. The time delay of the operate signals is defined with the *Operate delay GFC* setting. The operate signal is the binary output OPERATE_GFC.

Faulted loop phase selection by the overcurrent method

The "Overcurrent" method is the basic method used for identifying the faulted phases. It can be used in applications where the fault current magnitude exceeds the load current despite the possible changes in the network configuration and fault type.

In the overcurrent-based faulted phase selection method, the amplitude of each phase current is compared to the *Str A Ph Sel GFC* threshold setting. If the phase current magnitude exceeds the value of *Str A Ph Sel GFC*, that particular phase is faulty.

Earth-fault recognition is always required to release a phase-to-earth impedance-measuring element.

Table 912: Conversion from element start to monitored data signals

Start of element	START_GFC	STARTS_GFC	RELEASE_PE	RELEASE_PP
I_A> & EARTH_FLT	TRUE	AG Fault	AG Fault	No fault
I_B> & EARTH_FLT	TRUE	BG Fault	BG Fault	No fault
I_C> & EARTH_FLT	TRUE	CG Fault	CG Fault	No fault
I_A> & I_B>	TRUE	AB Fault	No fault	AB Fault

Table continues on the next page

Start of element	START_GFC	STARTS_GFC	RELEASE_PE	RELEASE_PP
I_B> & I_C>	TRUE	BC Fault	No fault	BC Fault
I_C> & I_A>	TRUE	CA Fault	No fault	CA Fault
I_A> & I_B> & EARTH_FLT	TRUE	AB Fault	AB Fault	AB Fault
I_B> & I_C> & EARTH_FLT	TRUE	BC Fault	BC Fault	BC Fault
I_C> & I_A> & EARTH_FLT	TRUE	CA Fault	CA Fault	CA Fault
I_A> & I_B> & I_C[4]	TRUE	ABC Fault	No fault	ABC Fault
I_A> & I_B> & I_C> & EARTH_FLT [5]	TRUE	ABC Fault	ABC Fault	ABC Fault

In case of a high-impedance earthed network, a phase preference logic can be added to complement the phase selection in case of a cross-country fault. This can affect the RELEASE_PE signals.

In case of a low-impedance earthed network, a faulted loop selection logic can be added to complement the phase selection in case of a two-phase-to-earth fault. This can affect the RELEASE_PE and RELEASE_PP signals.

Faulted phase selection, the voltage-dependent overcurrent method

The "Voltdep overcur" method combines the overcurrent and undervoltage conditions. The phase current amplitude is compared to the *Str A Ph Sel GFC* threshold setting but a lower current *Lo A Ph Sel GFC* threshold is valid during an undervoltage condition. This increases the sensitivity of the fault detection. The amplitude of phase-to-earth and phase-to-phase voltages is compared to the *Ph V Ph Sel GFC* and *PP V Ph Sel GFC* settings. In case of a three-phase fault, the phase-to-phase voltages are monitored and compared to the *PP V Ph Sel GFC* setting.

Earth-fault recognition is always required to release a phase-to-earth impedance-measuring element.

[4] This applies to near three-phase faults. If voltages are still relatively high, all PP releases are given.

[5] This applies to near three-phase faults with EF indication. If voltages are still relatively high, all PE and PP releases (except ABC Fault) are given.

Faulted phase selection, the underimpedance method

The "Under impedance" and "OC AND Und impedance" methods use fault loop impedance for identifying the faulted phases. The advantage of the underimpedance criterion is that the sensitivity of the fault detection is independent of the source impedance. The underimpedance function has six impedance measuring elements. The phase-to-earth measuring elements are calculated:

$$\underline{Z}_A = \frac{\underline{U}_A}{\underline{I}_A}$$

(Equation 261)

[6] This applies to near three-phase faults. If voltages are still relatively high, all PP releases are given.

[7] This applies to near three-phase faults with EF indication. If voltages are still relatively high, all PE and PP releases (except ABC Fault) are given.

$$\underline{Z}_B = \frac{\underline{U}_B}{\underline{I}_B}$$

(Equation 262)

$$\underline{Z}_C = \frac{\underline{U}_C}{\underline{I}_C}$$

(Equation 263)

The phase-to-phase measuring elements are based on the formula:

$$\underline{Z}_{AB} = \frac{\underline{U}_{AB}}{\underline{I}_{AB}}$$

(Equation 264)

$$\underline{Z}_{BC} = \frac{\underline{U}_{BC}}{\underline{I}_{BC}}$$

(Equation 265)

$$\underline{Z}_{CA} = \frac{\underline{U}_{CA}}{\underline{I}_{CA}}$$

(Equation 266)

The faulted phase identification is done by comparing the measured impedance to the operating characteristics in the impedance domain. If a measured fault loop impedance is inside the characteristics, the corresponding phases are identified as faulty.

The shape of the characteristic is selected with the *Z Chr Mod Ph Sel GFC* setting. Two shapes are available.

- "Mho (circular)", Non-directional mho
- "Quadrilateral", Non-directional quadrilateral

The two shapes can be flexibly configured. It is possible to set the reactive reaches independently in forward and in reverse direction and for phase-to-earth (Gnd) and phase-to-phase (PP) measurement elements, for example, the *X Gnd Fwd reach GFC*, *X Gnd Rv reach GFC*, *X PP Fwd reach GFC* and *X PP Rv reach GFC* settings. Also, the resistive reach in case of quadrilateral characteristic can be set both forward and reverse independently of reactive reaches, for example, the *Ris Gnd Fwd Rch GFC, Ris Gnd Rv Rch GFC, Ris PP Fwd Rch GFC* and *Ris PP Rv Rch GFC* settings. The characteristic is always mirror-symmetric around the reactance axis.

The impedance settings are in primary ohms.

In case of heavy loaded feeders, the optional load encroachment logic can be enabled with the *Load Dsr mode GFC* setting. The logic reserves an area for load

impedance defined by the *Ris Fwd Rch Lod GFC, Ris Rv Rch Lod GFC* and *Angle load area GFC* settings.

The underimpedance characteristics in case of phase-to-earth measuring elements are illustrated in *Figure 529* and *Figure 530*. Similar characteristics apply also to phase-to-phase measuring elements with independent settings.

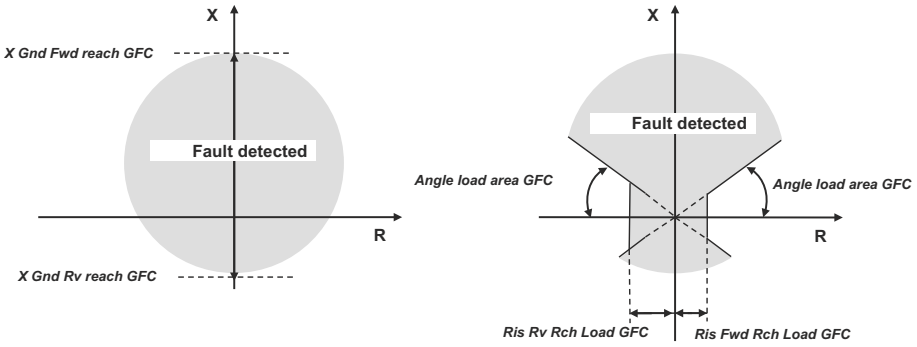

Figure 529: Circular mho underimpedance characteristics

In case of a high-impedance earthed network, a phase preference logic can be added to complement the phase selection in case of a cross-country fault. This can affect the RELEASE_PE signals.

In case of a low-impedance earthed network, a faulted loop selection logic can be added to complement the phase selection in case of a two-phase-to-earth fault. This can affect the RELEASE_PE and RELEASE_PP monitored data signals.

Cross-country fault detection function for high-impedance earthed networks

In isolated and high-impedance earthed networks, the overvoltages produced by a single-phase earth fault may lead to a cross-country fault, where two simultaneous single-phase earth faults are present in the system but in different locations and phases. The cross-country fault is hazardous because the magnitude of the fault current through earth can be as high as in the case of a two-phase short circuit fault. The protection must therefore remove the cross-country fault quickly without sacrificing the selectivity. This can be done with a phase preference logic which is activated by the cross-country fault detection function. The phase preference logic transforms the fault into an ordinary single-phase earth fault by selectively tripping one of the faulted feeders.

The cross-country detecting function can become active only if the network is either isolated or high-impedance earthed (*System grounding GFC* = "High impedance" or selection "From input" and binary input SYS_EARTHING is active).

The fault detection is based on monitoring two quantities.

- Residual current
- Phase-to-phase voltages

A cross-country fault is detected if:

- An earth fault is detected, EARTH_FLT = TRUE.

AND

[8] This applies to near three-phase faults. If voltages are still relatively high, all PP releases are given, depending on the impedances seen inside the GFC zone.

[9] This applies to near three-phase faults with EF indication. If voltages are still relatively high, all or some PE and PP releases (except ABC Fault) are given, depending on the impedances seen inside the GFC zone.

- The calculated residual current exceeds the value of *Gnd Op A XC GFC* setting. This setting value should exceed the highest expected single-phase earth-fault current (calculated from phase currents). The condition is needed because the cable current transformer saturates easily due to the high fault current.

AND

- The residual overcurrent condition must be valid at least for the duration defined by the *Cross-country DI GFC* setting. This shows that the detection is not misled by the high-magnitude initial transients of a single-phase earth fault.

OR

- Any phase-to-phase voltage drops below the value of the *PP voltage XC GFC* setting. The undervoltage condition is based on the fact that during a single-phase earth fault, the phase-to-phase voltages are unaffected in isolated and high-impedance earthed networks. The fulfilment of this criterion in combination with the residual overcurrent condition avoids the need for any delays.

The detection of a cross-country fault is indicated by the `XC_FLT` output signal.

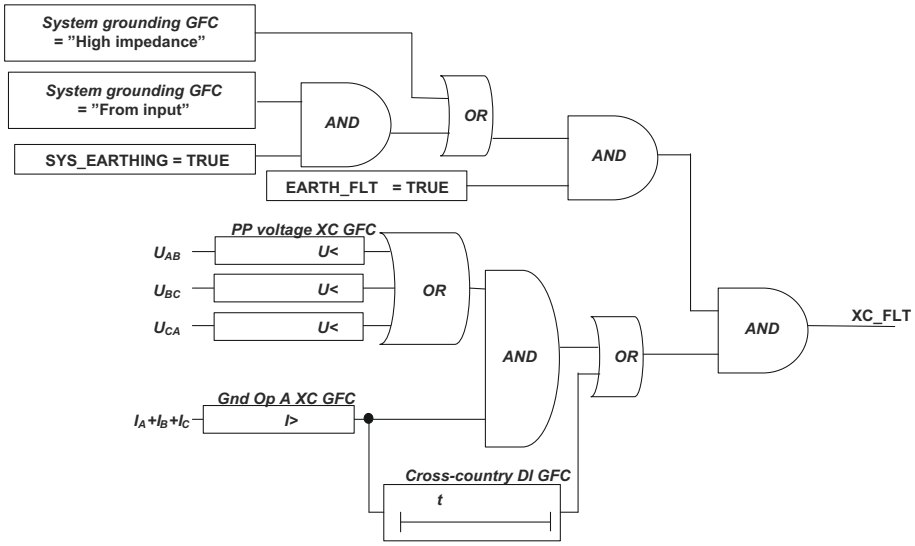

Figure 531: Cross-country fault detection logic for high-impedance earthed networks

Phase preference logic for high-impedance earthed networks

The phase preference logic is applicable only in isolated and high-impedance earthed networks. The phase preference logic for high-impedance earthed networks is a supplement to the faulted phase identification function. It provides selective filtering of phase-to-earth measurement elements in case of a cross-country fault or double earth-fault in isolated and high-impedance earthed networks.

The logic releases the preferred phase-to-earth loop for measurement when a cross-country fault with two faulted phase-to-earth loops is detected. If only one faulted phase-to-earth loop is detected by phase selection logic (GFC), the other faulted phase-to-earth loop is determined by analysing voltages. The phase preference scheme must be set in the same way for the entire system so that all distance relays measure the same preferred phase-to-earth loop. As a result, the cross-country fault is changed into an ordinary single-phase earth-fault by selectively tripping one of the faulted feeders.

The phase preference logic influences only the selection of the phase-earth loops and has no effect on the selection of the phase-to-phase loops. The influence is seen in the RELEASE_PE monitored data. The logic does not affect the RELEASE_PP monitored data or START_GFC/STARTS_GFC outputs.

All schemes, except "No filter", require a cross-country fault detection XC_FLT = TRUE; otherwise all the phase-to-earth measuring elements are blocked resulting in RELEASE_PE value "No fault". This guarantees that tripping at a single-phase earth fault in the high-impedance earthed network is blocked.

If a cross-country fault is detected, XC_FLT = TRUE and only a single fault loop can be identified as faulty by the faulted phase selection function, then that loop is directly selected for measurement. In such a case, simultaneous tripping of both faulted feeders during a cross-country fault is expected.

Example

Consider a cross-country fault where phases A and B become faulted simultaneously. All relays, R1, R2, R3 and R4, are equipped with an "Acyc C-A-B" phase preference scheme.

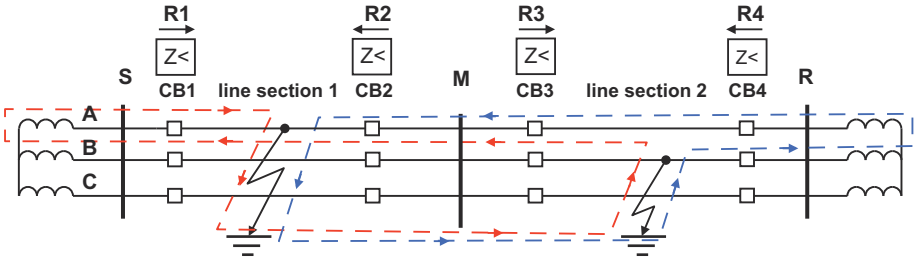

Figure 532: Cross-country fault (or double earth fault) in a high-impedance earthed system

The expected operations of the relays are:

- R1: The cross-country fault cannot be detected as the residual current does not flow through relay R1. The phase-to-phase loop AB is measured in the forward direction but the estimated impedance represents an average impedance between two fault locations and therefore is not seen in zone Z1.
- R2: The cross-country fault is detected as a high residual current flows through relay R2. Phase A earth fault is seen in forward direction and phase B earth fault in reverse direction. Based on "Acyc C-A-B" phase preference scheme, phase A is selected for measurement. Relay R2 operates without delay and opens the CB2 circuit breaker.
- R3: The cross-country fault is detected when a high residual current flows through relay R3. The phase A earth fault is seen in reverse direction and phase B earth fault in forward direction. Based on the "Acyc C-A-B" phase preference scheme, phase A is selected for measurement. As the fault direction does not coincide with the zone direction, relay R3 does not operate.
- R4: Same as relay R1

As a result of the circuit breaker CB2 operation, the cross-country fault is transformed into an ordinary single-phase earth fault.

Table 915, *Table 916* and *Table 917* summarize the available phase preference logic schemes and their operation in different fault scenarios. The logic is selected with the *Ph Prf mode Hi Z GFC* setting. In case the logic is not required, then the "No filter" option should be selected.

"No filter" option does not block the single-phase earth-faults, therefore this option should be used with caution.

Faulted loop phase selection for low-impedance earthed networks

The faulted loop selection logic for low-impedance earthed networks serves as a supplement to the faulted phase identification function and it provides a selective filtering of measurement elements in case of a two-phase-to-earth fault in low-impedance earthed networks. The earth faults can be located close to each other.

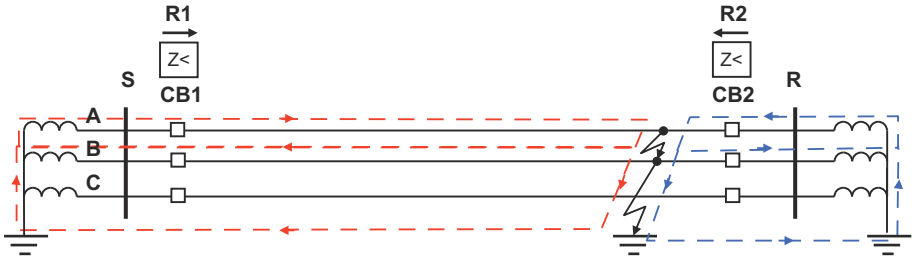

Figure 533: Two-phase-to-earth fault in low-impedance earthed system

Impedance can be measured during a two-phase-to-earth fault when the earth faults are located in the same direction and they are in close proximity to each other. Generally, too large an impedance is measured for the lagging phase-to-earth loop, for example phase B in an AB-E fault. Similarly, low impedance is measured for the leading phase-to-earth loop, for example phase A in an AB-E fault. The corresponding phase-to-phase loop is measured correctly, for example phase-to-phase loop AB in an AB-E fault.

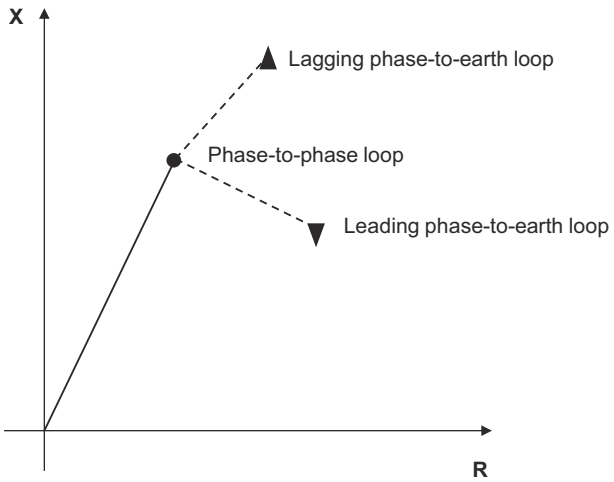

Figure 534: Impedance measured during a two-phase-to-earth fault

The available faulted loop selection logic schemes allow blocking the phase-earth loop of the leading phase to prevent overreaching *Ph Prf mode Lo Z GFC* = "BLK leading PE".

It is also possible to block the lagging phase-earth loop, *Ph Prf mode Lo Z GFC* = "BLK lagging PE". If only the phase-to-phase loop or phase-to-earth loops must be measured, settings *Ph Prf mode Lo Z GFC* = "PP only" or *Ph Prf mode Lo Z GFC* = "PE only" should be used, and if the logic is not required, "All loops" option should be selected.

The tables summarize the available faulted loop selection logic schemes and their operations. The logic is selected with the *Ph Prf mode Lo Z GFC* setting.

Impedance protection zones

DSTPDIS has five flexible and configurable impedance zones Z1..Z5. The number of active zones has to be selected by setting *Select active zones*. For example, all five zones can be set active by selection "All 5 zones" and only zone 1 is activated by "Zone 1". The purpose of this setting is effectively dimming non-active zone settings in PCM600 or the protection relay's HMI.

Example

If only zones 1 and 3 should be activated, "Zones 1-3" should be selected and then zone 2 timers can be disabled or `BLOCK_Z2` can be activated to hide zone 2 operations.

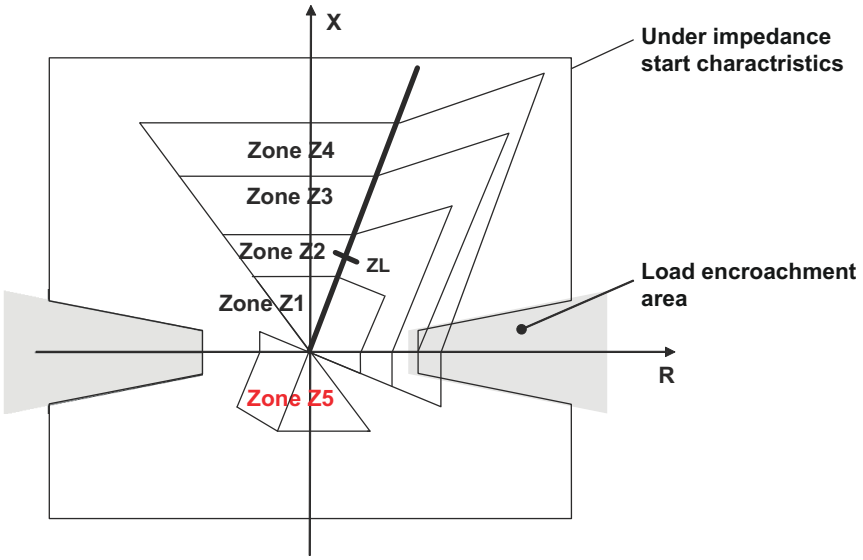

Figure 535: Zones of DSTPDIS function (example 1)

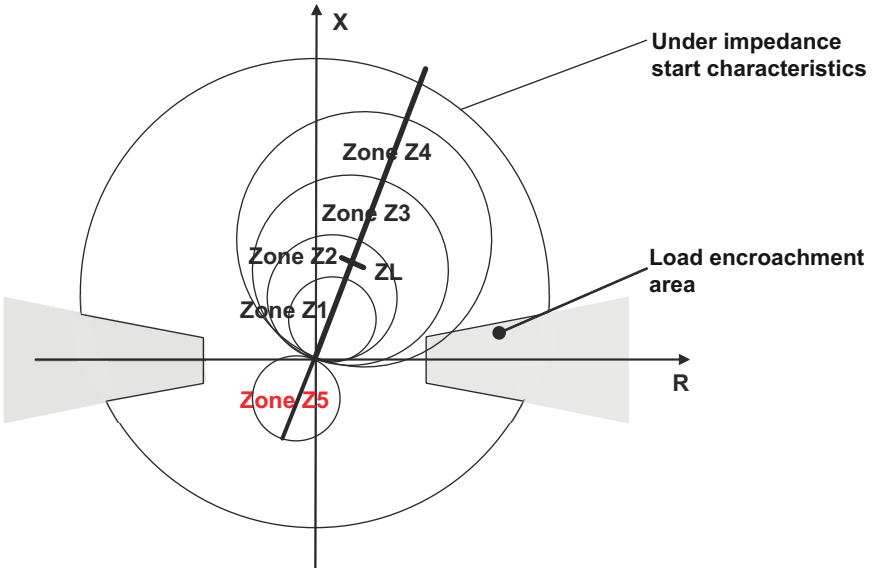

Figure 536: Zones of DSTPDIS function (example 2)

Each zone in DSTPDIS provides three independent phase-to-earth and three phase-to-phase measuring elements. A three-phase fault is measured with a dedicated measuring element. Each measuring element is controlled by the faulted loop phase selection function. Based on the recognized fault type, the release signals are given for the corresponding measuring elements.

DSTPDIS supports both fault detection dependent control of zone timers and zone-dedicated timer control for maximum application flexibility. Zone-dedicated timer control is enabled when configuration parameter *Zone timer mode* is set to "Independent" (change requires relay reboot). In this case, operate delay timers of protection zones are independent of each other and start when a fault is seen in their protection zone. Fault detection dependent control of zone timers is enabled when *Zone timer mode* is set to "Common". In this case, operate delay timers of all protection zones start simultaneously as soon as the fault is seen by the GFC.

The operation of a particular zone is given after the set operate delay time for the particular zone has elapsed (considering the fault type). The actual operate time is the value calculated from the initial fault detection and it is not affected, for example, in case the fault moves between zones.

The general indication of fault for each zone is given in the START_Zx (x = 1...5) binary output. The faulted phase information can be found from the STARTS_Zx (x = 1... 5) integer type output signal. This signal indicates (bitwise) the started measuring elements for the corresponding phase. Value 0 does not exist but due to the IEC 61850 standard requirement, it is shown by value “-5” as “No fault”. Value range is thus -5, 1..63. The three-phase fault is here indicated by “AB Fault, BC Fault, CA Fault”. However, three-phase fault indication for GFC depends also on the additional condition for voltage (see *Table 913*).

The operate signal from each zone is the OPERATE_Zx (x = 1...5) binary output signal.

The output from each zone can be blocked and the timers are also reset with the BLOCK_Zx (x = 1...5) binary input signal.

The TLT_ANG_CONFLICT monitored data is an assisting integer output which supervises the validity of a tilt angle of quadrilateral characteristics so that the characteristics always produce a closed boundary.

Impedance measurement

DSTPDIS provides three independent phase-to-earth and phase-to-phase measuring elements per zone. The three-phase fault is measured with a dedicated measurement element.

The impedance measurement is done similarly regardless of the zone shape. The operation is based on impedance mapping where the fault loop impedance is first calculated and then compared with the zone boundaries. If impedance is recognized inside the operation zone, the corresponding operate output is activated after the operate time has elapsed.

Phase-to-earth impedance measuring elements

The phase-to-earth impedance measuring elements provide the basic earth-fault protection in direct or low-impedance earthed networks. The earth-fault protection is enabled with the setting *Op Mod Gnd loops Znx* (x = 1...5) = "True". The enabling requires that all three phase-to-earth voltages are measured. Otherwise, the release of the earth-fault measuring elements is automatically blocked.

The reach of phase-to-earth measuring elements is based on loop impedance

$$\underline{Z}_1 + \underline{Z}_N + RF = \left(R_1 + \frac{R_0 - R_1}{3} \right) + j \cdot \left(X_1 + \frac{X_0 - X_1}{3} \right) + RF$$

(Equation 267)

The earth return path impedance is included in the calculated fault loop impedance of the phase-to-earth measuring element.

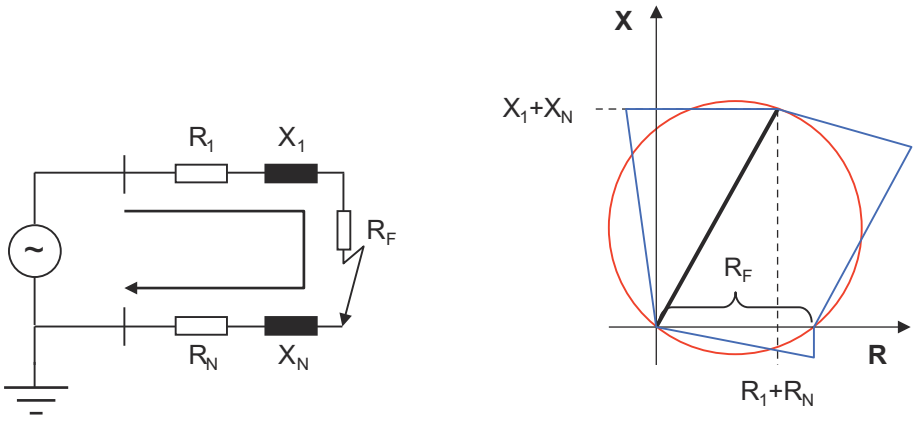

Figure 537: The fault loop impedance model for phase-to-earth impedance measuring elements

R_1	Positive-sequence resistance from measuring point to fault location
X_1	Positive-sequence reactance from measuring point to fault location

Table continues on the next page

R_N Earth return path resistance = (R0 - R1)/3 from measuring point to fault location

X_N Earth return path reactance = (X0 - X1)/3 from measuring point to fault location

R_0 Zero-sequence resistance from measuring point to fault location

X_0 Zero-sequence reactance from measuring point to fault location

R_F Physical fault resistance between phase and earth (includes arc and earthing resistances)

Considering the load in case of a single line-to-earth fault, conventional distance protection might overreach at the exporting end and underreach at the importing end. DSTPDIS has a load compensation functionality which increases the security in such applications. Load compensation is enabled with the setting *Load Comp zone x* (x = 1...5) = "True".

Load compensation is used only with single phase-to-earth faults. Load compensation is not used if multiple phases are included in the fault (more than one single earth fault release).

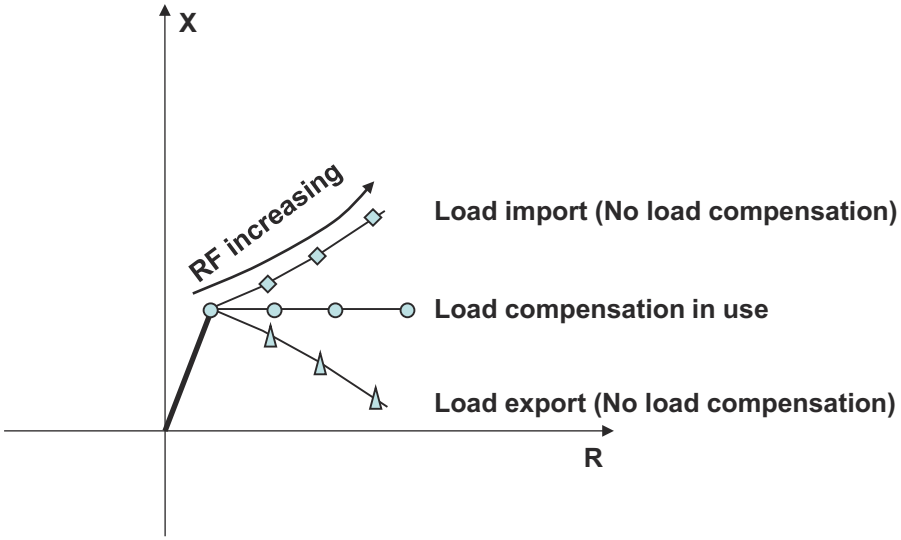

Figure 538: Operation principle of load compensation functionality

When three-phase feeders are placed close to each other, a mutual inductive zero-sequence coupling of the current path exists. This has an impact during earth faults. If no measures are taken, this leads to errors in the impedance calculation. The residual current of the parallel line induces a voltage in the protection line and changes the measured voltage at the relay location. The influence depends on the system configuration, that is, the magnitude and polarity of the residual current in a parallel line.

The phase-to-earth impedance measuring elements in DSTPDIS take the zero-sequence mutual coupling into account in impedance calculation. The compensation is enabled and set with settings *Par line Comp zone x* ("True"), *Mutual R0 zone x* and *Mutual X0 zone x* (x = 1...5). The residual current of the parallel line must be available and connected to the `I3P_PAR` input. The earth-current balance logic is implemented to prevent malfunctioning of the protection relay on the healthy parallel line. This means that the parallel compensation functionality is internally

blocked when the ratio between residual current of the parallel line and protected lines exceeds the *Fact EF current Bal* configuration setting.

The parallel line compensation functionality is only used with single phase-to-earth faults. Parallel line compensation is not used if multiple phases are included into fault (more than one single earth fault releases).

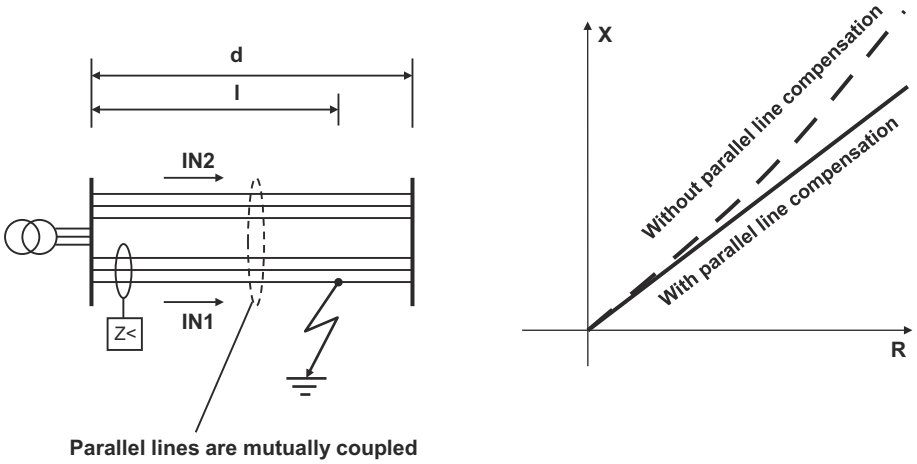

Figure 539: Operation principle of parallel line compensation functionality

The operation time delay is defined with the *Gnd operate Dl Znx* (x = 1...5) setting. The timer can be disabled with the *Gnd Op Dl mode Znx* = "False" setting. This blocks the `OPERATE_Zx` (x = 1...5) output of the phase-to-earth measuring elements.

Phase-to-phase impedance measuring elements

The phase-to-phase distance protection is suitable as a basic protection function against two-phase short circuit faults in various networks, regardless of the treatment of the neutral point. The short circuit fault protection is enabled with the *Op Mod PP loops Znx* (x = 1...5) = "True" setting.

The reach of the phase-to-phase measuring elements is based on the loop impedance

$$\underline{Z}_{l} + \frac{R_F}{2} = R_l + j \cdot X_l + \frac{R_F}{2}$$

(Equation 268)

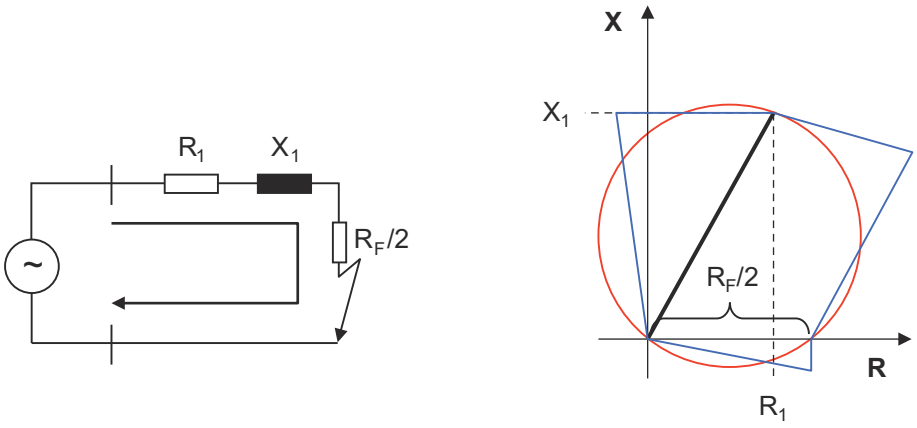

Figure 540: The fault loop impedance model for phase-to-phase impedance measuring elements

R_1 Positive-sequence resistance from measuring point to fault location.

X_1 Positive-sequence reactance from measuring point to fault location.

R_F Physical fault resistance between phases, for example, arc resistance.

The phase-to-phase impedance measuring elements measure only half of the physical fault resistance between phases. This must be taken into account when the resistive reach of the phase-to-phase elements is set (that is, setting the value of 5 Ω corresponds 5+5=10 Ω of physical arc resistance between phases).

The resistive reach setting is common for phase-to-phase and three-phase impedance measuring elements.

The operation time delay is defined with the setting *PP operate delay Znx* (x = 1... 5). The timer can be disabled with the setting *PP Op delay Mod Znx* = "False". This blocks the `OPERATE_Zx` (x = 1... 5) output of the phase-to-phase measuring elements.

Three-phase impedance measuring element

DSTPDIS has a dedicated measuring element for a three-phase short circuit fault for each zone. The three-phase measuring element uses the positive-sequence quantities for a fault loop impedance estimation which increases the accuracy by reducing the influence of line parameter asymmetry. This is advantageous especially in case of non-transposed, asymmetrical lines. The three-phase impedance measuring element is enabled together with the phase-to-phase impedance elements by the setting *Op Mod PP loops Znx* (x = 1... 5) = "True".

The reach of the three-phase measuring element is based on the loop impedance

$$\text{Three-phase measuring element reach} = Z_1 + R_F = \quad R_1 + j\,X_1 + R_F$$

(Equation 269)

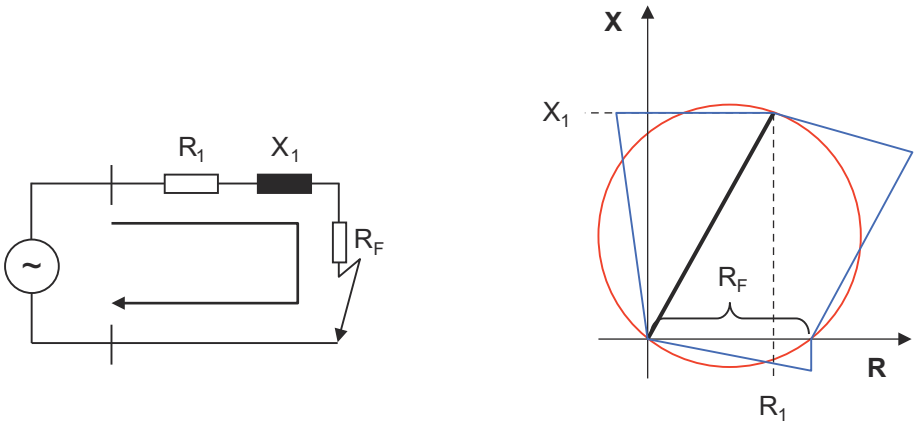

Figure 541: The fault loop impedance model for three-phase impedance measuring element

R_1	Positive-sequence resistance from measuring point to fault location
X_1	Positive-sequence reactance from measuring point to fault location.
R_F	Physical fault resistance per phase, for example, arc resistance.

The three-phase impedance measuring element measures the physical fault resistance per phase. The resistive reach setting is common for three-phase and phase-to-phase impedance measuring elements.

The time delay of operation is defined with the *PP operate delay Znx* (x = 1... 5) setting. The timer can be disabled with the setting *PP Op delay Mod Znx* = "False". This blocks the `OPERATE_Zx` (x = 1... 5) output of the three-phase measuring elements.

Entering the line reach

The line reach is entered in primary ohms. The impedance format is selected with *Impedance mode Zn* = "Rectangular" for the vectors R, X and "Polar" for the magnitude and angle.

Impedance mode Zn = Rectangular

In case of phase-to-phase or three-phase impedance measuring elements, the line reach is defined with:

- Resistive reach: *R1 zone x* (x = 1...5)
- Reactive reach: *X1 zone x* (x = 1...5)

In case of non-directional characteristics, the reactive reach in reverse direction is defined with the *X1 reverse zone x* (x = 1...5) setting. The characteristic line angle, denoted as α, is the same for both forward and reverse direction.

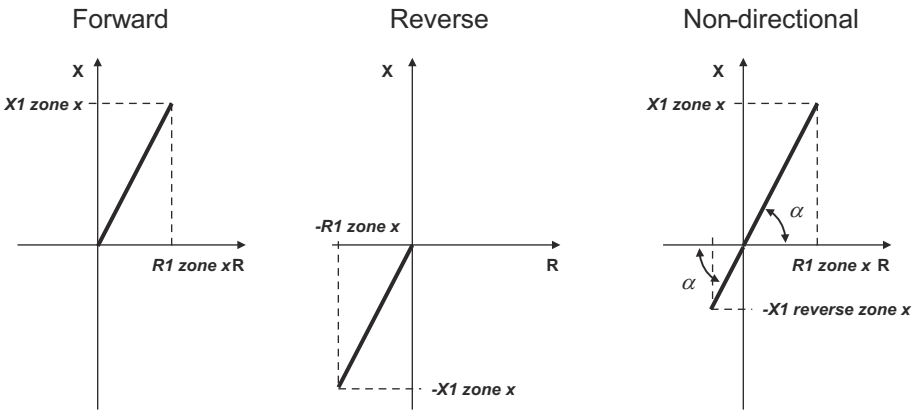

Figure 542: Settings which define the line reach for phase-to-phase or three-phase impedance measuring elements if Impedance mode Zn = "Rectangular"

In case of phase-to-earth impedance measuring elements, the line reach is defined with:

- Resistive reach : (2·*R1 zone x* + *R0 zone x*)/3, (x = 1...5)
- Reactive reach : (2·*X1 zone x* + *X0 zone x*)/3, (x = 1...5)

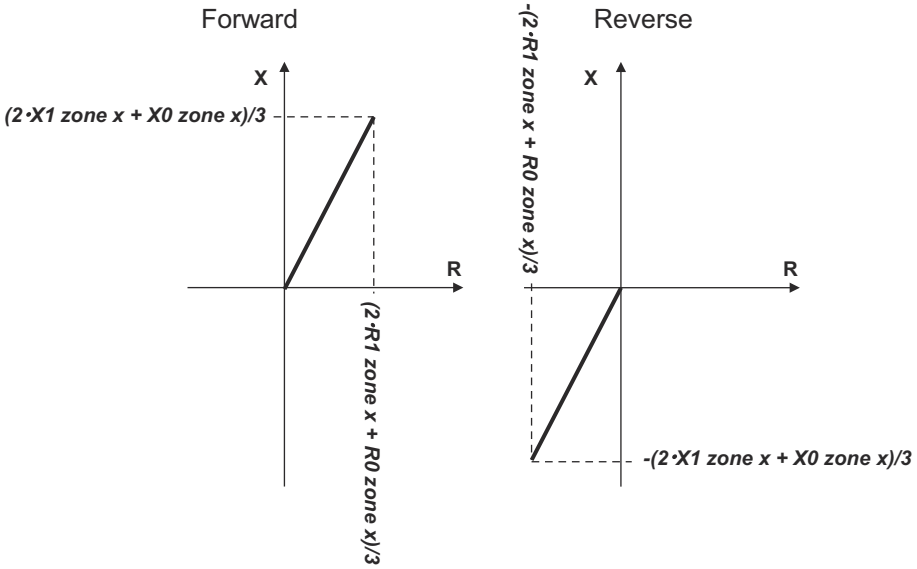

Figure 543: Settings which define the line reach for phase-to-earth impedance measuring elements if Impedance mode Zn = "Rectangular", forward or reverse directionality

In case of non-directional characteristics, the reactive reach in reverse direction is defined with the *X1 reverse zone x* (x = 1...5) setting. The total reactive reach in reverse direction includes a part which is common to both forward and reverse direction. This part is automatically calculated based on the values of the settings *R1 zone x, R0 zone 0, X1 zone x* and *X0 zone x*. The characteristic line angle, denoted as α, is the same for forward and reverse direction.

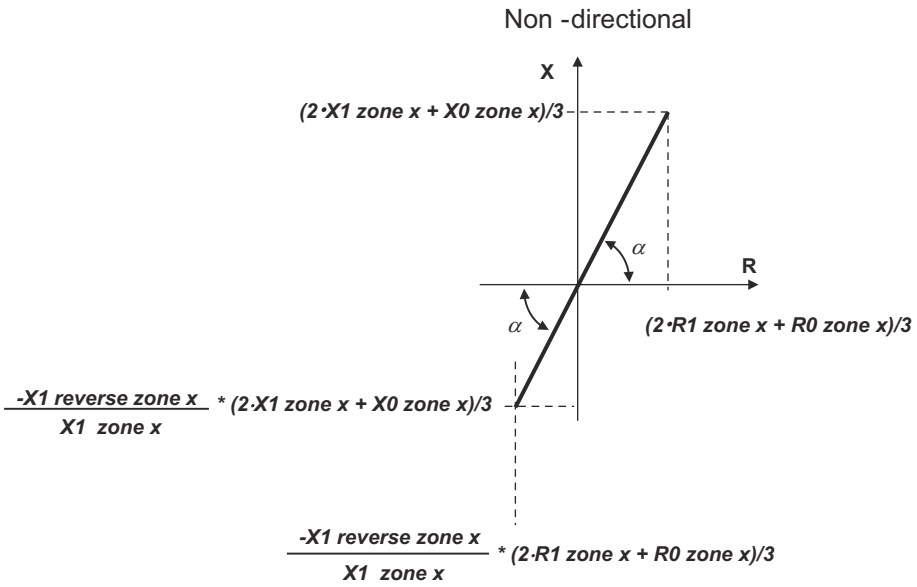

Figure 544: Settings which define the line reach for phase-to-earth impedance measuring elements if Impedance mode Zn = "Rectangular", non-directional directionality

Impedance mode Zn = Polar

In case of phase-to-phase or three-phase impedance measuring elements, the line reach is defined with:

- *Z1 zone x* (x = 1...5)
- *Z1 angle zone x* (x = 1...5)

In case of non-directional characteristics, the reactive reach magnitude in reverse direction is defined with the *Z1 reverse zone x* (x = 1...5) setting. The characteristic line angle, *Z1 angle zone x,* is the same for forward and reverse direction.

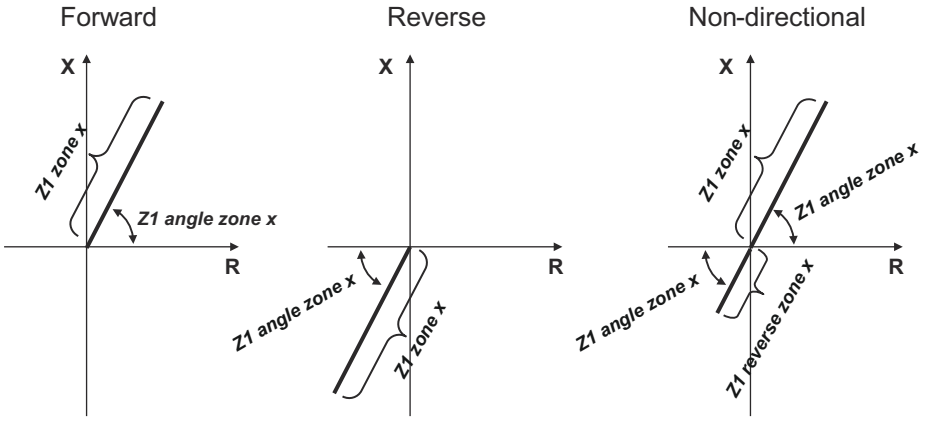

Figure 545: Settings which define the line reach for phase-to-phase or three-phase impedance measuring elements if Impedance mode Zn = "Polar"

In case of phase-to-earth impedance measuring elements, the line reach is defined with:

- *Z1 zone x* (x = 1...5)

- *Z1 angle zone x* (x = 1...5)
- *Factor K0 zone x* (x = 1...5)
- *Factor K0 angle Zn x* (x = 1...5)

The reach magnitude and angle are:

$$Magnitude = abs(\underline{Z}1 + \underline{Z}1 \times \underline{K}_N)$$

(Equation 270)

$$Angle = angle(\underline{Z}1 + \underline{Z}1\underline{K}_N)$$

(Equation 271)

$$\underline{Z}_1 = Z1\ zone\ x(\cos(Z1 angle\ zone\ x) + j\sin(Z1 angle\ zone\ x))$$

$$\underline{K}_N = Factor\ K0\ zone\ x(\cos(Factor\ K0 angle\ znx) + j\sin(Factor\ K0 angle\ znx))$$

In case of non-directional characteristics, the reactive reach in reverse direction is defined with the *Z1 reverse zone x* (x = 1...5) setting.

$$\underline{Z}1R = Z1\ reverse\ zone\ x(\cos(Z1 angle\ zone\ x) + j\sin(Z1 angle\ zone\ x))$$

(Equation 272)

The total reactive reach in reverse direction includes a part which is defined by the residual compensation factor $\underline{K}_N$. The characteristic line angle, denoted as α, is the same for forward and reverse direction.

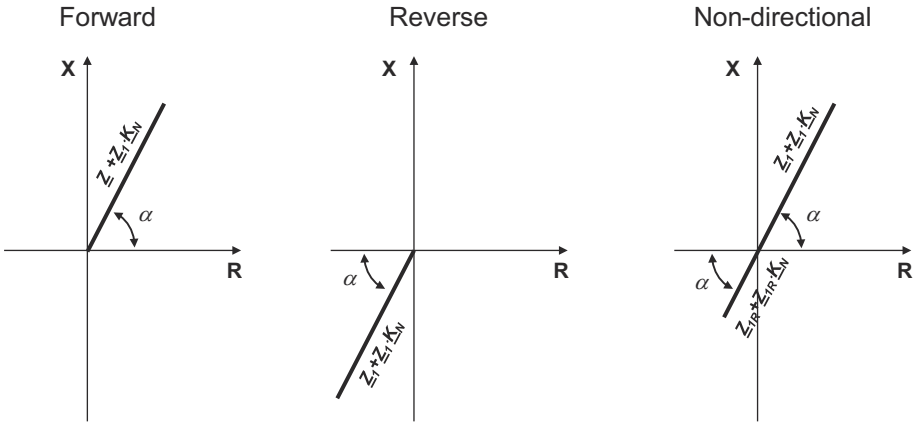

Figure 546: Settings which define the line reach for phase-to-earth impedance measuring elements if Impedance mode Zn = "Polar"

Protection zone characteristics

DSTPDIS has both “Quadrilateral” and “Mho (circular)” characteristics available for the protection zones and they can be combined also with the bullet characteristic. The shape of a tripping characteristic can be set independently for phase-to-earth, phase-to-phase or three-phase impedance elements. The zone shape is defined with the *Impedance Chr Gnd Zn* setting for phase-to-earth impedance elements, and with the *Impedance Chr PP Zn* setting for phase-to-phase or three-phase impedance elements. The alternatives are "Quadrilateral", "Mho (circular)", "Mho Dir line", "Offset Dir line" and "Bullet (combi)".

All impedance values defining the zone shape are entered in primary ohms. Angles are given in degrees.

Quadrilateral characteristic

If the zone has the "Quadrilateral" shape, DSTPDIS has a polygonal tripping characteristic.

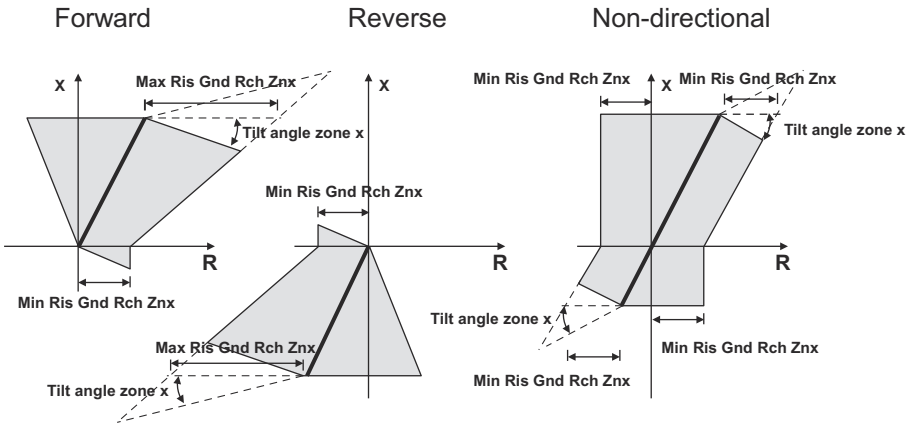

Figure 547: Tripping characteristic for phase-to-earth impedance elements if the zone shape is quadrilateral. The tilt angle is set to compensate for possible under- or overreaching.

The reach in the reactive direction is defined by the line reach independently for phase-to-earth and for phase-to-phase/three-phase elements. The resistive reach is defined at the minimum and maximum resistive reach with settings *Min Ris Gnd Rch Znx, Max Ris Gnd Rch Znx, Min Ris PP Rch Znx, Max Ris PP Rch Znx* (x = 1...5). In case of a non-directional zone, only settings *Min Ris Gnd Rch Znx and Min Ris PP Rch Znx* (x = 1...5) are valid. The resistive reach can be set independently for phase-to-earth and for phase-to-phase or three-phase elements.

In case of phase-to-earth impedance elements, the resistive reach value corresponds to the physical fault resistance between phase and earth including arc and earthing resistance.

The reactive reach can be adjusted by tilting the top reactance boundary line by an angle defined with *Tilt angle zone x* (x = 1...5). The negative value decreases the tripping zone area while the positive value increases the tripping area. The negative value is used in case of underreaching zones to compensate a possible overreaching. The positive value is used in case of overreaching zones to compensate a possible underreaching.

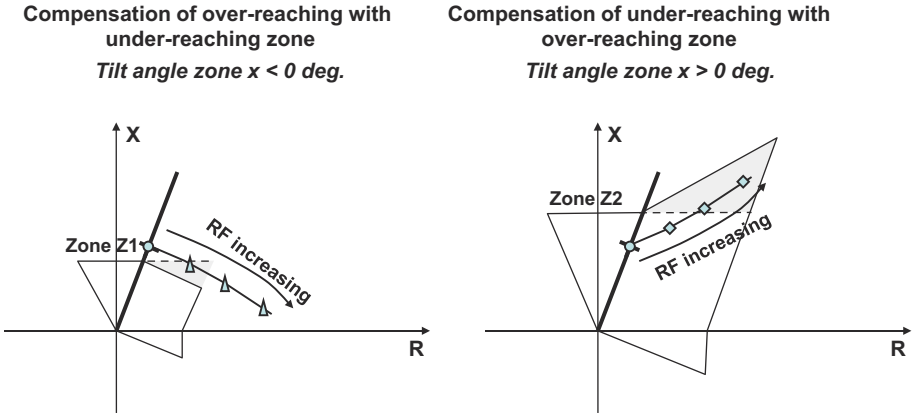

Figure 548: Operation principle of top reactance line tilting

The tilt angle must be carefully set. If the tilt angle has been set to a value where polygon boundaries do not form a close loop for an element, an internal mechanism modifies the tilt angle for that element so that the polygon boundary is always closed. If the set tilt angle is suitable for another element, the tilt angle of that element is not internally modified. Tilt angle conflicts are monitored by TLT_ANG_CONFLICT value. This integer value is a ten-bit value indicating tilt angle modifications per zone and fault type.

Table 921: TLT_ANG_CONFLICT description

TLT_ANG_CONFLICT bit field	Description
(MSB) xx xx xx xx YZ (LSB)	Y active = Zone 1 earth-fault impedance element tilt angle modified Z active = Zone 1 short circuit impedance element tilt angle modified
(MSB) xx xx xx YZ zz (LSB)	Y active = Zone 2 earth-fault impedance element tilt angle modified Z active = Zone 2 short circuit impedance element tilt angle modified
(MSB) xx xx YZ xx xx (LSB)	Y active = Zone 3 earth-fault impedance element tilt angle modified Z active = Zone 3 short circuit impedance element tilt angle modified
(MSB) xx YZ xx xx xx (LSB)	Y active = Zone 4 earth-fault impedance element tilt angle modified Z active = Zone 4 short circuit impedance element tilt angle modified
(MSB) YZ xx xx xx xx (LSB)	Y active = Zone 5 earth-fault impedance element tilt angle modified Z active = Zone 5 short circuit impedance element tilt angle modified

For example, TLT_ANG_CONFLICT value “36” = “00 00 10 01 00” indicates that the tilt angles of the zone 2 earth-fault impedance element and zone 3 short circuit or

three-phase impedance element have been modified. These zone settings should be checked to see whether a non-zero TLT_ANG_CONFLICT value has been found although, internally, the polygon boundary has been closed for existing settings.

Directional lines

The direction of a zone is defined with setting *Directional mode Znx* = "Nondirectional", "Forward" or "Reverse". The directionality of each zone can be set independently of other zones. For example, zones Z1 and Z2 can be set in the "Forward" direction and Z3 in the "Reverse" direction. Furthermore, the optionally supervised earth-fault directional criteria (in low-impedance earthed networks) given for GFC are checked here together with zone direction criteria fulfilment.

The directionality of a quadrilateral zone is defined with two independent directional lines. The directional lines can be included into the mho characteristics to secure the directionality or to transform the non-directional mho characteristic into a directional one.

The directional lines are adjusted with the *Min phase angle zone* and *Max phase angle zone* settings, which are common for all the zones. The angles are given in degrees. The directional lines are polarized with the *Pol quantity zone* method. By default, the polarization method is positive-sequence voltage ("Pos. seq. volt.").

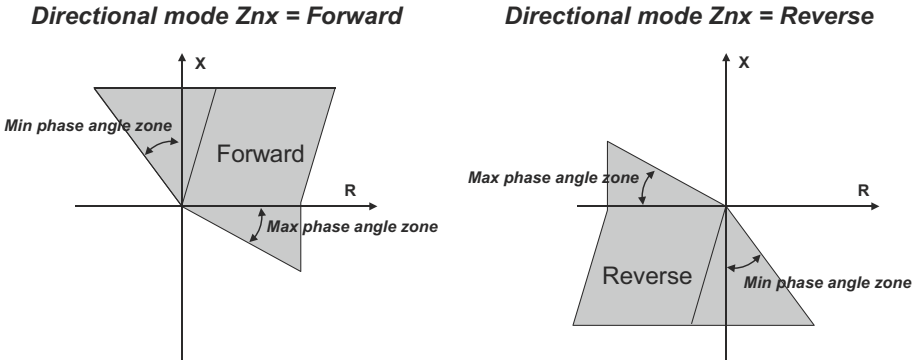

Figure 549: Settings that adjust directional lines in case of quadrilateral characteristics

The calculated direction of the fault or load (if there is no fault present) current is indicated for each zone with outputs DIRECTION_Z1 - Z5 which may have values "unknown", "forward", "backward" or "both". It is important to check setting *X1 reverse zone x* (or *Z1 reverse zone x* reactance part) for quadrilateral directional characteristics (see *Figure 541* and the corresponding phase-to-earth impedance given in *Figure 543*) so that it does not restrict the negative-reactance reach defined by settings *Min Ris Gnd/PP Rch Znx* and *Max phase angle zone.*

Memory voltage

The memory voltage is based on the healthy positive-sequence voltage stored during the network healthy state. This fictive voltage is substituted for the measured voltage with any impedance measurement element polarization if the corresponding voltage drops too low (limit is 5% Un). Fictive voltage use is indicated by the active monitored data output VMEM_USED. The polarized impedance direction for a corresponding impedance element is frozen after a fixed 100 ms of fictive voltage use, but the memory function enables impedance polarization to operate up to a maximum of 300 s. This time can be set with the

Voltage Mem time setting. After set *Voltage Mem time* elapses, fictive voltage (and frozen impedance direction) can no more be used without memory refreshment by a healthy positive-sequence voltage and also the frozen impedance direction is reset.

Switch onto fault function (CVPSOF) should be used together with distance protection. CVPSOF accelerates and secures the operation of the protection if a close-in three-phase fault is detected immediately after circuit breaker closing.

Mho circular characteristic

When the zone characteristic is "Mho (circular)", the distance protection has a circular tripping characteristic. The zone reach is defined independently by the line reach for phase-to-earth and phase-to-phase or three-phase elements. The resistive reach of the tripping characteristic depends on the selected polarization method defined with setting *Pol quantity zone* = "Cross pol", "Pos. seq. volt." or "Self pol". The non-directional mho characteristic is an exception as it is independent of the selected polarization method. It is always explicitly defined by the reach settings and thus fixed in the impedance plane.

Table 922: Polarization methods and corresponding polarization voltages

Fault loop	Self pol	Cross pol	Pos. seq. volt.
Z_A	U_{L1}	$j \cdot U_{L23}/\sqrt{3}$	U_1
Z_B	U_{L2}	$j \cdot U_{L31}/\sqrt{3}$	$U_1 \cdot 1\angle -120°$
Z_C	U_{L3}	$j \cdot U_{L23}/\sqrt{3}$	$U_1 \cdot 1\angle 120°$
Z_{AB}	U_{L12}	$j \cdot (U_{L23}-U_{L31})/\sqrt{3}$	$U_1 \cdot \sqrt{3} \cdot 1\angle 30°$
Z_{BC}	U_{L23}	$j \cdot (U_{L31}-U_{L12})/\sqrt{3}$	$U_1 \cdot \sqrt{3} \cdot 1\angle -90°$
Z_{CA}	U_{L31}	$j \cdot (U_{L12}-U_{L23})/\sqrt{3}$	$U_1 \cdot \sqrt{3} \cdot 1\angle 150°$
Z_{ABC}	U_1		

In case of cross-polarization "Cross pol", the polarization voltages are theoretically quadrature to the fault loop voltage. The phase angle of the polarization voltage is rotated 90° to match the original fault loop voltage. The cross-polarization expands the tripping characteristic according to the prevailing system conditions. In case of short circuit faults, the circle expands as a function of the source impedance magnitude $Z_{1source}$. In case of an earth fault, the circle expands as a function of the source impedance $Z_{1source}$, $Z_{0source}$ and earthing impedance magnitudes Z_E as $(2 \cdot Z_{1source} + Z_{0source})/3 + Z_E$.

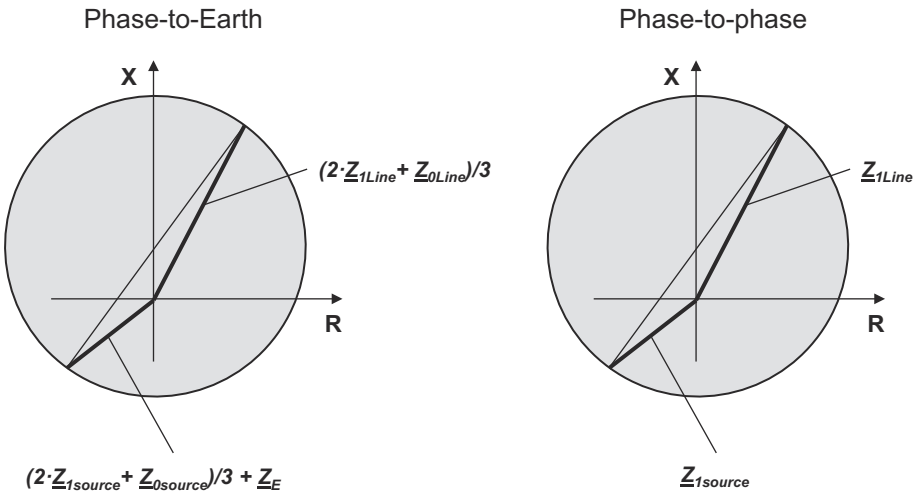

Figure 550: Tripping characteristic in case the zone characteristic is "Mho (circular)" and Pol quantity zone is "Cross pol"

In case of positive-sequence polarization "Pos. seq. volt.", the polarization voltage is the positive-sequence voltage. The voltage phase angle is rotated to match the original fault loop voltage. The positive-sequence polarization expands the tripping characteristic according to the prevailing system conditions. In case of short circuit faults, the circle expands as a function of the source impedance magnitude $\underline{Z}_{1source}/2$. In case of an earth fault, the circle expands as a function of source impedance and earthing impedance magnitudes: $(Z_{1source} + Z_{0source})/3 + Z_E$.

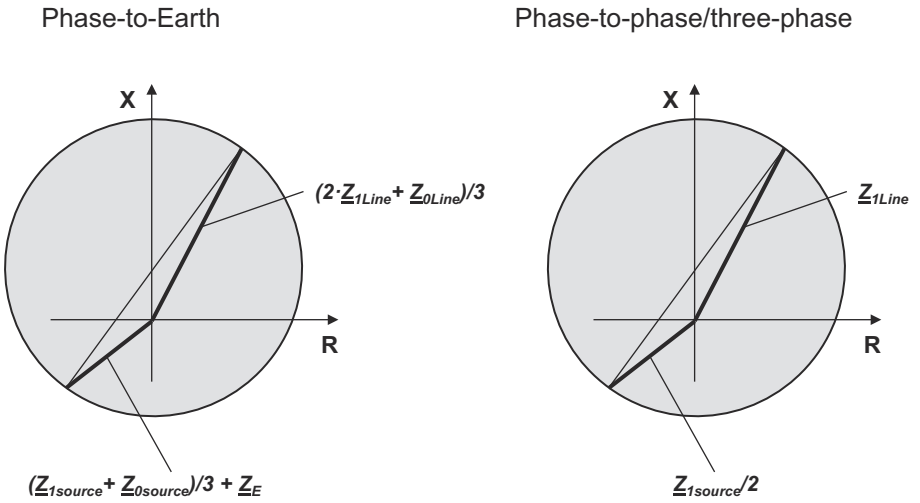

Figure 551: Tripping characteristic in case the zone characteristic is "Mho (circular)" and Pol quantity zone is "Pos. seq. volt."

One alternative for polarization is also "Self pol" despite the drawbacks when using it as a polarization method. The mho circle does not expand when using this polarization method.

In case of cross and positive-sequence polarization, the expansion of the mho circle is a positive feature as the fault resistance coverage is increased. The reach of the zone is not affected by the expansion. The greatest expansion is obtained with cross-polarization.

The directional offset mho is explicitly defined by the reach settings and is thus fixed in the impedance plane. The polarization method does not expand this circle even for directional mode. However, directional lines criteria are defined using polarized signals.

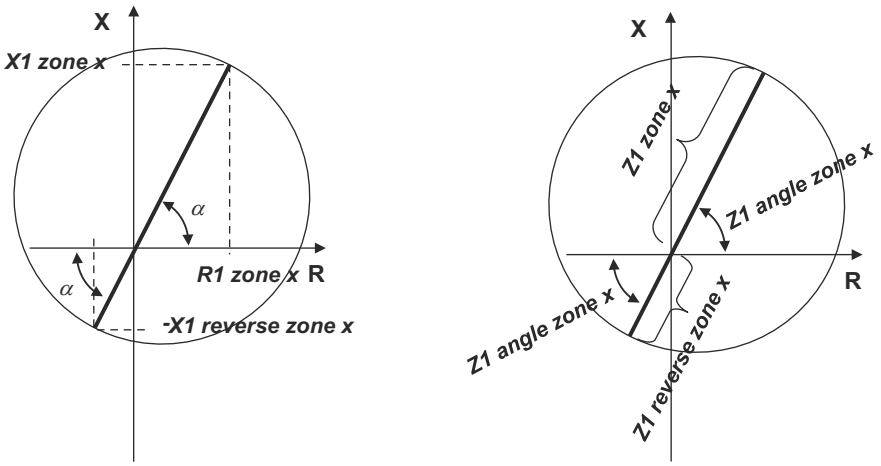

Figure 552: Tripping characteristic for phase-to-phase or three-phase impedance measuring elements if Impedance Chr PP Zn is "Mho (circular)" and Directional mode Znx is "Non-directional". On the left, Impedance mode Zn is "Rectangular". On the right, Impedance mode Zn is "Polar".

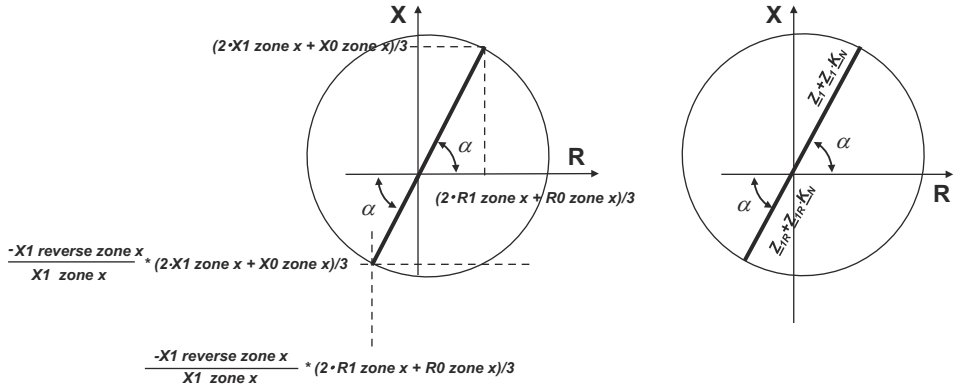

Figure 553: Tripping characteristic for phase-to-earth impedance measuring elements if Impedance Chr GND Zn is "Mho (circular)" and Directional mode Znx is "Non-directional". On the left, Impedance mode Zn is "Rectangular". On the right, Impedance mode Zn is "Polar".

Adding of directional lines into circular mho characteristic

Directional lines which are always included in the directional quadrilateral characteristic can also be included in the mho characteristics to secure the directionality or to transform the non-directional mho characteristics into a directional one.

Directional lines with mho are available only when the zone is set to directional, that is, *Directional mode Znx* is "Forward" or "Reverse".

The directionality of the directional mho characteristic is secured with directional lines by setting *Impedance Chr Gnd Zn and Impedance Chr PP Zn* to "Mho Dir line". The directional mho characteristic can also be created by adding directional lines in

the offset mho characteristic. This is done by selecting *Impedance Chr Gnd Zn* and *Impedance Chr PP Zn* as "Offset Dir line".

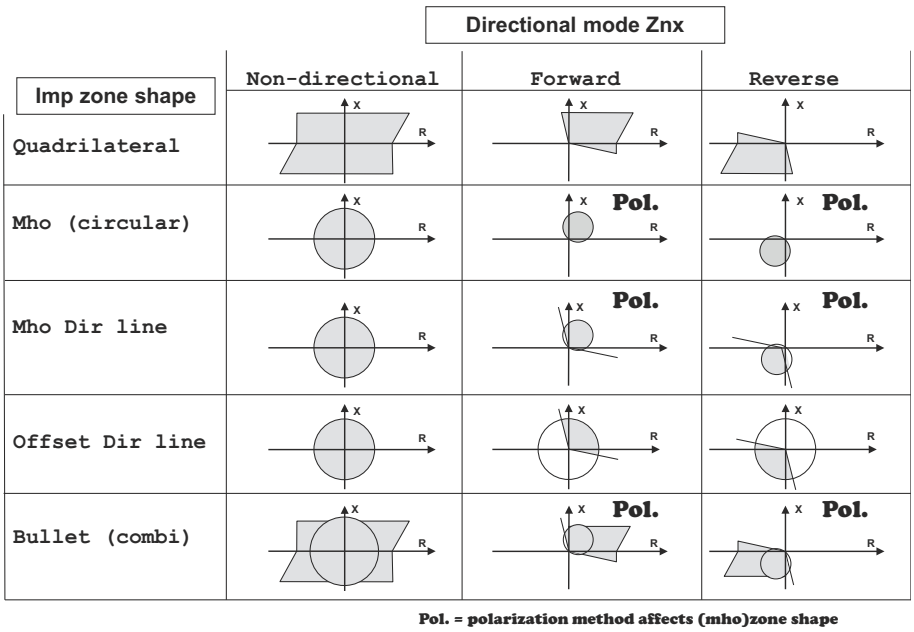

Figure 554: Possible combinations of Directional mode Znx and zone characteristics settings. Pol. in the figure means that the shape of the characteristic is affected by the selected polarization method of the mho circle, Pol quantity zone = "Cross pol", "Pos. seq. volt.", "Self pol").

Bullet combi characteristic

If the impedance zone shape equals "Bullet (combi)", the distance protection has a tripping characteristic which is a combination of the quadrilateral and mho. All settings relevant to the quadrilateral and mho are applicable. The shape of the "Bullet (combi)" characteristic is affected by the selected polarization method of the mho circle (*Pol quantity zone* = "Cross pol", "Pos. seq. volt.", "Self pol").

The directionality of the "Bullet (combi)" characteristic is defined by the directional lines when *Directional mode Znx* is "Forward" or "Reverse". For directional "Bullet (combi)" characteristic, the quadrilateral resistance does not reach negative (positive) values for “Forward” (“Reverse”) direction (see *Figure 555*).

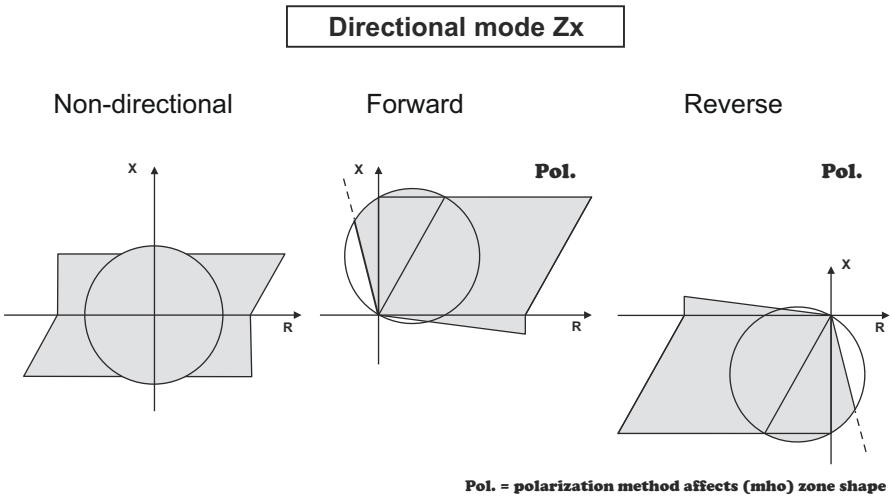

Figure 555: Bullet combi tripping characteristic. Pol. in the figure means the shape of the characteristic is affected by the selected polarization method, Pol quantity zone = "Cross pol", "Pos. seq. volt.", "Self pol"

4.7.1.6 Recorded data

The required information for later fault analysis is recorded when the recording function of DSTPDIS is triggered by activating TRIGG_REC input or writing to the corresponding DO “LD0.GFCPDIS1.RcdTrg.Oper.ctlVal”. During external triggering (input signal TRIGG_REC), the recorded data of all zones and the phase selection function are recorded.

A total of three sets of recorded data are saved in data banks Fault 1, 2 and 3. Data bank Fault 1 holds the most recent recorded data and the older data is moved into the following banks (1->2 and 2->3) when triggering occurs. When all three banks have data and a new triggering occurs, the latest data is placed into bank 1 and the data in bank 3 is overwritten by the data from bank 2.

Table 923: Recorded data for the phase selection function

Parameter name	Description
Time	Recorded data time stamp
Release PE-loop	Release signals for PE loops, GFC
Release PP-loop	Release signals for PP/3P loops, GFC
Earth fault detected	Indication of a single-phase earth fault, GFC
Cross country fault	Indication of a cross-country fault (high imp. earthed), GFC
Earth fault direction	Earth-fault direction (low imp. earthed), GFC
Operate of all zones	Operate signals of all zones (this is zone information but it is taken here because it represents all zone information combined)

The values of parameter Operate of all zones indicate by a number (0...31) which zones have been operated.

Table 924: Enumerator values for parameter Operate of all zones

Enumerator value	Description
0	No zone operates
1	Zone 1
2	Zone 2
3	Zones 1 and 2
4	Zone 3
5	Zones 1 and 3
6	Zones 2 and 3
7	Zones 1,2 and 3
8	Zone 4
9	Zones 1 and 4
10	Zones 2 and 4
11	Zones 1,2 and 4
12	Zones 3 and 4
13	Zones 1,3 and 4
14	Zones 2,3 and 4
15	Zones 1,2,3 and 4
16	Zone 5
17	Zones 1 and 5
18	Zones 2 and 5
19	Zones 1,2 and 5
20	Zones 3 and 5
21	Zones 1,3 and 5
22	Zones 2,3 and 5
23	Zones 1,2,3 and 5
24	Zones 4 and 5
25	Zones 1,4 and 5

Table continues on the next page

Enumerator value	Description
26	Zones 2,4 and 5
27	Zones 1,2,4 and 5
28	Zones 3,4 and 5
29	Zones 1,3,4 and 5
30	Zones 2,3,4 and 5
31	Zones 1,2,3,4 and 5

Table 925: Recorded data parameters regarding specific zones

Parameter	Description
Fault/load Dir Znx	Direction of fault or load zone Zx
Dir resistance Znx	Direction resistance, zone Zx
Dir reactance Znx	Direction reactance, zone Zx
Flt loop 1st Ris Znx	First PE-Loop resistance, zone Zx
Flt loop 1st Rea Znx	First PE-Loop reactance, zone Zx
Flt loop 2nd Ris Znx	Second PE-Loop resistance, zone Zx
Flt loop 2nd Rea Znx	Second PE-Loop reactance, zone Zx
Flt PP-loop Ris Znx	PP-Loop resistance, zone Zx
Flt PP-loop Rea Znx	PP-Loop reactance, zone Zx
Phase reactance Znx	Phase reactance Znx

In case of a no-fault condition, the direction of the load current seen by a three-phase fault measuring element (based on positive-sequence signal data) is indicated. DIR_LOOP_R and DIR_LOOP_X are the loop resistance and reactance from the impedance calculation used in directional discrimination for zone 1. Depending on the released fault loops, the calculated fault loop impedance can be read from the parameters FLTLOOP_RFST, FLTLOOP_XFST, FLTLOOP_RPP and FLTLOOP_XPP. If two phase-to-earth loops are released simultaneously for measurement, the second phase-to-earth impedance can be found from the parameters FLTLOOP_RSND and FLTLOOP_XSND. The corresponding positive-sequence phase-to-earth fault reactance can be found from parameter FLTPH_X.

The impedances are shown in primary ohms.

4.7.1.7 Application

DSTPDIS provides a fast and reliable protection for overhead lines and power cables. The function is applied in distribution and sub-transmission networks where three-phase tripping is allowed for all kinds of faults.

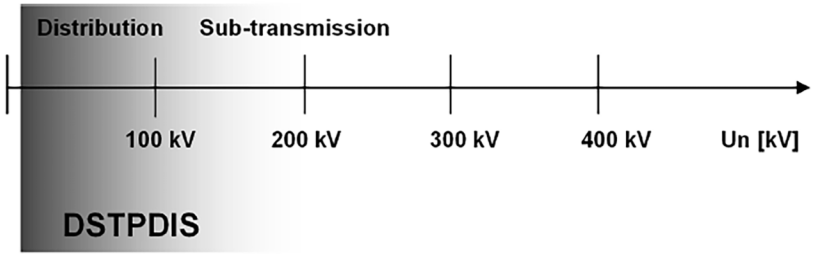

Figure 556: Application scope of DSTPDIS

Typically these networks are operated in ring or meshed type configurations. The switching state of these networks is changed frequently due to daily operation and load flow considerations. The networks also include varying capacities of distributed generation which makes it impossible to apply simple overcurrent-based schemes. In these networks, DSTPDIS is used to provide a fast and selective protection for overhead lines and power cables. It can also be applied for radial feeders to increase the sensitivity of the protection, especially if the short circuit power of the source is low or it changes due to network operation.

From the selectivity point of view, it is advantageous that in the protection chain all functions in different positions operate according to the same measuring principle. Therefore, DSTPDIS can also be applied for the backup protection of main transformers and buses. This way, selectivity in the distance protection of the outgoing lines is easier to achieve.

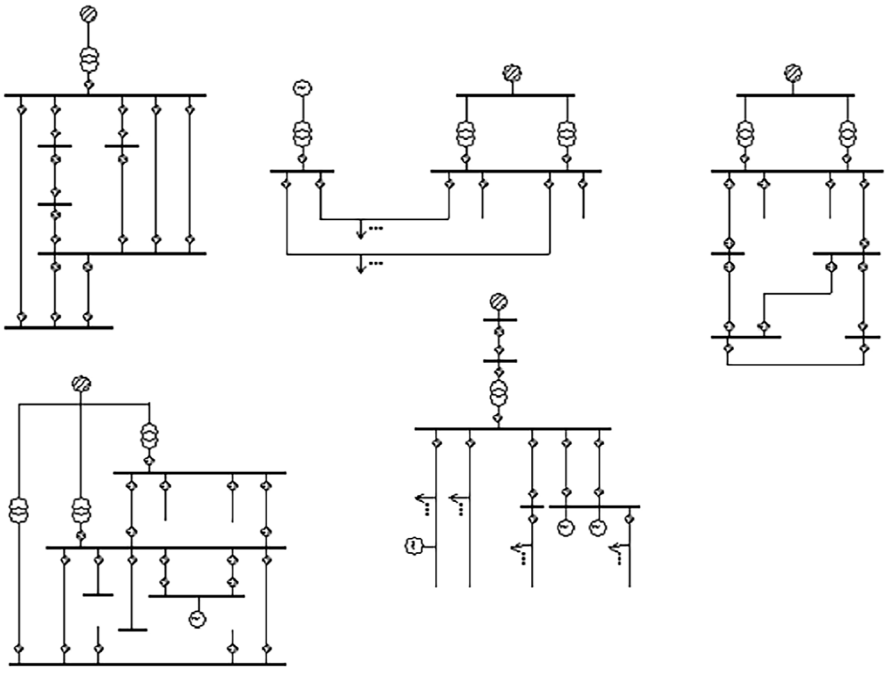

Figure 557: Typical network configurations for DSTPDIS application

DSTPDIS has five flexible configurable impedance zones for protection (Z1...Z5).

Phase-to-earth distance protection is a basic earth-fault protection in solidly or low-impedance earthed networks. Together with the phase preference logic, it also serves as a selective protection function at cross-country faults in isolated or Petersen coil compensated networks. In certain applications, system earthing is changed during operation from high-impedance to low-impedance earthed system due to fault location procedures. DSTPDIS can be used in such applications by setting System grounding GFC to "From input" and by providing information about the type of earthing through binary input SYS_EARTHING. Low (inactive) SYS_EARTHING input indicates low-impedance earthing system.

DSTPDIS is suitable as a basic protection function against two- and three-phase faults in various networks, regardless of the treatment of the neutral point. The independent setting of the reach in the reactive and the resistive directions makes it possible to create a fast and selective short circuit protection in many applications.

4.7.1.8 Signals

DSTPDIS Input signals

Table 926: DSTPDIS Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
I3P_PAR	SIGNAL	-	Three-phase currents
I3P_REF	SIGNAL	-	Three-phase currents
U3P	SIGNAL	-	Three-phase voltages
URES	SIGNAL	-	Residual voltage
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode
SYS_EARTHING	BOOLEAN	0=False	Network earthing method
TRIGG_REC	BOOLEAN	0=False	External triggering for all recorded data
BLOCK_GFC	BOOLEAN	0=False	Block GFC operate
BLOCK_Z1	BOOLEAN	0=False	Block zone 1
BLOCK_Z2	BOOLEAN	0=False	Block zone 2
BLOCK_Z3	BOOLEAN	0=False	Block zone 3
BLOCK_Z4	BOOLEAN	0=False	Block zone 4
BLOCK_Z5	BOOLEAN	0=False	Block zone 5

DSTPDIS Output signals

Table 927: DSTPDIS Output signals

Name	Type	Description
OPERATE_GFC	BOOLEAN	Time delayed operate signal, GFC
OPERATE_Z1	BOOLEAN	Time delayed operate signal, zone 1
OPERATE_Z2	BOOLEAN	Time delayed operate signal, zone 2
OPERATE_Z3	BOOLEAN	Time delayed operate signal, zone 3
OPERATE_Z4	BOOLEAN	Time delayed operate signal, zone 4
OPERATE_Z5	BOOLEAN	Time delayed operate signal, zone 5
START_GFC	BOOLEAN	Start, GFC
START_Z1	BOOLEAN	General start signal, zone 1
START_Z2	BOOLEAN	General start signal, zone 2
START_Z3	BOOLEAN	General start signal, zone 3
START_Z4	BOOLEAN	General start signal, zone 4
START_Z5	BOOLEAN	General start signal, zone 5
XC_FLT	BOOLEAN	Indication of a cross-country-fault (high imp. earthed), GFC
DIRECTION_Z1	Enum	Direction of fault or load zone 1
DIRECTION_Z2	Enum	Direction of fault or load zone 2
DIRECTION_Z3	Enum	Direction of fault or load zone 3
DIRECTION_Z4	Enum	Direction of fault or load zone 4
DIRECTION_Z5	Enum	Direction of fault or load zone 5

4.7.2.2 Function block

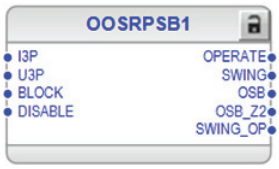

Figure 558: Function block

4.7.2.3 Functionality

The Out-of-step protection with double blinders function OOSRPSB detects out of step conditions by monitoring impedance.

[2] SIR = Source impedance ratio

The protection uses two impedance measurement elements known as inner and outer blinders on mho characteristics with a timer. The function calculates the impedance. If the measured impedance stays between inner and outer blinder for a predetermined time and moves farther inside the inner blinder, then an out of step condition is indicated. Operate is generated if out of step is indicated and impedance moves out of mho characteristics. The mho characteristic can be divided into two zones so separate trips can be generated based on the zone. Operating can also be selected to occur when the impedance is on the way into the zone or for when the impedance is on the way out of the zone.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.7.2.4 Analog channel configuration

OOSRPSB has two analog group inputs which must be properly configured.

Table 935: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 936: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.7.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of OOSRPSB can be described using a module diagram. All the modules in the diagram are explained in the next sections.

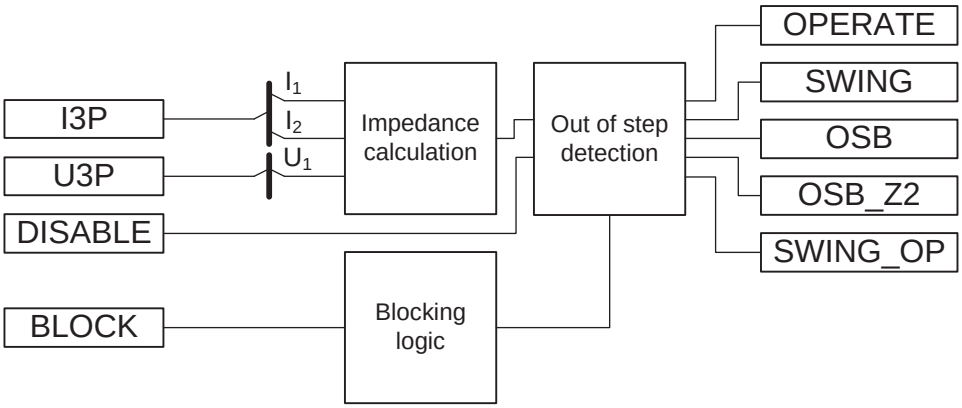

Figure 559: Functional module diagram

Impedance calculation

This module calculates the positive-sequence impedance (Z1) using positive-sequence voltage and current. For the module to calculate impedance it is required that the positive-sequence current is above *Min Ps Seq current* setting and the negative-sequence current is below the *Max Ng Seq current* setting.

The calculated positive-sequence impedance amplitude Z1_AMPL and angle Z1_ANGLE are available in ohms and degrees, respectively, in the Monitored data view.

The calculated impedance is converted to ohms as the operating characteristics are defined with the ohm settings.

Out of step detection

The operating characteristic is a circular offset mho on the impedance plane with two pair of blinders. The mho characteristic is defined with the *Forward reach*, *Reverse reach*, and *Impedance angle* settings. *Forward reach* defines the impedance from the origin to the edge of circle on the top side. *Reverse reach* defines the impedance from the origin to the edge of the circle on the bottom side. The diameter of the mho characteristics is the sum of *Forward reach* and *Reverse reach* settings. Two sets of blinders are defined by *Inner blinder R* and *Outer blinder R* intercepting at R-axis. The blinders are at the same angle as the *Impedance angle*. The second blinder of each outer and inner pair is automatically made symmetrical with the origin of the R-X plane.

For a correct operation, it is required that the setting for *Inner blinder R* is less than the setting for *Outer blinder R*.

The circular mho characteristic can be further divided into two zones by setting *Zone 2 enable* to “Yes”. The boundary between zones is set using the setting *Zone 1 reach*. The lower portion of the circle, Zone 1, is separated from the upper portion, Zone 2, by a line, perpendicular to the blinders, located at a set percentage of the *Forward reach* setting from the origin.

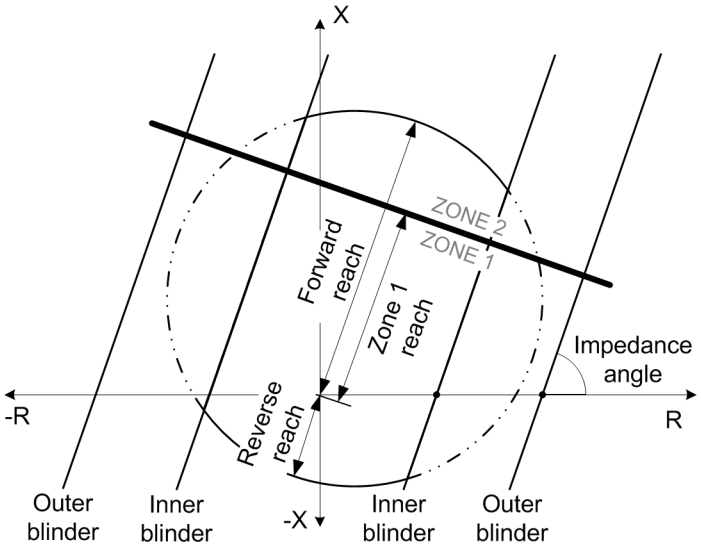

Figure 560: Operating region for out of step with double blinder

An impedance is only considered to be within the mho circle if it is also between the inner blinders.

A third zone, Zone 3, can be enabled by setting *Zone 3 enable* to “Yes”. Zone 3 is defined to include the area outside of the circular mho characteristic but inside the area that is bound with the magnitude of the minimum positive-sequence current defined by setting *Min Ps Seq*. *Figure 561* shows the three zones. Settings that determine the shape of the zones should be coordinated with the settings for any distance protection functions. The zones and their respective slip counters are applicable only for Way out operations when the *Oos operation mode* setting option is “Way out” or “Adaptive”.

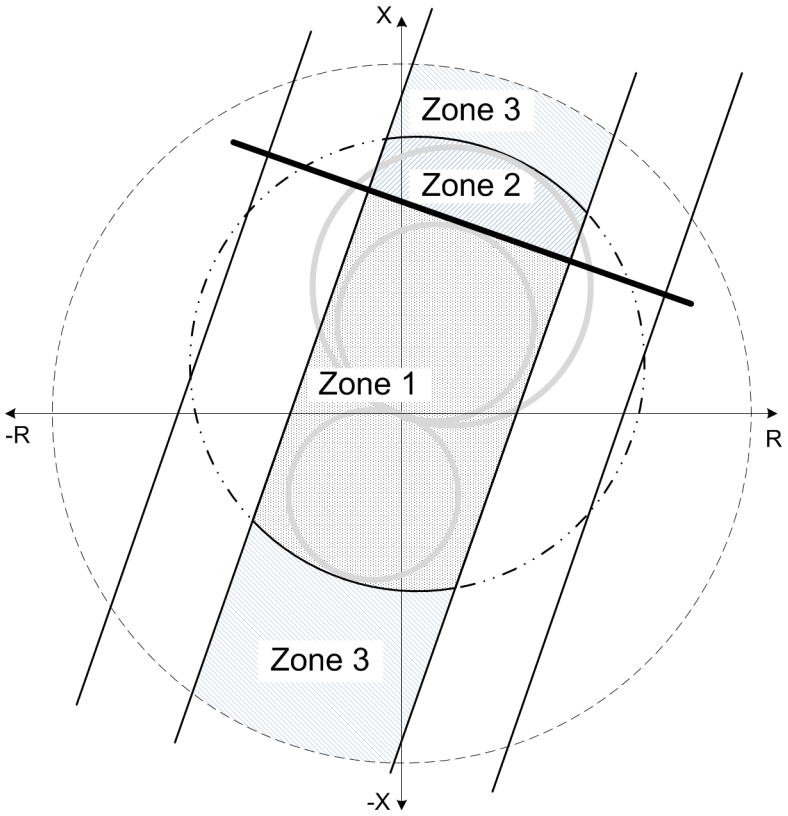

Figure 561: Defined zones

The impedance is continuously monitored for detecting an out of step condition. When the impedance enters inside from the outer blinder, the out of step detection timer is triggered. If impedance remains between outer and inner blinder for the duration of the *Swing time* setting, output SWING is activated. If the impedance enters the mho circle in zone 1, out of step blocking (OSB) for zone 1 is detected and output OSB is activated, or if the impedance enters the mho circle in zone 2, OSB for zone 2 is detected and output OSB_Z2 is activated if setting *Zone 2 enable* is set to “Yes”. Both OSB and OSB_Z2 can be activated if the impedance passes through zone 1 and zone 2 while inside the mho circle. The OSB or OSB_Z2 output deactivates when impedance exits and remains outside the mho circle and the inner blinder for a duration of five cycles.

Activation of the OPERATE output depends on the *Oos operate mode* selected. The available options are “Way in”, “Way out”, and “Adaptive”. If the “Way in” option is selected, the function triggers the delay timer after detecting an OSB condition. When the set *Operate delay time* has elapsed, the OPERATE output is activated. When using the “Way in” option, the zone-related settings and zone slip counters are not applicable.

If the “Way out” option is selected, after detecting an OSB condition, the function further checks if impedance exits the outer blinder. On exiting the outer blinder, Way out timer defined by *Operate delay time* setting is triggered and the respective zone slip counter is incremented after the set *Operate delay time* has elapsed. If the slip counter value is equal to the set number of slips in the respective enabled zone, the OPERATE output is activated. If the swing impedance passes through both zone 1 and zone 2, only the zone 1 slip counter is incremented. The zone 2 slip counter is incremented if the impedance passes through the Mho circle but only through the zone 2 portion. The zone 3 slip counter is incremented if the impedance misses the

Mho circle entirely and the setting *Zone 3 enable* is also set to “Yes”. Increment of the slip counter triggers also the Reset timer. All of the zone slip counters reset after the set *Reset time* has elapsed and the impedance does not cross into the outer blinder again, or on activation of the OPERATE output.

When the “Way out” or "Adaptive" option is selected, the breaker open time, if known, can be incorporated to optimize breaker trip time when a way out trip command is issued. The ideal time for the breaker to interrupt current is when the swing angle approaches zero. If the swing angle is δ_0 when the impedance exits the outer blinder, the dynamic Trip delay, T_{od}, can be set as shown in *Equation 273*.

$$T_{od} = \frac{1 - 2 \cdot f_{slip} \cdot (T_{co} + BrkropenTm)}{2 \cdot f_{slip}}$$

(Equation 273)

T_{od}	Dynamic Trip delay
T_{co}	The time for the impedance to travel from the center impedance line (where the swing angle is π radians) to the outer blinder on the opposite side from which it entered.
BrkopenTm	Set *Breaker open time*
f_{slip}	Slip frequency

The *Breaker open time* setting should include the time from when the relay issues a trip command to the time when the breaker receives the command. The function uses the *Breaker open time* setting to determine the trip delay time if it is not set to “0”. If the *Breaker open time* is set to “0”, the function does not dynamically calculate a trip delay but uses the fixed *Operate delay time* before activating the OPERATE output.

The slip frequency is calculated using *Equation 274*.

$$f_{slip} = \frac{\delta_i - \delta_0}{2 \cdot \pi \cdot T_{oi}}$$

(Equation 274)

f_{slip}	Slip frequency
T_{oi}	The time for the impedance to pass from the outer to the inner blinder.
δ_0	Swing angle at the outer blinder
δ_I	Swing angle at the inner blinder

The swing angles, δ_0 and δ_I, are estimated from the measured impedance when crossing the blinders. It is the difference in these quantities that is important for determining the slip frequency.

If the “Adaptive” option is selected, after detecting an OSB condition, the function further examines the slip frequency f_{slip}, *V dip time* setting, and swing angle at the outer blinder (δ_0) to determine if the operate is asserted on the way in or on the way out. OPERATE is activated on the way in, entering the mho circle from an inner blinder, if the relationship in *Equation 275* is true.

$$f_{slip} \le \frac{(\pi - \delta_0)}{\pi \cdot VoltagedipTm}$$

(Equation 275)

f_{slip}	Slip frequency
δ_0	Swing angle at the outer blinder
VoltagedipTm	Set *V dip time*

Otherwise, OPERATE is activated on the way out, when the impedance exits an outer blinder and the swing repeats for the set *Max number slips* count in the respective enabled zone that the swing has passed through.

If the *Swing time* has elapsed but the impedance exits the inner blinder and continues through the opposite blinders without passing through the mho circle, the SWING output is activated. The SWING output remains activated for a time determined by the *Reset time* setting unless another swing occurs before the reset time expires causing the output to remain active for another *Reset time* interval. If this swing is repeated for the set *Max Num slips Zn3* count and the *Zone 3 enable* setting is “Yes”, the SWING_OP output is activated. The SWING_OP output remains activated for a time determined by the *Operate dropout time* setting.

If the “Adaptive” option is selected and an OSB condition is not detected, but the impedance enters the mho circle after remaining between the inner and outer blinders for greater than 1.5 cycles, the function assumes a severe swing and assert the OPERATE output.

The drop out delay for OPERATE output can be set by *Operate dropout time* setting.

If the polarity of the voltage signal is opposite to the normal polarity, the correction can be done by setting *Voltage reversal* to “Yes”, which rotates the impedance vector by 180 degrees.

The DISABLE input can be used to coordinate the correct operation during the start-up situation. The function is blocked by activating the DISABLE signal. Once the DISABLE signal is deactivated, the function remains blocked (outputs disabled) for additional time duration as set through the setting *Disable time*.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, the function operates normally but the OPERATE output is not activated.

4.7.2.6 Application

Out of step protection functions detect stable power swings and out of step conditions based on the fact that the voltage/current variation during a power swing is slow compared to the step change during a fault. Both faults and power swings may cause the measured impedance to enter into the operating characteristic of a distance relay element. The apparent impedance moves from the pre-fault value to a fault value in a very short time, a few milliseconds, during a fault condition. However, the rate of change of the impedance is much slower during a power swing or out of step condition than during a fault depending on the slip frequency of the out of step. The impedance measurement should not be used by itself to distinguish between a fault condition and an out of step condition from a phase fault. The fundamental method for discriminating between faults and power swings is to track the rate of change of the measured impedance.

The function measures the rate of change of the impedance using two impedance measurement elements known as blinders together with a timing device. If the measured impedance stays between the blinders for a predetermined time, the function declares a power swing condition and asserts an output that can be used to block the distance protection. However, if the impedance passes the inner blinder and exits on the other side of the mho characteristics (that is, the resistive component of impedance has opposite sign as at the time of point of entry) an out of step operate is issued by the function. *Figure 562* gives an example of out of step detection.

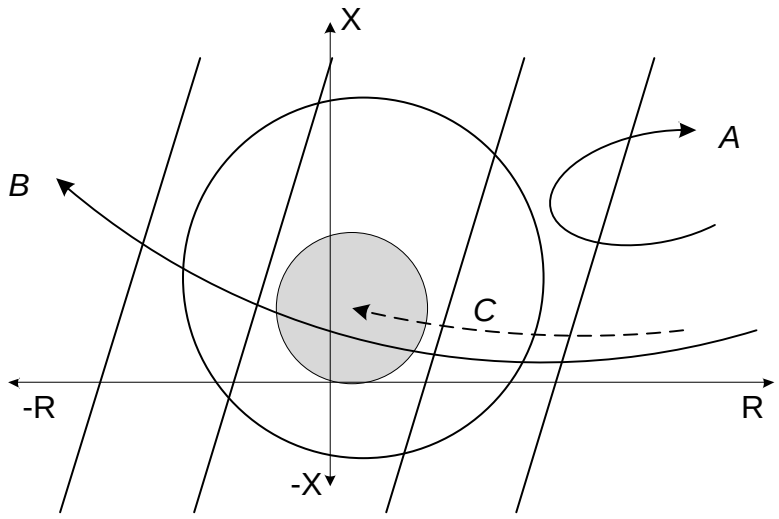

Figure 562: Example of out of step detection

The shaded region indicates a fault zone in a distance protection function. For curve A, the impedance moves into the out of step zone and leaves slowly, indicating the occurrence of a swing that quickly stabilizes. For curve B, the impedance moves slowly into the out of step zone and exits the zone indicating that the network is becoming unstable. For curve C, impedance rapidly moves into, and remains in, the fault zone indicating an actual fault and not an out of step condition.

4.7.2.7 Signals

OOSRPSB Input signals

Table 937: OOSRPSB Input signals

Name	Type	Default	Description

Three-phase underexcitation protection	UEXPDIS	X<	40

4.7.3.2 Function block

Figure 563: Function block

4.7.3.3 Functionality

The three-phase underexcitation protection function UEXPDIS is used to protect the synchronous machine against the underexcitation or loss of excitation condition.

The protection is based on the offset-mho circular characteristics on the impedance plane. The function calculates the apparent impedance from the machine terminal voltages and currents. If the impedance vector enters the offset-mho circle, the function gives the operating signal after a set definite time. The operating time characteristics are according to definite time (DT).

This function contains a blocking functionality. It is possible to block the function outputs, timer or the function itself.

4.7.3.4 Analog channel configuration

UEXPDIS has two analog group inputs which all must be properly configured.

Table 945: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 946: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected (*Phase Sel for Z Clc* set to "A or AB", "B or BC" or "C or CA"), if the setting *Impedance Meas mode* is set to "1Phase-to-earth" or "1Phaseto- phase".
	The function requires that at least two (the third voltage will be derived) or all three voltage channels are connected if *Impedance Meas mode* is set to "3Phase-to-earth", "3Phase-to-phase" or "Pos sequence".

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.7.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of UEXPDIS can be described using a module diagram. All the modules in the diagram are explained in the next sections.

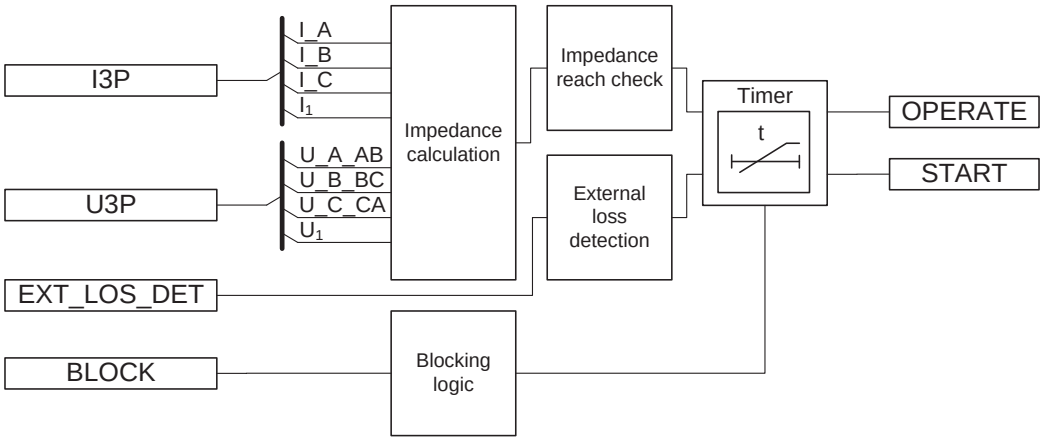

Figure 564: Functional module diagram

Impedance calculation

This module calculates the apparent impedance based on the selected voltages and currents. The *Measurement mode* and *Phase Sel for Z Clc* settings determine which voltages and currents are to be used. If the *Measurement mode* is set to "1Phase-earth" or "1Phase-phase", the *Phase Sel for Z Clc* setting is needed for determining which phase or phase-phase voltages ("A or AB", "B or BC" and "C or CA") and currents should be used for calculating the impedance.

Table 947: Voltages and currents used in impedance calculation

Measurement mode	Phase Sel for Z Clc	Voltages and currents
1Phase-earth	A or AB	U_A, I_A
1Phase-earth	B or BC	U_B, I_B
1Phase-earth	C or CA	U_C, I_C
1Phase-phase	A or AB	U_AB, I_A, I_B
1Phase-phase	B or BC	U_BC, I_B, I_C
1Phase-phase	C or CA	U_CA, I_C, I_A
3Phase-earth	N/A	U_A, U_B, U_C, I_A, I_B, I_C

Table continues on the next page

Measurement mode	Phase Sel for Z Clc	Voltages and currents
3Phase-phase	N/A	U_AB, U_BC, U_CA, I_A, I_B, I_C
Pos seqn	N/A	{ U_A,U_B,U_C } or { U_AB,U_BC,U_CA } and I_A, I_B, I_C

If all three phase voltages and phase currents are fed to the protection relay, the positive-sequence alternative is recommended.

If the polarity of the voltage signals is opposite to the normal polarity, the correction can be done by setting *Voltage reversal* to "Yes", which rotates the impedance vector by 180 degrees.

If the magnitude of the voltage is less than $0.05 \cdot U_N$, the calculated impedance is not reliable and the impedance calculation is disabled. U_N is the rated phase-to-phase voltage.

The calculated impedance magnitudes and angles are available in the Monitored data view. The impedance angles are provided between -180...180 degrees.

The calculated apparent impedance is converted to pu impedance as the operating characteristics are defined with the pu settings.

Impedance reach check

The operating characteristic is a circular offset mho on the impedance plane. The operating characteristics are defined with the *Offset*, *Diameter* and *Displacement* settings. If the calculated impedance value enters the circle in the impedance plane, the module sends an enabling signal to start the Timer.

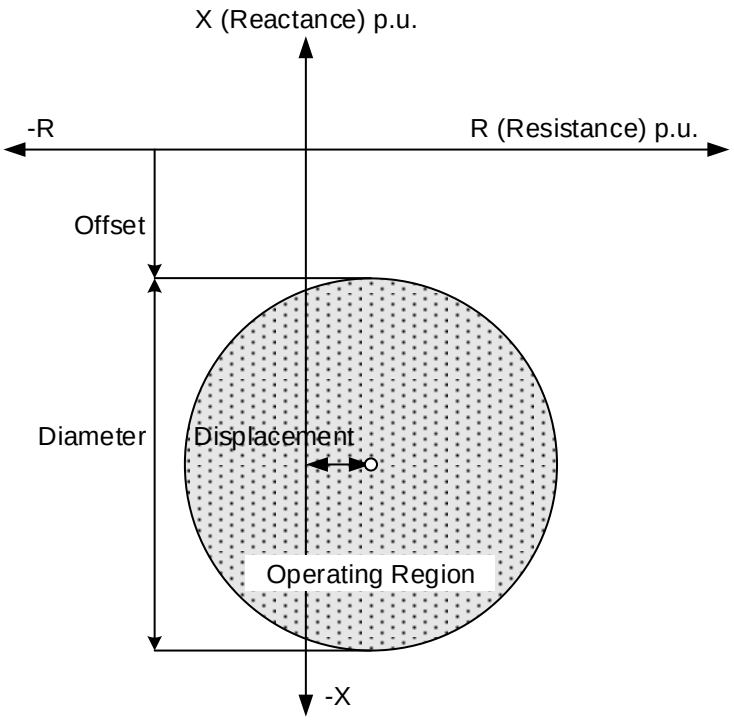

Figure 565: Operating region of the impedance mho circle

It is possible to add a restraint with the help of settings *Restraint enable*, *Rst offset X* and *Rst offset X angle*, as shown in the Figure *Figure 566*.

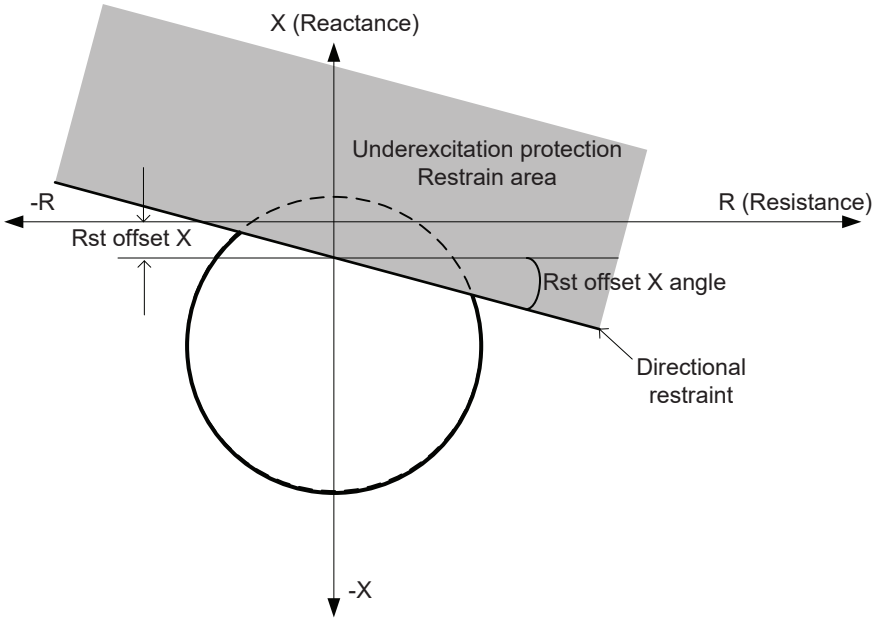

Figure 566: Settings Restraint enable, Rst offset X and Rst offset X angle

The directional restraint shown in *Figure 566* is obtained when both *Rst offset X* and *Rst offset X angle* are set with negative signs.

A fault in Automatic Voltage Regulator (AVR) or in the excitation system may cause a total loss of excitation. A short circuit on the slip rings reduces the excitation voltage to zero. This causes a gradual reduction of the excitation current and eventually a loss of excitation. An open circuit in the field circuit also causes a loss of excitation. These are typical examples which cause underexcitation in synchronous machines. This module detects the underexcitation condition for the above cases when the calculated impedance enters the operating characteristics.

External loss detection

The module checks the status information of the excitation system. It is activated when the *External Los Det Ena* setting is set to "Enable". The total loss of excitation current or a failure in the excitation system is indicated by connecting the external binary signal to the EXT_LOS_DET input. The Timer is enabled immediately when the EXT_LOS_DET input is activated.

Timer

Once activated, the Timer activates the START output. The time characteristic is according to DT. When the duration of the underexcitation exceeds the set definite *Operate delay time*, the OPERATE output is activated. If the impedance locus moves out of the offset-mho operating characteristics before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operating timer resets and the START output is deactivated.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time (DT). The value isavailable in the Monitored data view.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.7.3.6 Application

There are limits for the underexcitation of a synchronous machine. A reduction of the excitation current weakens the coupling between the rotor and the external power system. The machine may lose the synchronism and start to operate like an induction machine, which increases the consumption of the reactive power. Even if the machine does not lose synchronism, it is not recommended to operate in this state. The underexcitation causes excessive heating in the end region of the stator winding. This can damage the insulation of the stator winding and even the iron core.

The underexcitation also causes the generator to operate in the asynchronous mode. This increases the rotor speed, which causes heating in the rotor iron and damps the windings. A high intake of the reactive power from the network during underexcitation causes problems in the network, for example voltage dip, stability and power swings. Power swings stress the prime mover, causing for example turbine blade cavitation and mechanical stress in the gearbox.

The capability curve of a synchronous generator describes the underexcitation capability of the machine. An excessive capacitive load on the synchronous machine causes it to drop out-of-step. The reason is the steady-state stability limit as defined by the load angle being 90°, which can only be reached when the unit is underexcited.

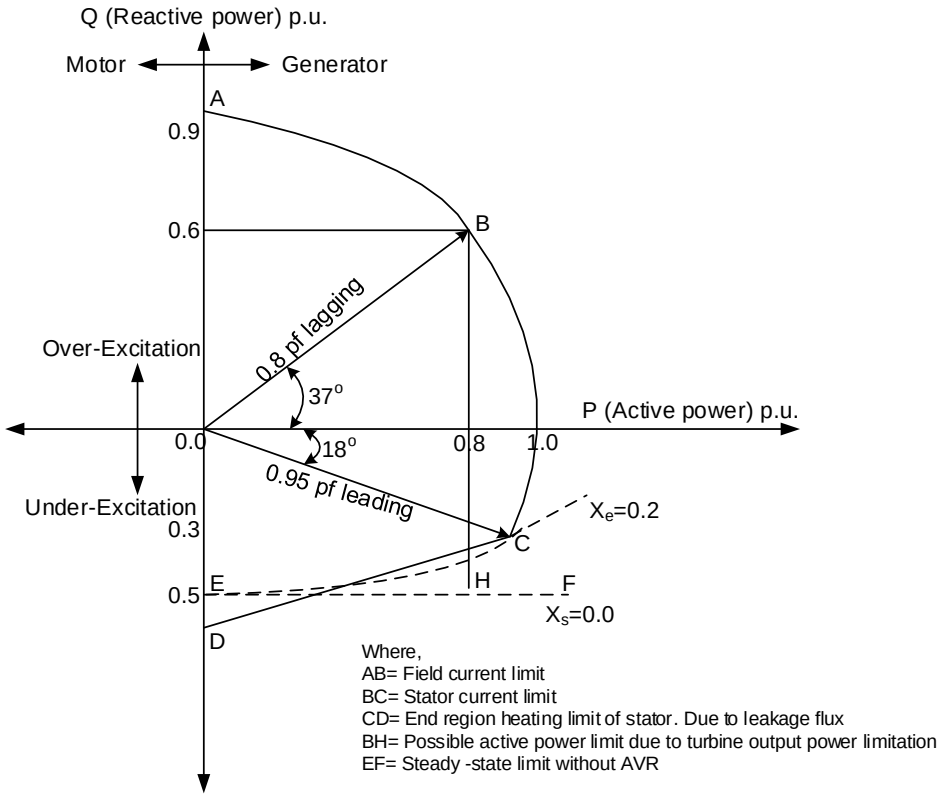

Figure 567: Capability curve of a synchronous generator

UEXPDIS protects the synchronous machines against an unstable operation due to loss of excitation. A partial or total loss of excitation causes a reactive power intake from the network to the machine, and the reactance of the system viewed from the machine terminals turns negative. This kind of drop-of-reactance condition can be detected by measuring the impedance of the system.

The operating characteristic is an offset-mho circle in the impedance plane, and the circle is parameterized with the *Offset*, *Diameter* and *Displacement* setting values. To avoid unwanted operation of the UEXPDIS function, a restrain area can be defined which is enabled with *Restraint enable* and parameterized with *Rst offset X* and *Rst offset X angle* setting values.

Table 948: Parameters of the circle

Setting values	Description
Offset	Distance of the top of the circle from the R-axis. This is usually set equal to - $x_d'/2$, where x_d' is the transient reactance of the machine. The sign of the setting value determines the top of the circle regarding the R-axis. If the sign is negative, the circle lies below the R-axis.
Diameter	Normally set equal to the machine's synchronous reactance x_d, which determines the size of the impedance circle.
Displacement	Displacement of the center of the circle from the reactance axis or the R-coordinate of the center. The setting can be used to adjust the sensitivity of the underexcitation protection. If the sign of the setting is positive, the circle is shifted to the right, that is, closer to the normal operating point. Respectively, if the sign is negative, the circle is shifted to the left and thus moves away from the normal operating point.
Rst offset X	Displacement from origin to a point on reactance axis (X-axis) through which the directional restraint line passes. The setting can be used to adjust the restrain area of the underexcitation protection along with *Rst offset X angle*. If the sign of the *Rst offset X* setting is positive, the restraint line passes through a point on X-axis which is above the R-axis and if it is negative, it passes through a point on X-axis which is below the R-axis.
Rst offset X angle	Angle between the R-axis (or *Rst offset X* line) and the directional restraint line. If the sign of the *OffsetXAng* setting is positive, the angle is taken in anti-clockwise direction from the R-axis (or *Rst offset X* line). Respectively, if the sign is negative, the angle is taken in clockwise direction from R-axis (or *Rst offset X* line).

The setting parameters of the off-set mho circle are to be given in pu values. The base impedance (Z_N) in ohms is:

$$Z_N = \left| \frac{U_N^2}{S_N} \right|$$

(Equation 276)

U_N	rated (phase-to-phase) voltage in kV
S_N	rated power of the protected machine in MVA

The corresponding calculation to convert ohms to pu values is:

$$X_{pu} = \frac{X_{ohm}}{Z_N}$$

(Equation 277)

X_{pu}	pu value
X_{ohm}	reactance in ohms
Z_N	base impedance

Example of impedance locus in underexcitation

In an example of a typical impedance locus, once the impedance locus enters the relay operation characteristics, the relay operates after a settable definite time.

Three-phase underimpedance protection	UZPDIS	Z<G	21G

4.7.4.2 Function block

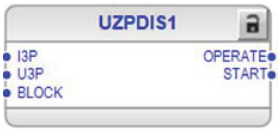

Figure 569: Function block

4.7.4.3 Functionality

The three-phase underimpedance protection UZPDIS is generally applied as a backup protection for generators and transformers against short circuit faults.

The protection is based on the origin-centric circular characteristics on the impedance plane. The function calculates the impedance value from the voltage and current phasors. If the impedance vector enters the origin-centric circle, the function produces the operating signal after a set delay. The operating time characteristics are according to definite time (DT).

However, it is also possible to enable separate zones of offset-mho based protection with multiple instances of the function.

This function contains a blocking functionality. It is possible to block the function outputs, reset timer or the function itself.

4.7.4.4 Analog channel configuration

UZPDIS has two analog group inputs which all must be properly configured.

Table 958: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 959: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected (*Phase Sel for Z Clc set* to "AB", "BC" or "CA"), if the setting *Impedance Meas* mode is set to "1Phase-to-phase".
	The function requires that at least two (the third voltage will be derived) or all three voltage channels are connected if *Impedance Meas mode* is set to "3Phase-to-phase".

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.7.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of UZPDIS can be described with a module diagram. All the modules in the diagram are explained in the next sections.

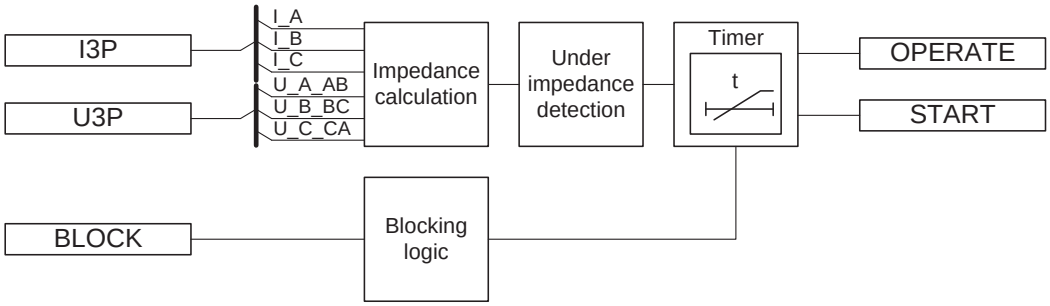

Figure 570: Functional module diagram

Impedance calculation

This module calculates the impedance based on the selected voltages and currents. The *Impedance Meas mode* and *Phase Sel for Z Clc* settings determine which voltages and currents are to be used. If *Impedance Meas mode* is set to "1Phase-phase", the *Phase Sel for Z Clc* setting is needed for determining which phase-phase voltages ("AB", "BC" and "CA") and currents should be used for calculating the impedance.

Table 960: Voltages and currents used in impedance calculation

Impedance Meas mode	Phase Sel for Z Clc	Voltages and currents used in impedance calculation [1]
1Phase-phase	AB	$\overline{ZAB} = \frac{U_AB}{I_A - I_B}$
1Phase-phase	BC	$\overline{ZBC} = \frac{U_BC}{I_B - I_C}$
1Phase-phase	CA	$\overline{ZCA} = \frac{U_CA}{I_C - I_A}$
3Phase-phase	N/A	$\overline{ZAB} = \frac{U_AB}{I_A - I_B}$ $\overline{ZBC} = \frac{U_BC}{I_B - I_C}$ $\overline{ZCA} = \frac{U_CA}{I_C - I_A}$

If all three phase or phase-phase voltages and phase currents are fed to the protection relay, the "3Phase-phase" mode is recommended.

[1] Voltages and currents in the calculations are given in volts and amps.

The current measurement of the function is based on two alternative measurement modes, "DFT" and "Peak-To-Peak". The measurement mode is selected using the *Measurement mode* setting.

If the current magnitude is below 0.02 · I_N, where I_N is the nominal phase current, the impedance value is not evaluated and the maximum impedance value (99.999 pu) is shown in the Monitored data view.

The calculated impedances are converted to a pu impedance as the operating characteristics are defined using the *Polar reach* setting in %Zb.

The calculated phase-phase impedance amplitudes Z_AMPL_AB, Z_AMPL_BC and Z_AMPL_CA are available as pu values in the Monitored data view.

Underimpedance detection

The operating characteristic is an origin-centric circle on the impedance plane. The origin-centric circular characteristic is defined using the *Polar reach* setting. If the calculated impedance value enters the circle in the impedance plane, the module sends an enabling signal to start the Timer.

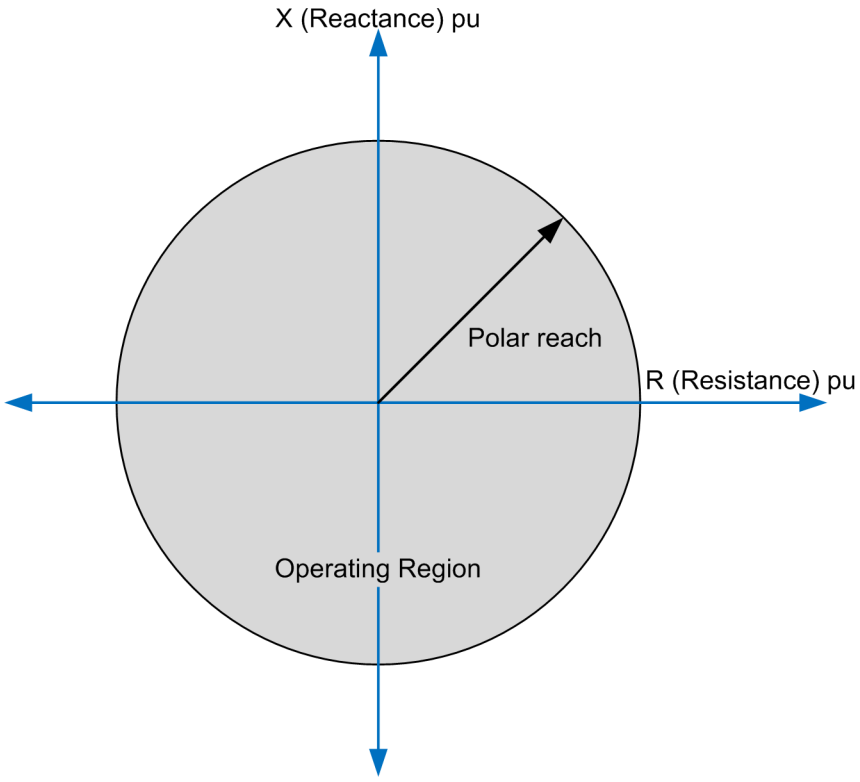

Figure 571: Origin-centric circular operating characteristics

Separate zones with an offset-mho characteristic can be designed using multiple instances of the UZPDIS function with *Offset enable* setting and parameterized with *Offset* and *Displacement* setting values as shown in Figure *Figure 572*. *Offset* is the distance of the top of the circle from R-axis. If the sign of the *Offset* is positive, the top of the circle is above the R-axis and if it is negative, the top of the circle will be below the R-axis. *Displacement* is the distance by which the center of the circle is displaced from the X-axis. If the sign of the *Displacement* setting is positive,

the circle is shifted to the right of the X-axis and if the sign is negative, the circle is shifted to the left of the X-axis. For an origin-centric mho characteristic, *Offset enable* is kept disabled.

When using the mho-characteristics, the *Offset* and *Displacement* settings are as given in the UEXPDIS function, but *Polar reach* is half of UEXPDIS *Diameter* setting.

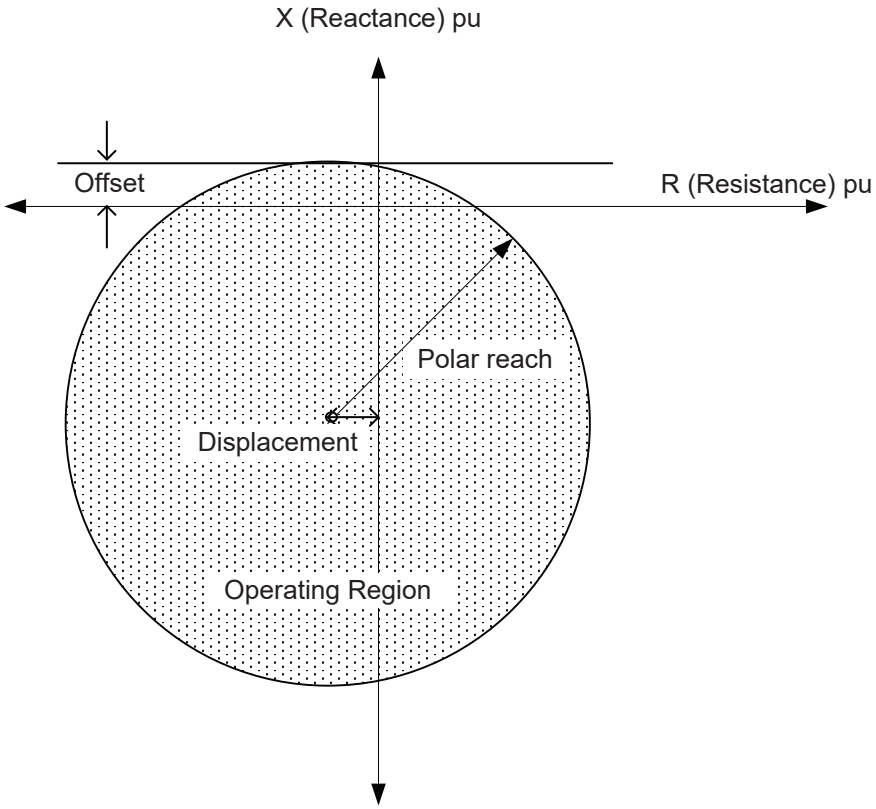

Figure 572: Designing zones with Offset and Displacement

The offset-mho characteristic shown in Figure *Figure 572* is designed with a positive value for *Offset* and a negative value for *Displacement*.

More than one impedance value is available when *Impedance Meas mode* is set to "3Phase-phase", and the function considers the lowest impedance value for starting and operating.

Timer

Once activated, the Timer activates `START` output. The time characteristic is according to DT. When the duration of the underimpedance condition exceeds the set definite *Operate delay time*, the `OPERATE` output is activated. If the impedance locus moves out of circular operating characteristics before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operating timer resets and the `START` output is deactivated.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time (DT). The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.7.4.6 Application

The three-phase underimpedance protection is used as a backup protection against short circuit faults at the generator terminals or on the high-voltage side of a step-up transformer. This function can be used either instead of the definite time voltage-dependent overcurrent protection or to obtain a limited protection zone and the optimum operating time instead of the non-directional overcurrent protection.

Comparison between overcurrent and underimpedance protection

Phase current for three-phase short circuit is shown in *Figure 573*. In this case, with an ordinary over current relay having the current setting as $1.2 \cdot I_n$, the time setting should be less than 0.2 seconds, since with a higher value the short-circuit current decays below the set value and the relay drops off. The current setting can also be reduced to $1.1 \cdot I_n$, although this provides no substantial rise in the time setting. In some situations, either of the above current settings is appropriate, but if longer tripping times are required to maintain the time selectivity, the underimpedance protection is needed.

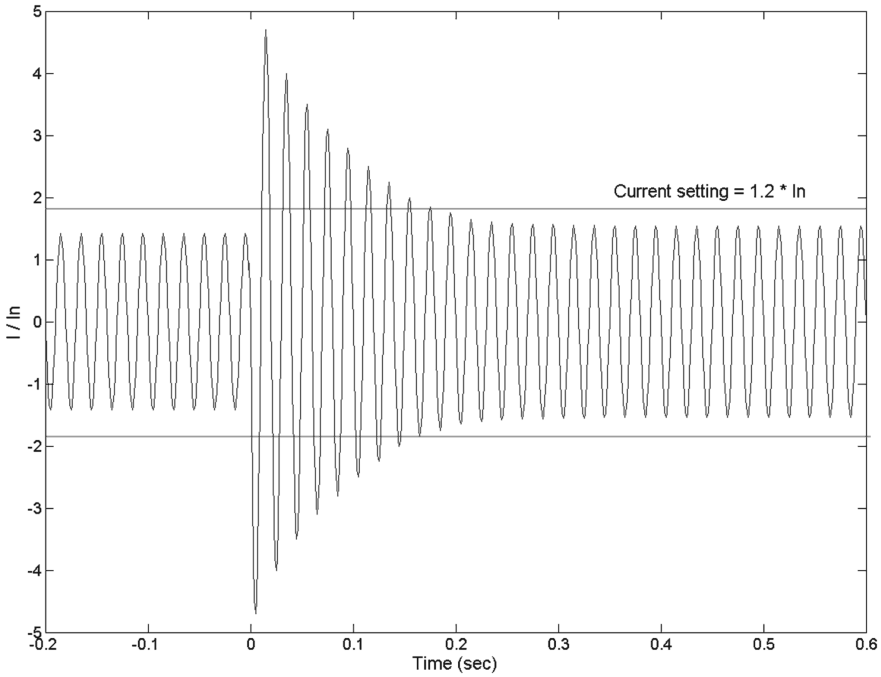

Figure 573: Short circuit current waveform, fault occurs at time 0 seconds (Current setting limit is multiplied by the square root of 2)

The phase voltage in a three-phase short circuit when a fault occurs at time = 0 s is shown in *Figure 574*. The voltage drop caused by a three-phase fault provides more time for determining the fault by means of an underimpedance protection.

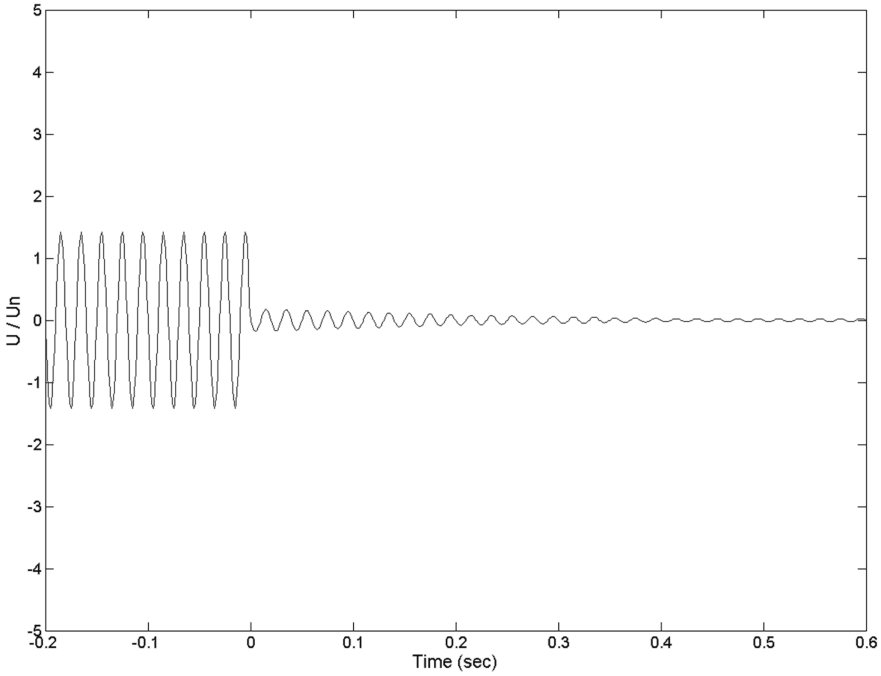

Figure 574: Short-circuit voltage waveform, fault occurs at time 0 seconds

In a typical impedance trajectory during a short circuit, the fault impedance remains inside the impedance circle for a longer time, in which case the underimpedance protection provides longer tripping delay times to maintain the time selectivity.

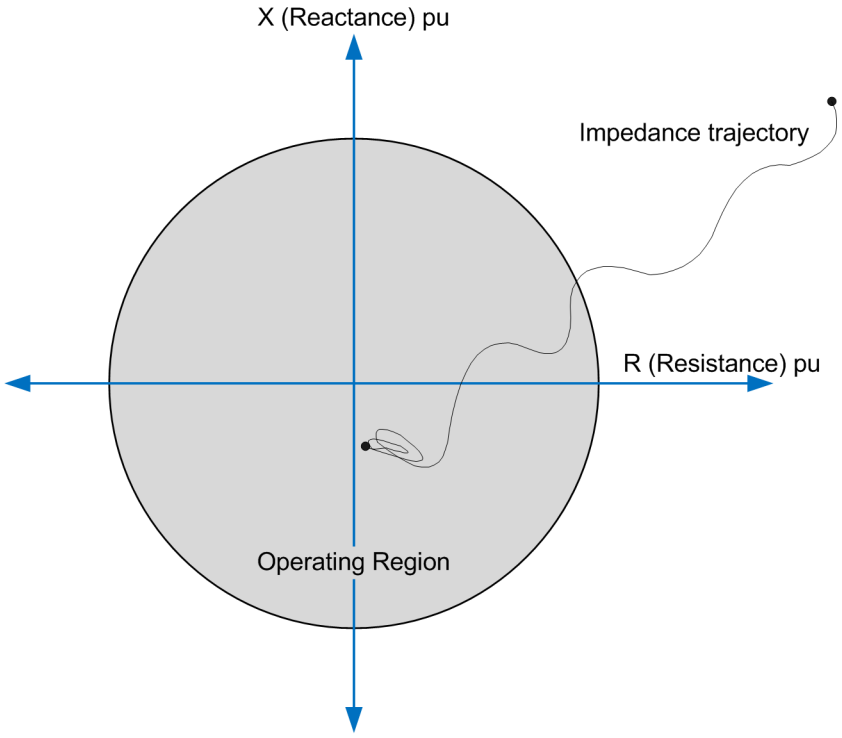

Figure 575: Typical impedance trajectory during a short circuit

Underimpedance protection for transformers

The underimpedance function is used as a short circuit protection instead of the overcurrent protection. It is also used as a backup to the differential protection of transformers.

The voltage and current phasors are measured with the VTs and CTs connected on the HV side of the transformer.

The phase and current shifts due to transformer D/Y connections and other factors complicate the settings for the faults in the secondary winding (as seen from the protection relay), and detailed calculations are necessary for a good coverage.

The *Polar reach* setting is set to a value equal to 150 percent of the transformer short circuit impedance. The setting also provides a backup protection for the busbar and feeder faults on the HV side.

Underimpedance protection for generators

The underimpedance protection is set to protect the zone between the generator windings and the generator side windings of the step-up transformer. The function mainly protects the generator bus, the low-voltage part of the step-up transformer and a part of the stator winding against any short circuits.

The voltages should be measured from the generator terminals and the phase currents from the neutral point of the generator.

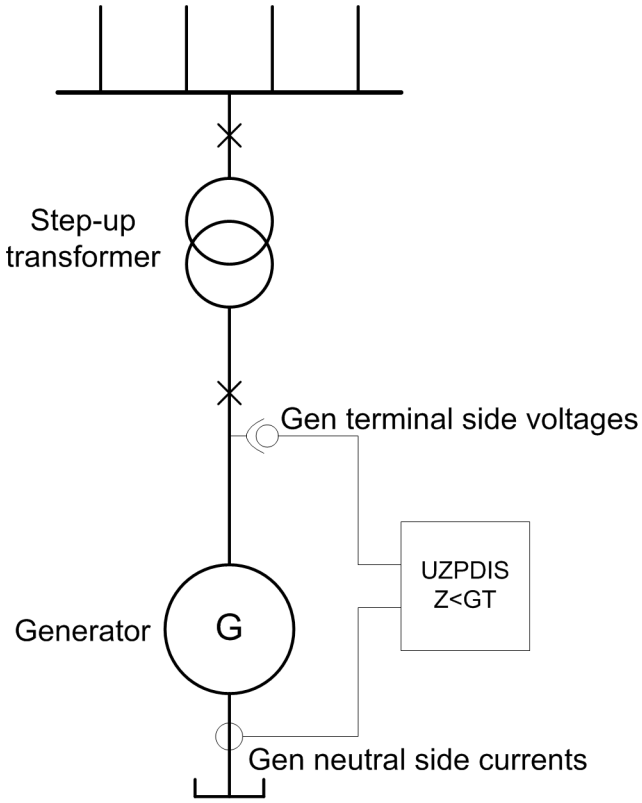

Figure 576: Current and voltage signals for underimpedance protection

To prevent malfunctioning of the underimpedance protection in case of nearby faults, the *Polar reach* setting is set to a value equal to 70 percent of the step-up transformer short circuit impedance.

In directly connected machines where the impedance towards the network is limited only by the lines or bus bars, it must be secured that the function does not cause any selectivity problems. In such cases, it is recommended to use the voltage-dependent overcurrent protection instead of the underimpedance protection.

Function blocking guidelines

The operation of the underimpedance protection must be restrained if the voltage in one or more phases suddenly drops close to zero without any significant change in the current observed at the same time. This situation is considered as a fuse failure or a miniature circuit breaker operation in the voltage transformer secondary circuit. The voltage drop could cause an unwanted operation of the function block since the calculated impedance could fall below the set operating limit even if there is no actual fault in the primary system.

The blocking operation is provided by an external function block, the fuse failure supervision SEQSPVC, whose output is connected to the `BLOCK` input of UZPDIS.

Directional negative sequence impedance protection	DNZPDIS	Z2 ->	Z2Q

4.7.5.2 Function block

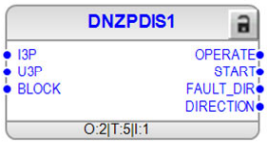

Figure 577: Function block

4.7.5.3 Functionality

Directional negative sequence impedance protection function (DNZPDIS) is used to detect the unsymmetrical fault such as the phase to phase fault, phase-ground fault and double phase to ground fault on power system network.

Operating principle is based on negative sequence impedance. Function compares the negative sequence impedance value against given setting values. Directional operation is based on following theory, impedance value is positive for forward faults and negative for reverse faults. Operate time is according to definite time characteristics.

4.7.5.4 Analog channel configuration

DNZPDIS has two analog group inputs which must be properly configured.

Table 970: Analog Inputs

Input	Description
I3P	Three phase currents
U3P	Three phase voltages

Table 971: Special conditions

Condition	Description
U3P connected real measurements	The function requires that at least two voltage channels are connected

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings.

4.7.5.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of DNZPDIS can be described by using a module diagram (see *Figure 578* below). All the modules in the diagram are explained in the next sections.

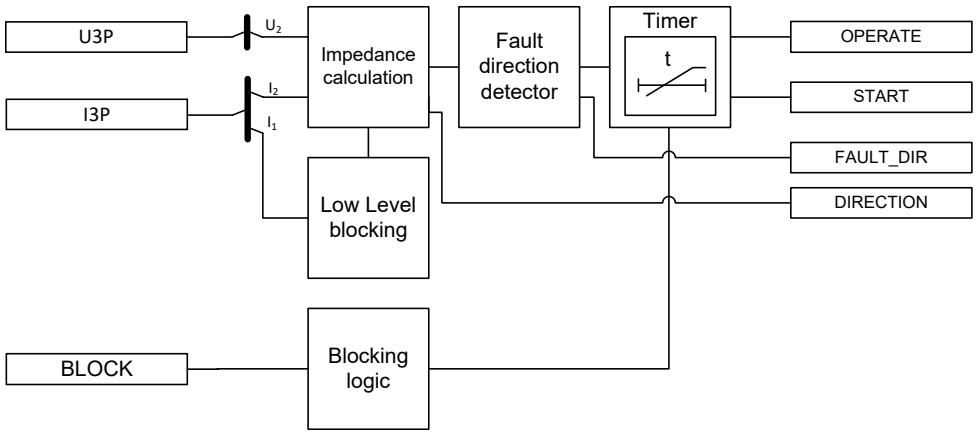

Figure 578: Functional module diagram

Low level blocking

This module receives positive sequence current (I_1) and negative sequence current (I_2). Both are calculated from fundamental frequency three phase currents.

Low level blocking is used to block the Impedance calculation if negative sequence current does not satisfy minimum level criteria. If negative sequence current exceeds setting *Min Ng Seq current Fw* value, impedance calculation is allowed in forward direction. Alternatively, if negative sequence current is exceeds setting *Min Ng Seq current Rv* value, impedance calculation is allowed in reverse direction.

The negative sequence current to positive sequence current ratio (I_2/I_1) should also exceed the setting *Restrain factor* to enable impedance calculation.

Impedance calculation

This module receives positive sequence voltage (U_1) and negative sequence voltage (U_2) which are calculated from fundamental frequency three phase voltages. Also positive sequence current (I_1) and negative sequence current (I_2) which are respectively calculated from fundamental frequency three phase currents.

Once activated the negative sequence impedance (Z_2) is calculated from the negative sequence current, the negative sequence voltage and Relay characteristic angle (RCA) using the below equation.

$$Z_2 = \left|\frac{U_2}{I_2}\right| * \cos\left(\angle U_2 + 180 - \angle I_2 - \angle RCA\right)$$

(Equation 278)

The RCA in the above equation can be obtained from *Characteristic angle* setting.

The Z_2 value in primary ohms is available as Z2_VALUE in monitored data.

Table 972: Direction value for monitored data view

Criterion for direction information	The value for DIRECTION
Default (low level blocking active)	0 = unknown
$Z_2 > 0$	1 = forward
$Z_2 < 0$	2 = backward

Fault direction detector

This module checks if the value of Z_2 meets the operation criteria. Detection to only forward direction can be achieved by setting the *Direction mode* to “Forward”. Thus, forward fault is detected if the value of Z_2 is higher than the *Ng Seq impedance Fw* setting. Respectively operation to only reverse direction can be activated by setting *Direction mode* is set to “Reverse”. Reverse fault is detected if the value of Z_2 is below the setting *Ng Seq impedance Rv* setting. In case *Direction mode* is set to “Non-directional”, operation is allowed if condition for forward or reverse direction is fulfilled.

The *Ng Seq impedance Fw* setting and *Ng Seq impedance Rv* settings are set in primary ohms.

FAULT_DIR gives the direction information during fault, if operation criteria is satisfied. that is, when the START output is active. The fault direction (FAULT_DIR) is available in monitored data and as function block output. FAULT_DIR values are the same as for DIRECTION output given in the *Table 972*. The FAULT_DIR is set to value 0 = unknown after the START output is deactivated.

Figure 579 illustrates the directional operating characteristics on negative sequence impedance level as shown in the vertical line.

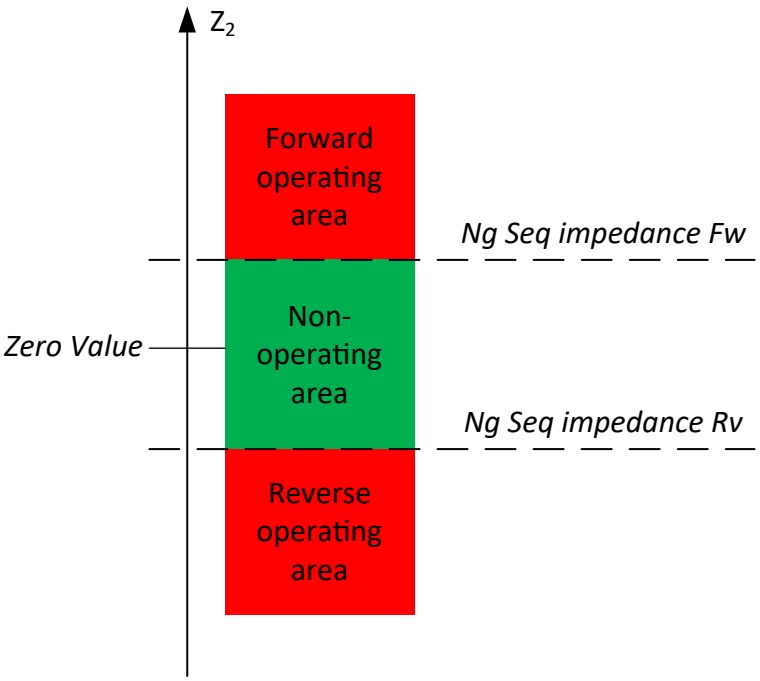

Figure 579: Fault direction estimation on negative sequence impedance level

Timer

Once activated, the Timer activates the START output. The timer characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated if the operating conditions persists.

If a drop-off situation happens, that is, a fault suddenly disappears before the operate delay is exceeded, the timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated. The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the relay program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timer" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.7.5.6 Application

The directional negative sequence impedance function is normally used on incoming line or feeder connected to the busbar, which is made to operate in the specified direction for secured operation. The fault direction can be either referred as forward or reverse of the relay.

There are different directional elements used to determine the direction of faults, one such element is negative sequence impedance. The calculated negative sequence impedance is sensitive enough to identify fault in power system networks with strong source where less negative-sequence voltage and current will be present during faults.

By using suitable restraint factor, it is also possible to avoid false tripping with systems having un-transposed lines where some default negative sequence current will be present during normal operation.

Application example

Relay setting calculation for the DNZPDIS function is shown with below application example of parallel lines with two end sources of power system network.

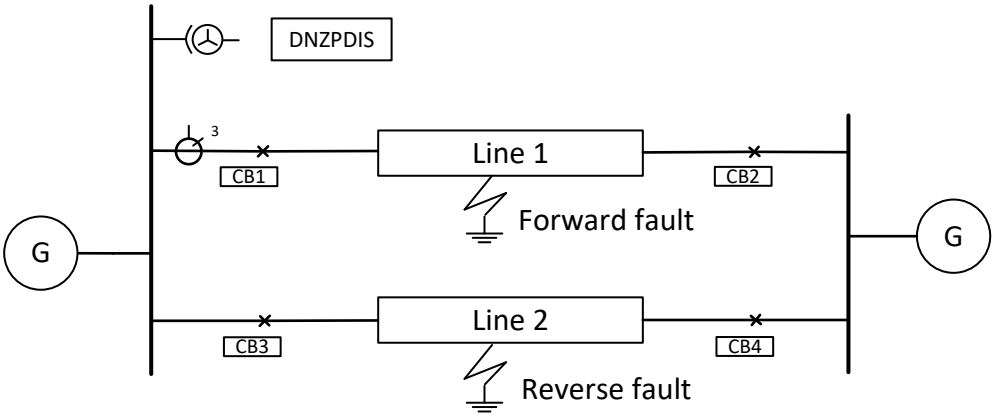

Figure 580: Power system network with parallel line and two sources

Setting value calculation

Line parameters:

Resistance = 0.126 ohm/km

Reactance = 0.600 ohm/km

Line length = 100 km

Total impedance (Z_1tot) of line1 or line2 is calculated below

$$Z_1\text{tot} = (0.126 + j0.60 \text{ ohm/km}) * 100 \text{ km}$$
$$= 12.6 + j60.1 \text{ in ohm}$$

(Equation 279)

Magnitude of positive sequence impedance (Z_1tot) = 60.4 ohm. The following settings are obtained to set the relay located at circuit breaker 1(CB1).

- *Ng Seq impedance Fw* can be set to 50% of the Z_1tot magnitude of the line 1 which equals in primary ohms 60.4/2 = 30.2.
- *Ng Seq impedance Rv* can be set to 50% of the Z_1tot magnitude of the line 2. Setting is for reverse fault in parallel line and therefore magnitude is negative. Thus setting value is in primary ohms -60.4/2 = -30.2.
- If *Characteristic angle* mode is set to “Fixed”, then the value for *Characteristic angle* setting can be calculated as below.

$$\begin{aligned}\text{Characteristic angle} &= \arctan(X/R)\\ &= \arctan(60.1/12.6)\\ &= 78.3 \text{ deg}\end{aligned}$$

(Equation 280)

The setting *Restrain factor* is set based on the minimum unbalance loading allowed in the power system network. In this case 10% unbalance is allowed in the given example system, hence the *Restrain factor* is set to 0.1.

Fault simulation

The phase to ground faults are simulated in the given example shown in *Figure 580*, the relay is located at the sending end of the line1 and the output is captured for forward and reverse direction fault.

The phase A to ground fault is applied on the line1 in the forward direction, the Z_2 value is positive as well as exceeds the *Ng seq impedance Fw* setting threshold, hence the START output issued, FAULT_DIR indicates the fault in the forward direction and the OPERATE output will be issued after the *Operate delay time* setting has passed as shown in below *Figure 581*.

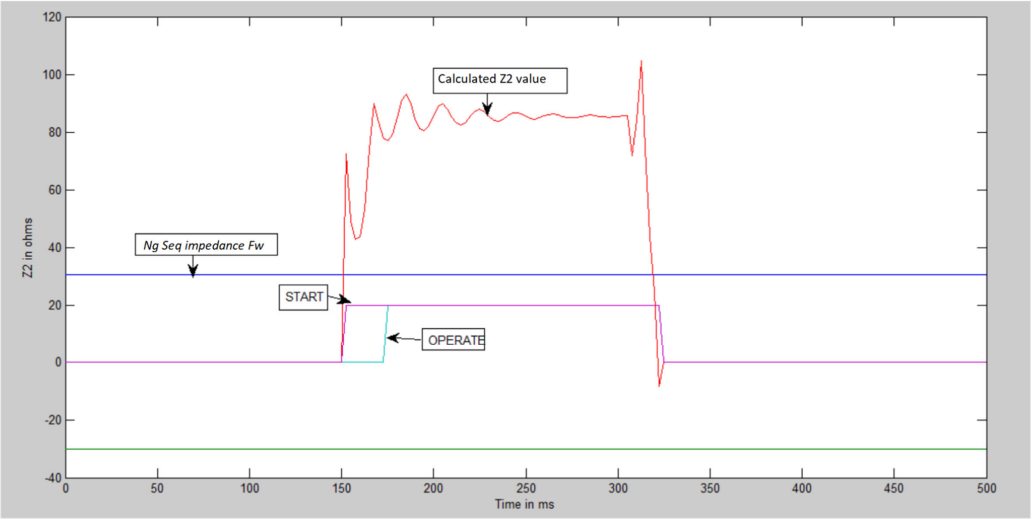

Figure 581: Phase A to ground fault on forward direction

The phase A to ground fault is applied on the line2 in the reverse direction, the calculated Z_2 value is negative as well as lower the *Ng seq impedance Rv* setting threshold, hence the START output issued, FAULT_DIR indicates the fault in the reverse direction and the OPERATE output will be issued after the *Operate delay time* setting has passed as shown in below *Figure 582*.

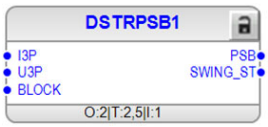

Figure 583: Function block

4.7.6.3 Functionality

The power swing detection function DSTRPSB detects power swing condition and can be used for blocking the distance protection function. The power swing detection function comprises an inner and an outer impedance characteristic. The supported zone characteristic shapes for inner and outer characteristic are quadrilateral and mho (circular). The power swing detection function is supervised by a load encroachment logic which ensures that the load impedance does not enter the characteristic of the power swing detection function during normal power system operation.

[1] Results based on statistical distribution of 1000 measurements
[2] Measured with static signal output (SSO)
[3] During fault, Z_2= 2.0 × *Ng Seq impedance Rv/Fw*

The function calculates the positive sequence impedance. Calculation is based on fundamental frequency components of positive sequence current and voltage. If the measured impedance stays between inner and outer characteristic longer than predetermined time and moves farther inside the inner characteristic, then a power swing condition is indicated.

4.7.6.4 Analog channel configuration

DSTRPSB has two analog group inputs which must be properly configured.

Table 980: Analog Inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

There are a few special conditions which must be noted with the configuration.

Table 981: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

4.7.6.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of DSTRPSB can be described by using a module diagram (see figure below). All the modules in the diagram are explained in the next sections.

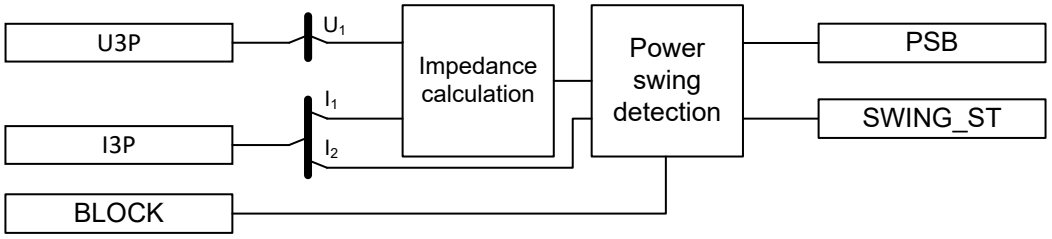

Figure 584: Function module diagram

Impedance calculation

This module receives positive sequence voltage which is calculated from fundamental frequency three phase voltages and positive sequence current calculated respectively from fundamental frequency three phase currents. For the module to calculate impedance it is required that the positive-sequence current is above 0.1xIn.

Operation is based on positive sequence impedance (Z_1) which is calculated using positive sequence voltage and current as follows:

$$\underline{Z}_1 = \frac{\underline{U}_1}{\underline{I}_1}$$

(Equation 281)

The calculated positive-sequence impedance amplitude Z1_AMPL and angle Z1_ANGLE are available in primary ohms and degrees, respectively, in the Monitored data view.

The calculated impedance is converted to ohms as the operating characteristics are defined with the ohm settings.

Power swing detection

Power swing detection function comprises an inner and outer quadrilateral /circular measurement characteristic. The positive sequence impedance is continuously monitored for detecting a power swing condition. During normal power system operation, the impedance is outside of outer characteristic. When the impedance enters outer characteristic, output `SWING_ST` is activated, and the power swing detection timer is triggered. The `SWING_ST` output will be deactivated if the impedance leaves the zone between inner and outer characteristic. If the impedance remains between the inner and outer characteristics longer than the time defined by the setting *Swing time* , and the impedance enters inner characteristic, output `PSB` is activated. The `PSB` output will be deactivated after the impedance leaves outer characteristic for the time defined by *Pulse time* setting.

When an unbalanced fault occurs during power swing, the `PSB` output should be deactivated to allow tripping. For the purpose module is monitoring negative sequence current which is calculated from fundamental frequency three phase currents. Negative sequence current level can be monitored if *Ng Seq current Spvn* is set to "Enable". When the negative sequence current is above the *Max Ng Seq current* setting longer than the time delay defined by the setting *Neg Seq current time*, the Power swing detection module is disabled. The module is disabled until negative sequence current drops below the setting value. The *Max Ng Seq current* setting should be set above the maximum negative sequence current which may appear during power swing.

Slow power swing can be used as criterion for disabling power swing detection. Monitoring is activated by setting *Slow swing Spvn* to "Enable". If the positive sequence impedance enters and remains inside outer characteristic longer than the time delay defined by the setting *Slow swing time*, the Power swing detection module is disabled. The module is disabled until the positive sequence impedance moves outside outer characteristics. The setting *Slow swing time* should be coordinated with network or cable current rating characteristics. Too long lasting large current may need to be cleared even if situation is classified as power swing.

In case of heavily loaded lines, the optional load encroachment logic can be enabled with the *Load discrimination* setting. The logic reserves an area for load impedance defined by the *Outer Fw Ld Ris Rch, Outer Rv Ld Ris Rch, Inner Fw Ld Ris Rch, Inner Rv Ld Ris Rch, Load angle1* and *Load angle2* settings.

Quadrilateral characteristic

If the *Pe Swg impedance Chr* is ‘Quadrilateral’, DSTRPSB has a double-polygon characteristic.

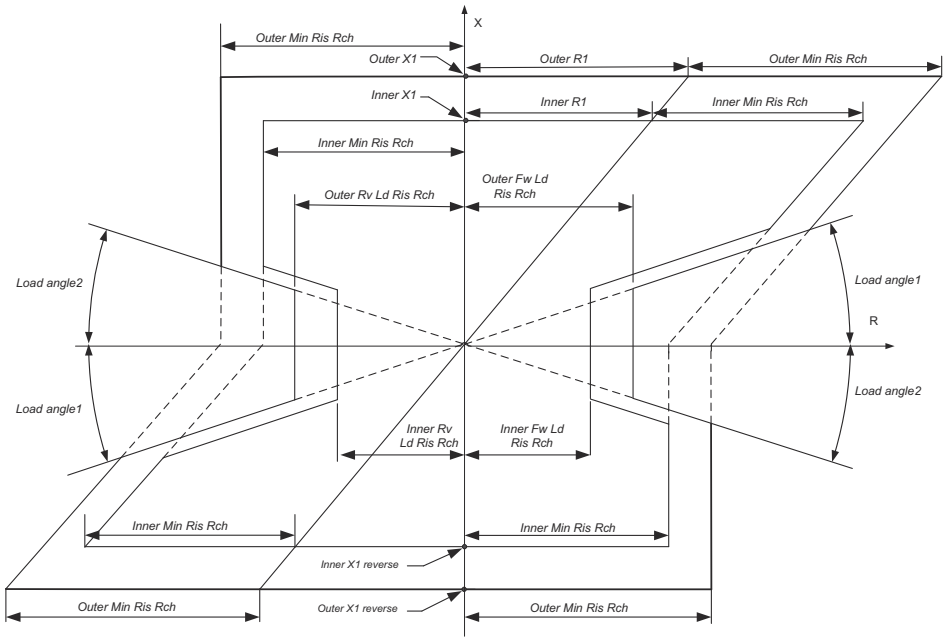

Figure 585: Quadrilateral operation characteristics

The reach of inner polygon in the reactive direction is defined by the line reach independently with the settings *Inner R1, Inner X1, Inner X1 reverse*. The resistive reach of inner polygon is defined at the minimum resistive reach with settings *Inner Min Ris Rch*. The reach of outer polygon in the reactive direction is defined by the line reach independently with the settings *Outer R1, Outer X1, Outer X1 reverse*. The resistive reach of outer polygon is defined at the minimum resistive reach with settings *Outer Min Ris Rch*.

Mho circular characteristics

When the *Pe Swg impedance Chr* is "Mho (circular)", the DSTRPSB has a double circular characteristic.

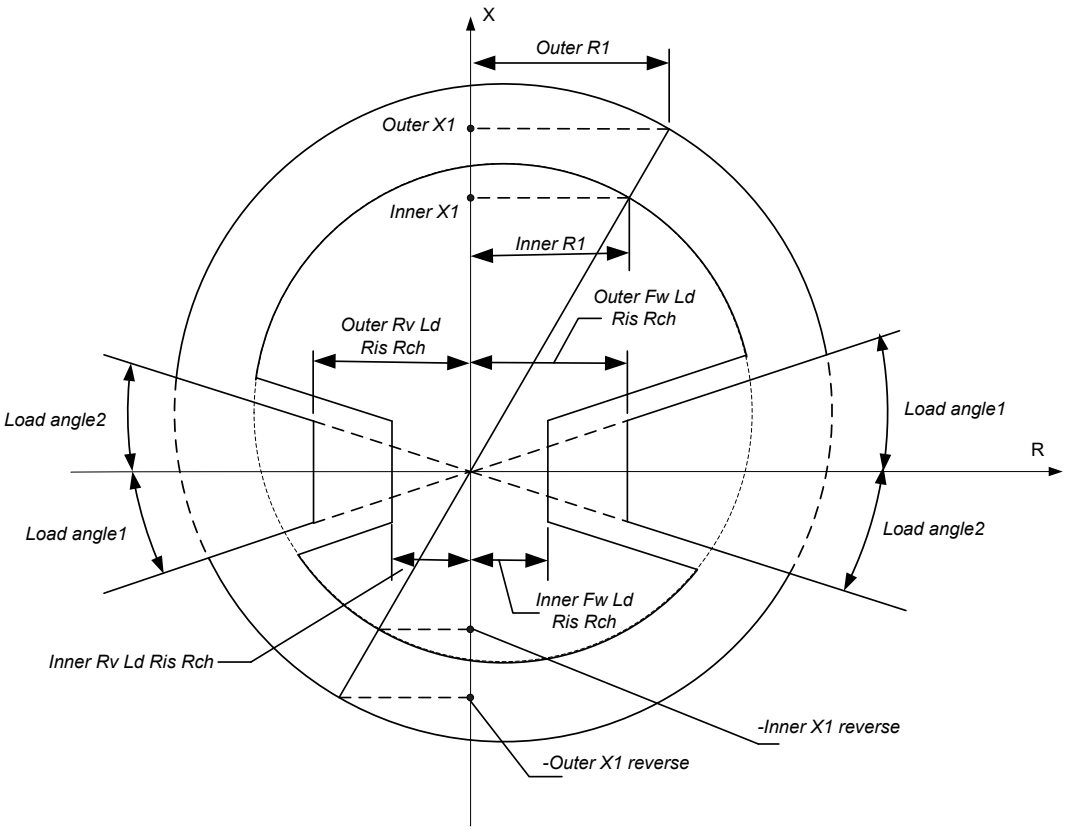

Figure 586: Mho operation characteristics

The reach of inner circle is defined by the settings *Inner R1, Inner X1, Inner X1 reverse*. Angle defined by settings *Inner R1* and *Inner X1* defines also reverse zone angle. The reach of outer circle is defined by the settings *Outer R1, Outer X1, Outer X1 reverse*. Angle defined by settings *Outer R1* and *Outer X1* defines also reserve zone angle.

The PSB and SWING_ST outputs can be blocked by activating BLOCK input. Blocking also resets internal timers and impedance calculation.

4.7.6.6 Application

Describe different application possibilities of the function. The application information answers one or more of the following questions:

- The problem of the application
- The purpose of the function
- Solution for the problem in general level
- Where can the function be used?
- When can the function be used?
- The application information shall NOT describe what the user should consider or should calculate, plan, dimension etc. to make the function work in the applications.

Power swing detection functions detect power swing conditions by using the fact that the voltage/current variation during a power swing is slow compared to the step change during a fault. Both faults and power swings may cause the positive sequence impedance to enter into the operating characteristic of a distance relay

element. The apparent impedance moves from the pre-fault value to a fault value in a very short time, a few milliseconds, during a fault condition. However, the rate of change of the positive sequence impedance is much slower during a power swing condition than during a fault. It should be noted that the impedance measurement should not be used by itself to distinguish between a power swing condition from a phase fault. The fundamental method for discriminating between faults and power swings is to track the rate of change of the measured impedance.

The function measuring the rate of change of the positive sequence impedance comprises an inner and an outer impedance characteristic with a timer. If the positive sequence impedance remains between the inner and outer characteristics for a predetermined time and enters the inner characteristic, the function declares a power swing condition and asserts an output that can be used to block the distance protection. Figure below gives an example of power swing detection.

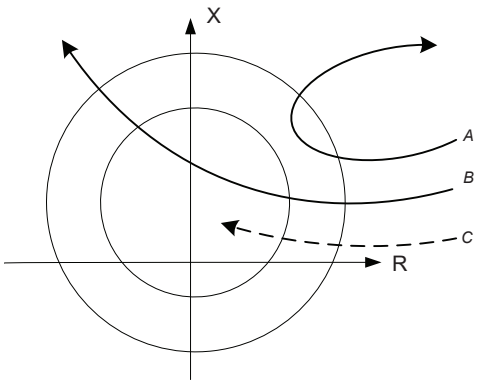

Figure 587: Example of power swing detection

In the above figure, the power swing detection characteristics and three typical positive sequence impedance trajectories are plotted. For trajectory A, the impedance moves into the power swing detection zone and leaves slowly, indicating the occurrence of a swing that quickly stabilizes. For trajectory C, impedance rapidly moves into, and remains in, the inner characteristic indicating an actual fault and not a power swing condition. For trajectory B, the impedance moves slowly into the power swing detection zone and exits the zone indicating that the network is becoming unstable. Only in this case power swing blocking functionality should be activated in order to avoid unwanted/unselective operation of distance protection.

The settings of outer impedance measurement characteristic of DSTRPSB should be set so that load impedance does not enter the outer characteristic during normal operation of the power system and covers the inner characteristic entirely. The settings of inner impedance measurement characteristic should be set to make the inner characteristic cover the distance protection zone entirely which will be blocked during power swing.

Underpower protection	DUPPDPR	P<	32U

4.8.1.2 Function block

Figure 589: Function block

4.8.1.3 Functionality

The underpower protection function DUPPDPR is used for protecting generators and prime movers against the effects of very low power outputs or reverse power condition.

The function operates when the measured active power falls below the set value. The operating characteristics are according to definite time DT.

This function contains a blocking functionality. It is possible to block the function outputs, timer or the function itself.

4.8.1.4 Analog channel configuration

DUPPDPR has two analog group inputs which must be properly configured.

[1] Measured with static power output (SPO)

Table 989: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 990: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with the corresponding one voltage channel connected if the measurement mode is set to "PhsAB", "PhsBC", "PhsCA", "PhsA", "PhsB" or "PhsC".
	The function requires that at least two (the third voltage will be derived) or all three voltage channels are connected for the other measurement modes.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.8.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”.

The operation of DUPPDPR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

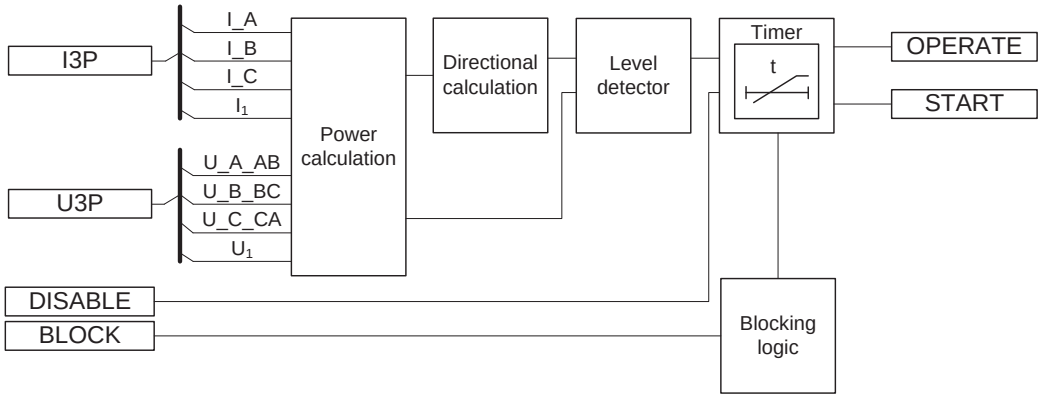

Figure 590: Functional module diagram

Power calculation

This module calculates the apparent power based on the selected voltage and current measurements as described in *Table 991*. The *Measurement mode* setting determines which voltage and current measurements are to be used.

It is also possible to use positive-sequence components for calculating apparent power, which makes the determination of power insensitive to the possible asymmetry in currents or voltages and corresponds to the real load of the prime mover of the generator. S¯ ¯¯s¯

Table 991: Power calculation

Measurement mode setting	Power calculation
PhsA, PhsB, PhsC	$\bar{S} = \bar{U}_a \cdot \bar{I}_a^* + \bar{U}_b \cdot \bar{I}_b^* + \bar{U}_c \cdot \bar{I}_c^*$ $P = Re(\bar{S})$
Arone	$\bar{S} = \bar{U}_{ab} \cdot \bar{I}_a^* - \bar{U}_{bc} \cdot \bar{I}_c^*$ $P = Re(\bar{S})$
Pos Seq	$\bar{S} = 3 \cdot \bar{U}_1 \cdot \bar{I}_1^*$ $P = Re(\bar{S})$
PhsAB	$\bar{S} = \sqrt{3} \cdot \bar{U}_{ab} \cdot (\bar{I}_a^* - \bar{I}_b^*)$ $P = Re(\bar{S})$
PhsBC	$\bar{S} = \sqrt{3} \cdot \bar{U}_{bc} \cdot (\bar{I}_b^* - \bar{I}_c^*)$ $P = Re(\bar{S})$
PhsCA	$\bar{S} = \sqrt{3} \cdot \bar{U}_{ca} \cdot (\bar{I}_c^* - \bar{I}_a^*)$ $P = Re(\bar{S})$
PhsA	$\bar{S} = 3 \cdot \bar{U}_a \cdot \bar{I}_a^*$ $P = Re(\bar{S})$
PhsB	$\bar{S} = 3 \cdot \bar{U}_b \cdot \bar{I}_b^*$

Table continues on the next page

Measurement mode setting	Power calculation
	$P = Re(\bar{S})$
PhsC	$\bar{S} = 3 \cdot \bar{U}_c \cdot \bar{I}_c^*$ $P = Re(\bar{S})$

If all three phase voltages and phase currents are fed to the protection relay, the positive-sequence alternative is recommended (default).

Depending on the set *Measurement mode*, the power calculation calculates active power, reactive power and apparent power values from the available set of measurements. The calculated powers S, P, Q and the power factor angle, PF_ANGL, are available in the Monitored data.

Directional calculation

Directional calculation determines the direction of the measured power. The measured power is considered to be in the forward direction if the active power is positive, else it is considered to be in the reverse direction.

A typical error is, for example, that the VT or CT poles are wrongly connected. This is seen as a power flow opposite to that of the intended direction. The *Pol Reversal* setting can be used to correct the situation. By setting the value to "True", the measured apparent power is turned 180 degrees.

Level detector

Level detector compares the calculated value of the active power with a set *Start value*. If the calculated value of the active power falls below *Start value* in the forward direction or if the measured power is in the reverse direction, Level detector enables the Timer module.

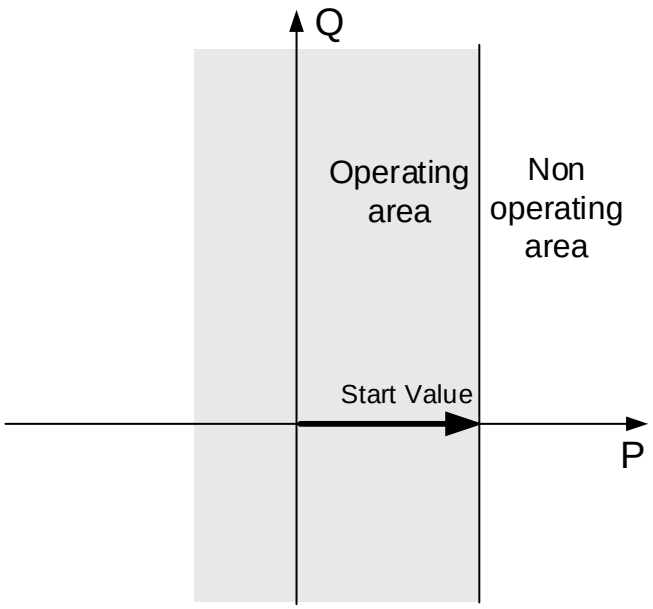

Figure 591: Operating characteristics of DUPPDPR with setting Start value

Timer

Once activated, the Timer activates the START output. The time characteristics are according to DT. When the operation timer has reached the value of *Operate delay time*, the OPERATE output is activated. In a drop-off situation, that is, if the underpower condition disappears before the operation delay is exceeded, the timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

The Timer calculates the START_DUR value which indicates the percentage of the time elapsed since the activation of the START output with respect to *Operate delay time*. The value is available in the Monitored data.

The DISABLE input can be used to coordinate the correct operation during the generator start-up situation. By activating the DISABLE signal, both the START and OPERATE outputs are blocked. Once the DISABLE signal is deactivated, the Timer remains blocked for an additional time duration as set through the setting *Disable time*.

Blocking logic

There are three operation modes in the blocking functionality. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode,

the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.8.1.6 Application

The task of a generator in a power plant is to convert mechanical energy into electrical energy. Sometimes the mechanical power from the prime mover may decrease so much that it does not cover the internal losses. The task of an underpower protection is to protect the generator from very low power output conditions.

Steam turbines become easily overheated if the steam flow becomes too low or if the steam ceases to flow through the turbine. Hydro turbine of the Kaplan type may be damaged due to the fact that the turbine blade surfs on the water and sets up axial pressure on the bearing. Diesel engines may be damaged due to insufficient lubrication.

If the generator size is very large, it is uneconomical to continue running it with low generated power. In the reverse power condition, large generators draw a considerable amount of power from the rest of the system to feed their internal losses. Hence, it is desirable to disconnect the generator in such situations.

In case of the parallel-connected generators, for example, the load of one generator may be so low that it is better to disconnect it and let the remaining generators feed the network.

Where a low value of power setting is required, for example less than 2%, the correction parameters should be used to compensate for the measuring errors. The manufacturer of the measuring devices is to be contacted for information on the measuring errors.

If the measuring errors are not compensated for, the underpower setting should not be lower than the sum of the current-measuring and voltage-measuring errors.

For example, if the error of the current-measuring device is 2% and that of the voltage-measuring device is 1%, the minimum setting is (2 + 1)% = 3%.

4.8.2.2 Function block

Figure 592: Function block

4.8.2.3 Functionality

The reverse power/directional overpower protection function DOPPDPR can be used for generator protection against delivering an excessive power beyond the generator's capacity to the grid, against the generator running like a motor, and against the motor running like a generator and for protecting a motor which consumes more reactive power due to loss of field. It can also be used in feeder protection for indicating overload on the distribution system, to indicate that a customer is supplying power into the grid and for protecting the transformer from delivering an excessive load.

The function starts and operates when the measured power exceeds the set limit and in a specified direction. The operate time characteristics are according to definite time (DT).

This function contains a blocking functionality. It is possible to block the function outputs, timer or the function itself.

4.8.2.4 Analog channel configuration

DOPPDPR has two analog group inputs which must be properly configured.

Table 999: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1000: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with the corresponding one voltage channel connected if the *Measurement mode* is set to "PhsAB", "PhsBC", "PhsCA", "PhsA", "PhsB" or "PhsC".
	The function requires that at least two (the third voltage will be derived) or all three voltage channels are connected for the other measurement modes.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.8.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of DOPPDPR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

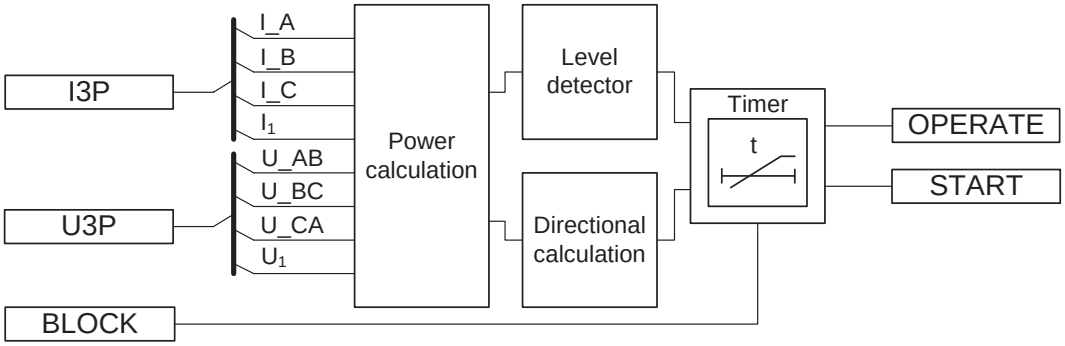

Figure 593: Functional module diagram

Power calculation

This module calculates the apparent power based on the selected voltages and currents. The *Measurement mode* setting determines which voltages and currents are used. It is also possible to use positive-sequence components for calculating the apparent power which makes the determination of power insensitive to a possible asymmetry in currents or voltages and corresponds to the real load on the prime mover of the generator.

Table 1001: Power calculation

Measurement mode setting	Power calculation
PhsA, PhsB, PhsC	$\bar{S} = \bar{U}_a \cdot \bar{I}_a^* + \bar{U}_b \cdot \bar{I}_b^* + \bar{U}_c \cdot \bar{I}_c^*$ $P = Re(\bar{S})$
Arone	$\bar{S} = \bar{U}_{ab} \cdot \bar{I}_a^* - \bar{U}_{bc} \cdot \bar{I}_c^*$ $P = Re(\bar{S})$

Table continues on the next page

Measurement mode setting	Power calculation
Pos Seq	$\bar{S} = 3 \cdot \bar{U}_1 \cdot \bar{I}_1^*$ $P = Re(\bar{S})$
PhsAB	$\bar{S} = \sqrt{3} \cdot \bar{U}_{ab} \cdot (\bar{I}_a^* - \bar{I}_b^*)$ $P = Re(\bar{S})$
PhsBC	$\bar{S} = \sqrt{3} \cdot \bar{U}_{bc} \cdot (\bar{I}_b^* - \bar{I}_c^*)$ $P = Re(\bar{S})$
PhsCA	$\bar{S} = \sqrt{3} \cdot \bar{U}_{ca} \cdot (\bar{I}_c^* - \bar{I}_a^*)$ $P = Re(\bar{S})$
PhsA	$\bar{S} = 3 \cdot \bar{U}_a \cdot \bar{I}_a^*$ $P = Re(\bar{S})$
PhsB	$\bar{S} = 3 \cdot \bar{U}_b \cdot \bar{I}_b^*$ $P = Re(\bar{S})$
PhsC	$\bar{S} = 3 \cdot \bar{U}_c \cdot \bar{I}_c^*$ $P = Re(\bar{S})$

If all three phase voltages and phase currents are fed to the protection relay, the positive-sequence alternative is recommended.

The calculated powers S, P, Q and the power factor angle PF_ANGL are available in the Monitored data view.

Level detector

The Level detector compares the magnitude of the measured apparent power to the set *Start value*. If the measured value exceeds the set *Start value*, the Level detector sends an enabling signal to the Timer module.

Directional calculation

The Directional calculation module monitors the direction of the apparent power. When the apparent power flow is in the operating area, the module sends the enabling signal to the Timer module. The directional operation can be selected with

the combination of the settings *Directional mode* and *Power angle*. The selectable options for the *Directional mode* setting are "Forward" and "Reverse". The *Power angle* setting can be used to set the power direction between the reactive and active power.

A typical error is, for example, that the VT or CT poles are wrongly connected. This is seen as a power flow opposite to that of the intended direction. The *Pol Reversal* setting can be used to correct the situation. By setting the value to "True", the measured apparent power is turned 180 degrees.

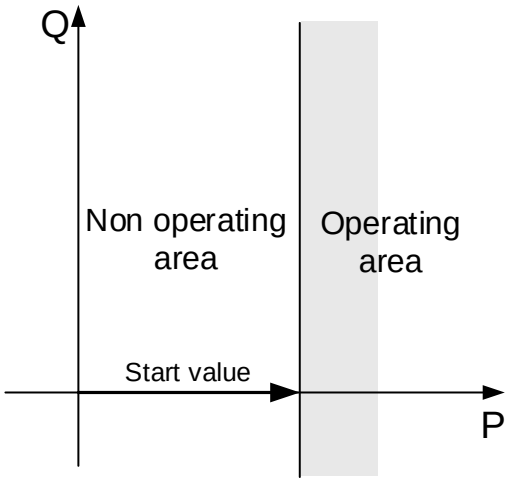

Figure 594: Operating characteristics with the Start Value setting, the Power angle setting being 0 and Directional mode "Forward"

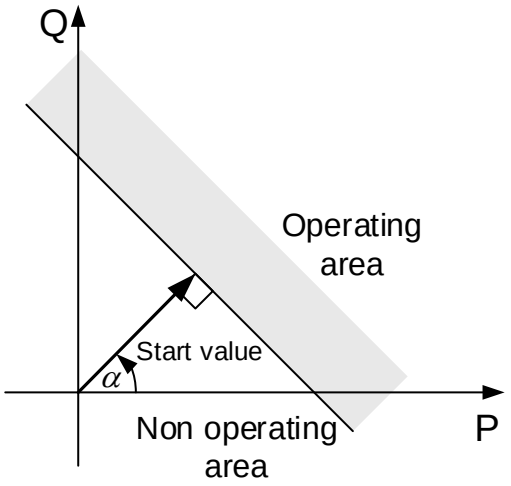

Figure 595: Operating characteristics with the Start Value setting, Power angle (α) being +45 and Directional mode "Forward"

Timer

Once activated, the Timer activates the START output. The time characteristics are according to DT. When the operation timer has reached the value of *Operate delay time*, the OPERATE output is activated. If a drop-off situation happens, that is, the value of power drops below *Start value* before the operate delay is exceeded, the timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, the operate timer resets and the START output is deactivated.

The Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time (DT). The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode**, which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operate timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.8.2.6 Application

DOPPDPR is used to provide protection against an excessive power flow in the set operating direction. The main application is the protection of generators and

turbines. It can also be used in feeder protection applications, for example, the ring network.

DOPPDPR in the forward direction can be used to protect the generators or motors from delivering or consuming excess power. For example, the generator overpower protection can be used to shed a noncritical feeder load or to start parallel generators. A synchronous motor may start consuming more reactive power in case of loss of excitation, in which case the forward overpower protection is used to detect such condition.

The DOPPDPR function has many applications when used as reverse power protection. A generator in a power plant converts mechanical energy to electrical energy. Sometimes the mechanical power from a prime mover may decrease to a limit that it does not cover the internal losses. The synchronous generator becomes a synchronous motor and starts importing power from the system. The effect of a generator acting as a motor implies no risk to the machine but can cause damage to the prime mover. The extent of the damage depends on the type of the prime mover.

Steam turbines become overheated easily if the steam flow drops too low or if the steam ceases to flow through the turbine. The break of a main steam pipe, damage to one or more blades in the steam turbine or an inadvertent closing of the main stop valves are typical causes for the low steam flow. The steam turbines of turbo generators can be protected during a low steam flow with the overpower protection operating in reverse direction. Hydroturbines tolerate reverse power much better than steam turbines do. There is a risk that the turbine runner moves axially and touches stationary parts. They are not always strong enough to withstand the associated stresses.

A hydroturbine that rotates in water with the closed wicket gates draws about 10 % of the rated power from the rest of the power system if the intake is blocked due to ice, snow, branches or leaves. A complete blockage of the intake may cause cavitations. If there is only air in the hydroturbine, the power demand drops to about 3 %. The risk of damages to the hydroturbines can justify the reverse operation of the overpower protection in unattended plants.

Whenever a low value of the reverse power setting is required, an underpower protection should also be used in conjunction with DOPPDPR. The limit depends on the CT and VT accuracy.

Diesel engines should have overpower protection in reverse direction. The generator takes about 15 % or more of its rated power from the system. A stiff engine may require 25 % of the rated power to motor it. A well run engine may need no more than 5 %. It is necessary to obtain information from the engine manufacturer and to measure the reverse power during commissioning.

Reverse overpower can also act as an alternative for an under excitation protection in case of small generators. If the field excitation is reduced, the generator may start importing the reactive power, making the generator run as an asynchronous generator. A synchronous generator is not designed to work asynchronously and may become damaged due to heating in the damper windings or heating in the rotor due to slip frequency current.

When operated in reverse power direction, DOPPDPR can be used as an alarm if the power flowing from the industry is feeding the grid, which may not be desired as per the rules and regulations of the utility owning the grid.

4.8.3 Directional reactive power undervoltage protection DQPTUV (ANSI 32Q,27)

4.8.3.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Directional reactive power under-voltage protection	DQPTUV	Q> ->,3U<	32Q,27

4.8.3.2 Function block

Figure 598: Function block

4.8.3.3 Functionality

The directional reactive power undervoltage protection function DQPTUV is used at the grid connection point of distributed power generating units as stipulated by various grid codes to prevent voltage collapse of the grid due to network faults. DQPTUV measures phase voltages and current at the grid connection point. The generating facility is disconnected from the network with a specific time delay if all phase voltages decrease and remain at or below the specified limit and if reactive power is simultaneously consumed (that is, under-excitation operation).

DQPTUV contains a blocking functionality to block function outputs, timer or the function itself.

4.8.3.4 Analog channel configuration

DQPTUV has two analog group inputs which must be properly configured.

Table 1009: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1010: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.8.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of DQPTUV can be described using a module diagram. All the modules in the diagram are explained in the next sections.

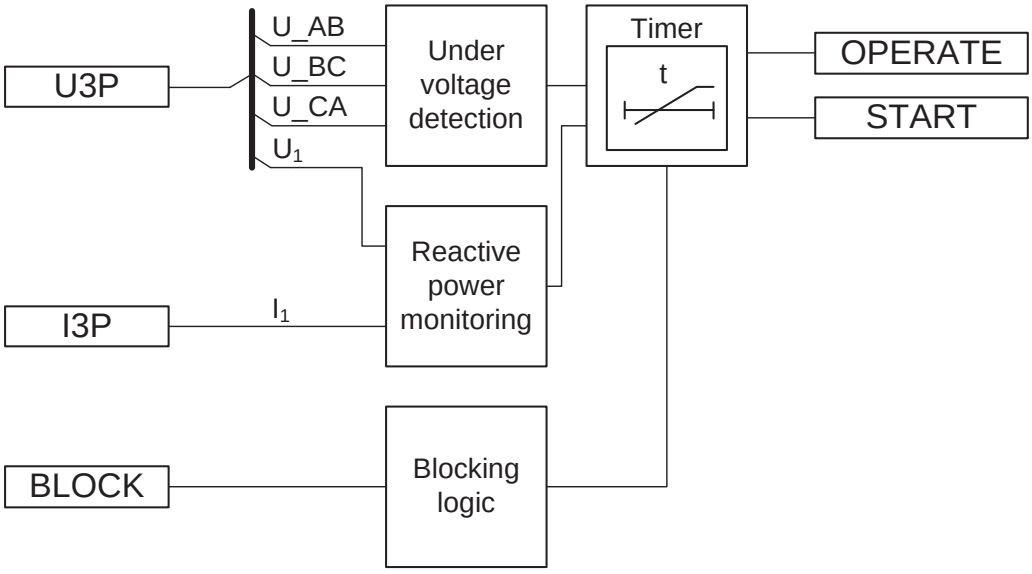

Figure 599: Functional module diagram

Under voltage detection

Under voltage detection compares the fundamental frequency component of all three phase-to-phase voltages with the set *Voltage start value*. When all three phase-to-phase voltages are lower than the set *Voltage start value*, the Under voltage detection module sends an enable signal to the Timer indicating an undervoltage condition at the grid connection point.

Reactive power monitoring

This module calculates and monitors the reactive power based on positive sequence current and voltage. The use of a positive sequence component makes the determination of power insensitive to a possible asymmetry in current and voltages.

When the reactive power exceeds *Min reactive power* and flows in the operating area, the module sends an enable signal to the Timer indicating that the reactive power is being consumed at the grid connection point. A slight tilt in the curve can be obtained by the setting *Pwr sector reduction*.

To avoid false tripping, reactive power calculation is blocked if the magnitude of positive sequence current is less than the set *Min Ps Seq current*.

The magnitude of calculated reactive power Q is available in the Monitored data view.

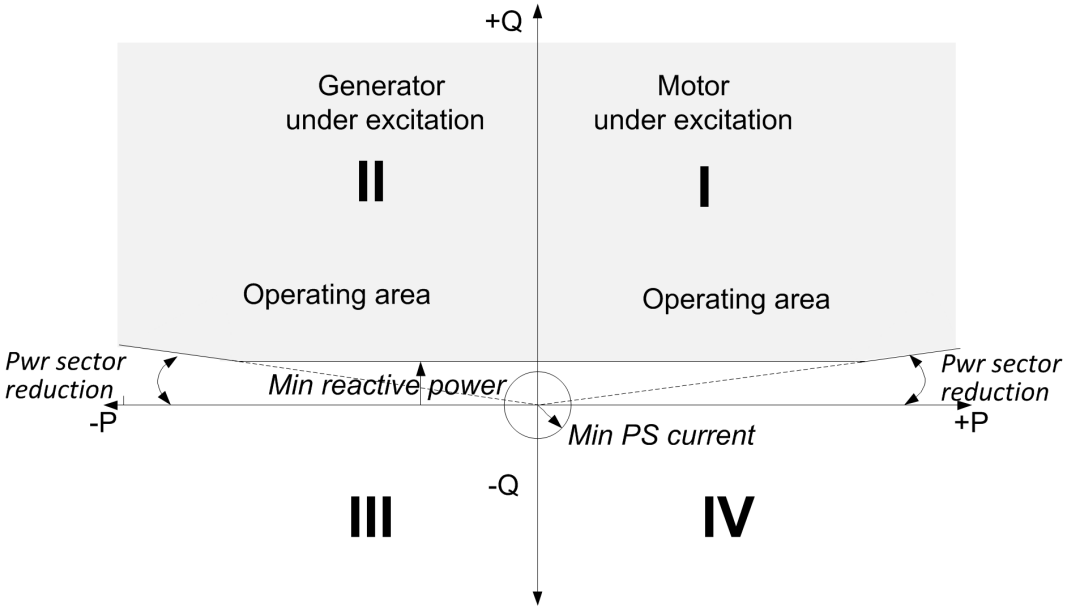

Figure 600: Operating area of DQPTUV function

Quadrant II	Generator produces active power, but draws reactive power (under-excited)
Quadrant III	Generator produces both active and reactive power

The power direction can be reversed by setting *Pol reversal* to “True”.

Timer

Once activated by both Under voltage detection and Reactive power monitoring module, the Timer activates the `START` output. The Timer characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the `OPERATE` output is activated. If the fault disappears before the module operates, the Timer is reset instantaneously.

The Timer calculates the start duration value "START_DUR" which indicates the percentage ratio of the start situation and the set operating time. The value is available through the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the `BLOCK` input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The `BLOCK` input can be controlled

by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode setting* has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.8.3.6 Application

Use of distributed power generating units (PGU) is rapidly increasing due to liberalized markets (deregulation) and the global trend to use more renewable sources of energy. As the capacity of these generating units increase, they are connected directly to medium voltage networks. Until recent years it had been a practice by grid operators to disconnect the distributed power generator from the network in case of fault in the network.

If there is a considerable loss in the power generation, it may affect the system’s ability to recover. To ensure power system stability, various grid codes have revised their requirements and therefore require that the distributed PGUs have to make a contribution to network support. In case of network faults, the distributed power generator should not be immediately disconnected from the network. Instead, as a matter of principle, generating plants connected to the medium-voltage network must be capable of participating in steady-state voltage control and dynamic network support. However, if the generators stay connected, it must be ensured that they do not take reactive power from the network because this may lead to collapse of the grid. DQPTUV is used for detecting such situations, that is, simultaneous undervoltage and reactive power (under excited generators) and trip the generators.

The protection function DQPTUV is developed considering various grid codes. For example, in the BDEW Technical Guideline “Generating Plants Connected to the Medium-Voltage Network” (June 2008 issue, Germany), it is stated that if all three phase-to-phase voltages at the grid connection point decrease and remain at and below a value of 85% of the rated and if reactive power is simultaneously consumed at the grid connection point (under-excited operation), the generating facility must be disconnected from the network with a time delay of 0.5 s.

4.8.4 Underpower factor protection MPUPF (ANSI 55U)

4.8.4.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Underpower factor protection	MPUPF	PF<	55U

[1] *Start value* = 0.05 × S_n, reactive power before fault = 0.8 × *Start value*, reactive power overshoot 2 times, results based on statistical distribution of 1000 measurements

[2] Includes the delay of the signal output contact

4.8.4.2 Function block

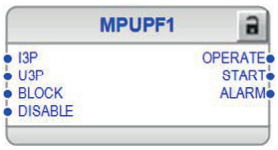

Figure 602: Function block

4.8.4.3 Functionality

The under power factor function MPUPF is used to provide out-of-step and loss of, or under excitation protection for small synchronous motors and generators. The function calculates the power factor and uses a threshold of under power factor as an indication of an out-of-step and/or loss of excitation condition.

In addition, the function can be applied as a power factor controller.

The function contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.8.4.4 Analog channel configuration

MPUPF has two analog group inputs which must be properly configured.

Table 1018: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1019: Special conditions

Condition	Description
U3P connected to real measurements	The function requires that any two voltage channels are connected.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.8.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of MPUPF can be described using a module diagram. All the modules in the diagram are explained in the next sections.

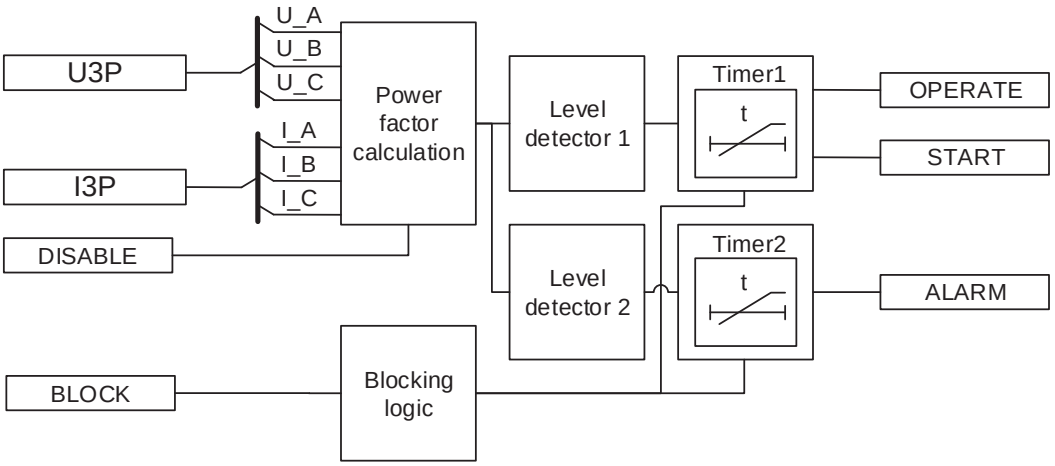

Figure 603: Functional module diagram

Power factor calculation

This module calculates three phase power factor using phase currents and voltages.

The three-phase power is calculated from the fundamental frequency components (DFT) of the phase-to-earth voltages and phase-to-earth currents.

$$\overline{S} = \overline{U}_A \cdot \overline{I}_A^* + \overline{U}_B \cdot \overline{I}_B^* + \overline{U}_C \cdot \overline{I}_C^*$$

Figure 604: Equation

$$P = \mathrm{Re}(\overline{S})$$

Figure 605: Equation

$$PF = \frac{P}{|\overline{S}|}$$

Figure 606: Equation

Figure 607 shows the resulting sign of the power factor. This should be consistent with the settings in the power and energy metering function of the relay.

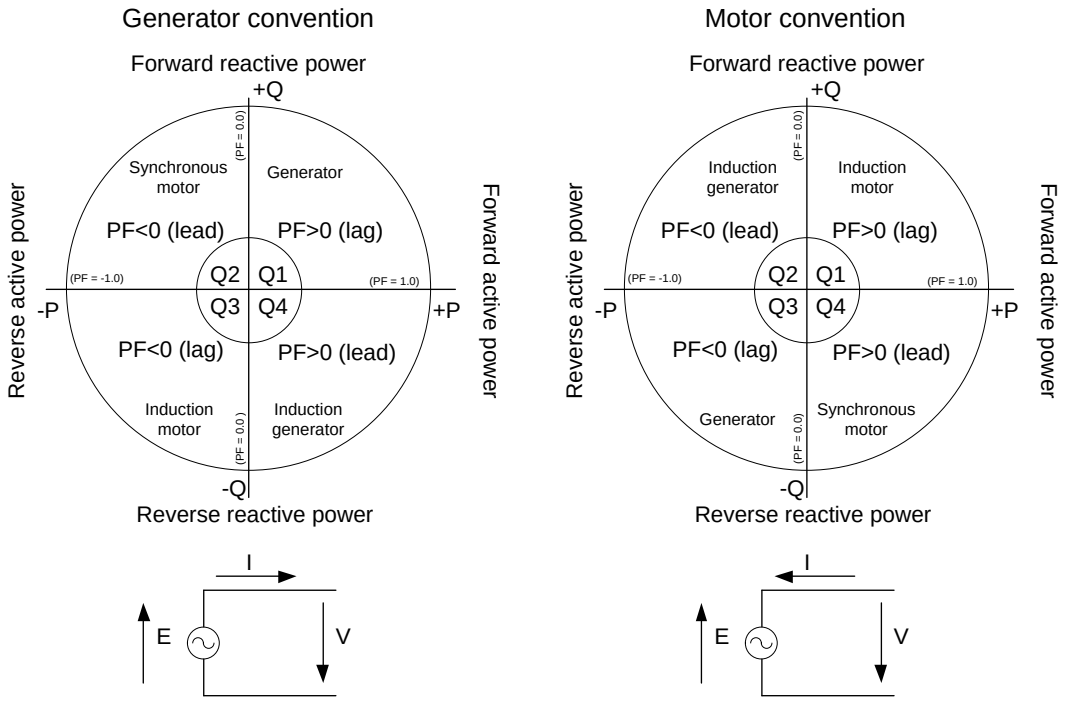

Figure 607: Power factor quadrant

If the polarity of the voltage signal is opposite to the normal polarity, the correction can be done by setting *Voltage reversal* to “Yes”, which rotates the power factor vector by 180 degrees.

If the magnitude of all three phase currents or voltages are respectively less than *Current block value* and *Voltage block value* settings, the power factor is set as unity that is 1.00 and the function is disabled internally.

The DISABLE input can be used to coordinate the correct operation during the startup situation. By activating the DISABLE signal, the power factor calculation is blocked. Once the DISABLE signal is deactivated, the function remains blocked for additional time duration as set through the setting *Disable time*.

Level detector 1

The Level detector 1 compares the calculated power factor to the set *Start value*. If the power factor value goes below the set *Start value* in the direction as defined by *Dir start value*, the Level detector sends an enabling signal to the Timer 1 module.

Level detector 2

The Level detector 2 compares the calculated power factor to the set *Alarm value*. If the power factor value goes below the set *Alarm value* in the direction as defined by *Dir alarm value*, the Level detector sends an enabling signal to the Timer 2 module.

Timer 1

Once activated, the Timer 1 activates the START output. The timer characteristic is according to DT. When the operate timer has reached the value set by *Start delay time* in the DT mode, the OPERATE output is activated. If a drop-off situation occurs, that is, a power factor improves and exceeds the *Start reset value* in the direction as defined by *Dir start reset value* before the operate delay is exceeded or either

magnitude of all three phase current or voltages goes below *Current block value* and *Voltage block value* respectively, the timer reset state is activated. The reset timer depends on the *Reset delay time* setting.

The Timer 1 calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operating time. The value is available in the Monitored data view.

Timer 2

Once activated, the Timer 2 activates the alarm timer. The timer characteristic is according to DT. When the alarm timer has reached the value set by *Alarm delay time* in the DT mode, the ALARM output is activated. If a drop-off situation occurs, that is, a power factor improves and exceeds the *Alarm reset value* in the direction as defined by *Dir alarm reset value* before the alarm delay is exceeded or either magnitude of all three phase current or voltages goes below *Current block value* and *Voltage block value* respectively, the timer reset state is activated. The reset timer depends on the *Reset delay time* setting.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.8.4.6 Application

The MPUPF function can be used to detect loss of excitation or for power factor correction. Synchronous motors are mostly operated at leading power factor and its operation as lagging power for extended period can be used an indication of an out-of-step condition possibly caused by under or loss of excitation. To detect such a situation, the relay is typically set to operate when the current into a motor lags more than 30 degrees, that is, a power factor goes below +0.87 lagging.

The function provides alarm facility which can be used as an early indication that the power factor is moving outside the allowable range; therefore the *Alarm value* setting should be set higher than the *Start value*. The delay time for alarm should also be set as low as possible, only long enough to prevent spurious activation of the output.

In a power factor correction application, the ALARM and START outputs can be used as controls to switch in capacitive loads when the *Alarm value* and *Start value* settings, respectively, are exceeded. The ALARM output is set for a higher value to add the first corrective load and the START output set for a second stage of corrective load, if needed. The *Start reset value* and *Alarm reset value* settings allow their respective outputs to remain activated to maintain the correction after power factor rises as a result, but to drop out after it reaches a level where corrective capacitive loading is no longer needed.

There are two general applications which can best utilize under power factor protection; power-factor control and loss of excitation.

When applying the function for power-factor control, both the start value and the start reset value should be the same sign (positive/negative) as well as the same direction (leading/lagging). Additionally, the absolute value of the start reset value should be greater than or equal to the absolute value of the start value. This allows the function to properly control any power factor controls within the system.

When applying the function for loss of excitation, both the start value and the start reset value should be the same sign (positive/negative), but the directions should be different (leading/lagging). This application is well-suited to protect against back-spinning. In this case the start reset value will only come into play once the system provides power in the opposite quadrant of the start value, for example, lagging PF turns to leading PF.

4.8.4.7 Signals

MPUPF Input signals

Table 1020: MPUPF Input signals

Name	Type	Default	Description

4.9 Arc protection ARCSARC (ANSI AFD)

4.9.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Arc protection	ARCSARC	ARC	AFD

4.9.2 Function block

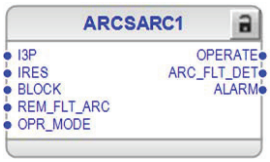

Figure 608: Function block

4.9.3 Functionality

The arc protection function ARCSARC detects arc situations in air-insulated metal-clad switchgears caused by, for example, human errors during maintenance or insulation breakdown during operation.

The function detects light from an arc either locally or via a remote light signal. The function also monitors phase and residual currents to be able to make accurate decisions on ongoing arcing situations.

The function contains a blocking functionality. Blocking deactivates all outputs and resets timers.

4.9.4 Analog channel configuration

ARCSARC has two analog group inputs which must be properly configured.

Table 1027: Analog inputs

Input	Description
I3P [1]	Three-phase currents, necessary when the operation mode "Light +current" is used
IRES [1]	Residual current (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.9.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of ARCSARC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

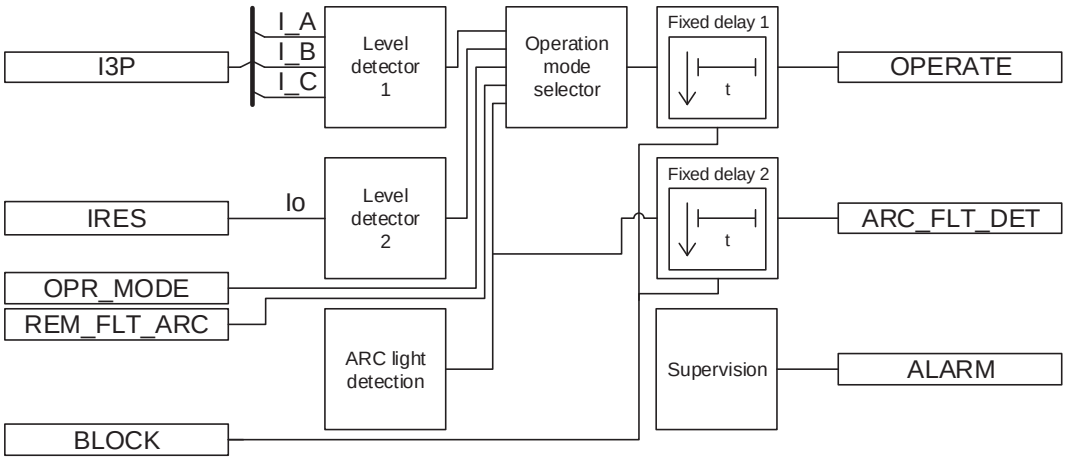

Figure 609: Functional module diagram

Level detector 1

The measured phase currents are compared phasewise to the set *Phase start value*. If the measured value exceeds the set *Phase start value*, the level detector reports the exceeding of the value to the operation mode selector.

[1] Can be connected to GRPOFF if "Light only" or "BI controlled" operation modes are used

Level detector 2

The measured residual currents are compared to the set *Ground start value*. If the measured value exceeds the set *Ground start value*, the level detector reports the exceeding of the value to the Operation mode selector.

ARC light detection

ARC detection information is received directly from the relay hardware input. The detected ARC fault is directly signalled to the Operation mode selector and Fixed delay 2 modules. There are four ARC detection inputs in the protection relay. Each input is connected to a dedicated ARCSARC function.

Table 1028: ARC detection inputs connected to ARCSARC

ARC input	ARC protection function
X11/ARC	ARCSARC1
X12/ARC	ARCSARC2
X13/ARC	ARCSARC3
X14/ARC	ARCSARC4

Operation mode selector

Depending on the *Operation mode* setting, Operation mode selector makes sure that all required criteria are fulfilled for a reliable decision of an arc fault situation. The operation is based on both current and light information in “Light+current” mode, on light information only in “Light only” mode or on remotely controlled information in “BI controlled” mode. When the "BI controlled" mode is in use and the OPR_MODE input is activated, the operation of the function is based on light information only. When the OPR_MODE input is deactivated, the operation of the function is based on both light and current information. When the required criteria are met, Fixed delay 1 timer is activated.

Fixed delay 1

Once this timer is activated, the OPERATE signal output is activated immediately. The output is kept active for minimum 25 ms or as long as the input is activated. The BLOCK signal can be used to block the OPERATE signal.

Fixed delay 2

Once this timer is activated, the ARC_FLT_DET output is activated immediately. The output is kept active for minimum 25 ms or as long as the input is activated. The BLOCK signal can be used to block the ARC light signal output ARC_FLT_DET.

Supervision

If a faulty arc sensor is internally detected or if the connection to the arc sensor is lost, ALARM output is activated if *Sensor supervision* is set to "on".

When *Sensor supervision* is set to "off", ALARM output stays false even though the arc sensor is faulty or unconnected.

4.9.6 Application

The arc protection can be realized as a stand-alone function in a single relay or as a station-wide arc protection, including several protection relays. If realized as a station-wide arc protection, different tripping schemes can be selected for the operation of the circuit breakers of the incoming and outgoing feeders. Consequently, the relays in the station can, for example, be set to trip the circuit breaker of either the incoming or the outgoing feeder, depending on the fault location in the switchgear. For maximum safety, the relays can be set to always trip both the circuit breaker of the incoming feeder and that of the outgoing feeder.

The arc protection consists of:

- Optional arc light detection hardware with automatic backlight compensation for lens type sensors
- Light signal output `ARC_FLT_DET` for routing indication of locally detected light signal to another relay
- Protection stage with phase- and earth-fault current measurement.

The function detects light from an arc either locally or via a remote light signal. Locally, the light is captured either by lens type point sensors or transparent fiber loop sensors connected to the light sensor input of the relay. This captured light is guided via optical fiber to the sensor input of the relay, where it is converted to electrical signal by means of a photo diode. The optical light sensors can be placed in the various compartments of the switchgear, for example, in the busbar compartment, the circuit breaker compartments, the bus riser and the outgoing feeder cable end compartments.

The light detected by the lens sensor inputs is compared to an automatically adjusted reference level. Each light sensor input has its own reference level. When the light exceeds the reference level of one of the inputs, the light is detected locally. When the light has been detected locally or remotely and, depending on the operation mode, if one or several phase currents exceed the set *Phase start value* limit, or the earth-fault current the set *Ground start value* limit, the arc protection stage generates an operation signal. The stage is reset in 30 ms, after all three-phase currents and the earth-fault current have fallen below the set current limits.

The light signal output from an arc protection stage `ARC_FLT_DET` is activated immediately in the detection of light in all situations. A station-wide arc protection is realized by routing the light signal output to an output contact connected to a binary input of another relay, or by routing the light signal output through the communication to an input of another relay.

It is possible to block the tripping and the light signal output of the arc protection stage with a binary input or a signal from another function block.

Arc protection with one protection relay

In installations, with limited possibilities to realize signaling between protection relays protecting incoming and outgoing feeders, or if only the protection relay for the incoming feeder is to be exchanged, an arc protection with a less selective level can be achieved with one protection relay. In arc detection, the arc protection stage trips the circuit breaker of the incoming feeder. The maximum recommended installation distance between the two lens sensors in the busbar area is six meters and the maximum distance from a lens sensor to the end of the busbar is three meters.

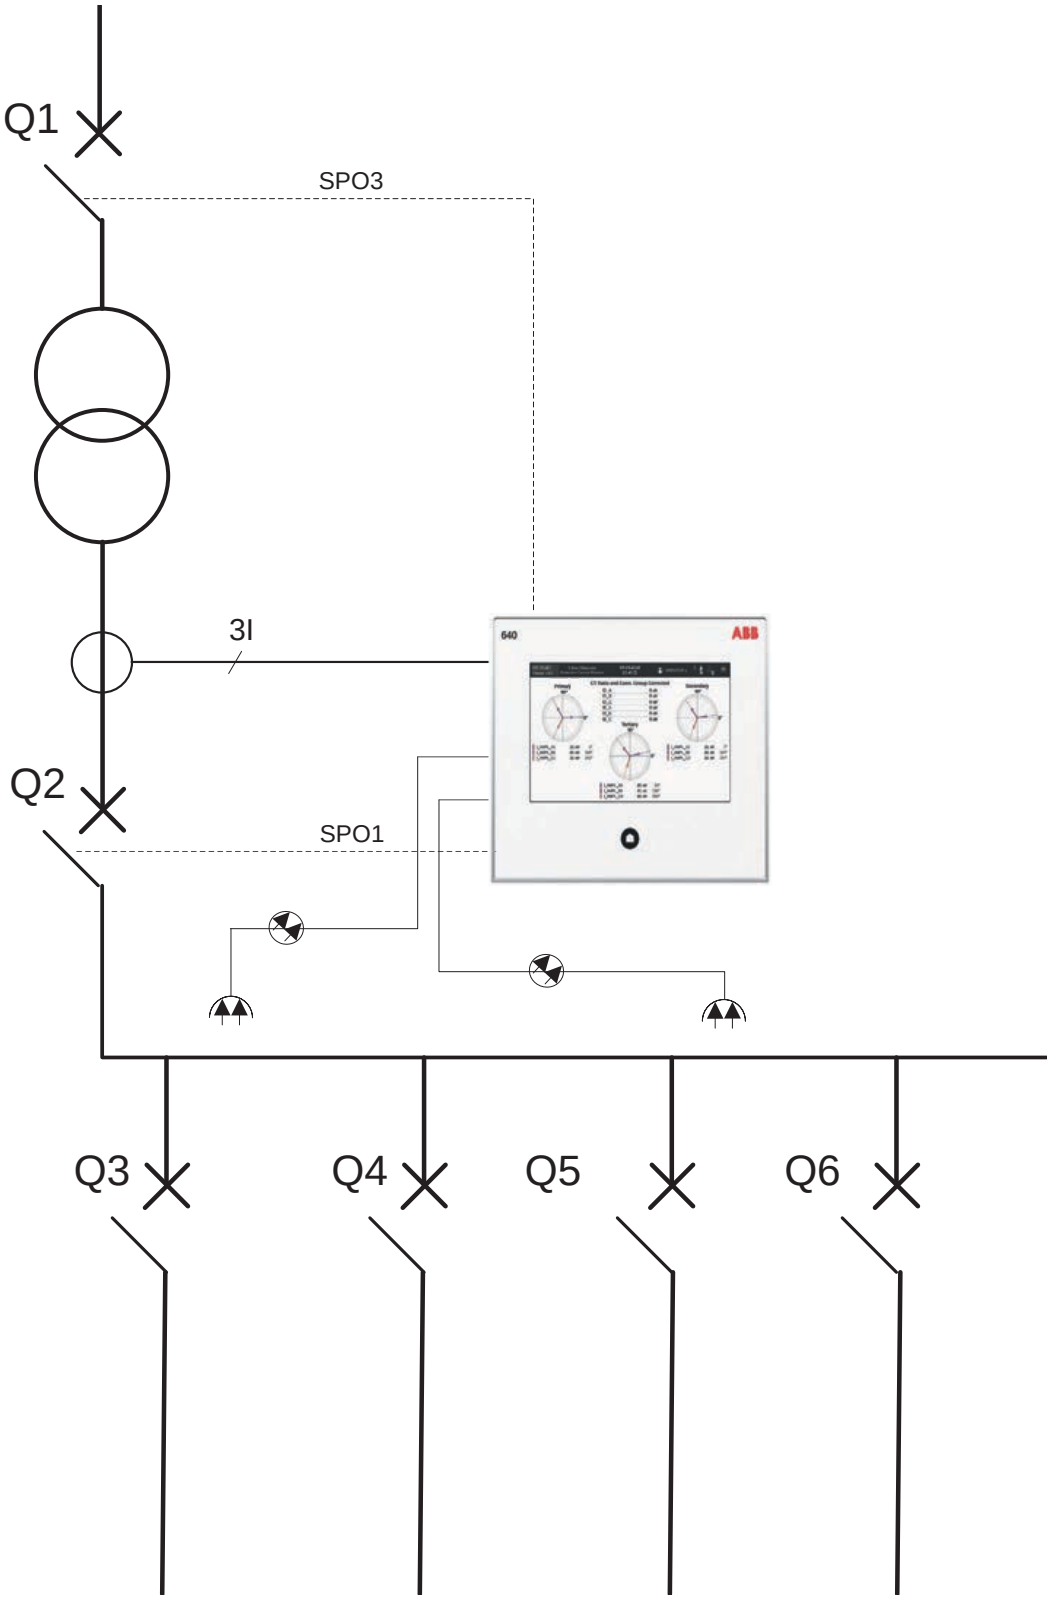

Figure 610: Arc protection with one protection relay

Arc protection with several protection relays

When using several protection relays, the protection relay protecting the outgoing feeder trips the circuit breaker of the outgoing feeder when detecting an arc at the cable terminations. If the protection relay protecting the outgoing feeder detects an arc on the busbar or in the breaker compartment via one of the other lens sensors, it generates a signal to the protection relay protecting the incoming feeder. When detecting the signal, the protection relay protecting the incoming feeder trips the circuit breaker of the incoming feeder and generates an external trip signal to all protection relays protecting the outgoing feeders, which in turn results in tripping of all circuit breakers of the outgoing feeders. For maximum safety, the protection relays can be configured to trip all the circuit breakers regardless of where the arc is detected.

[2] Includes the delay of the power output (PO) contact
[3] Measured with static power output (SPO)

4.10.2 Function block

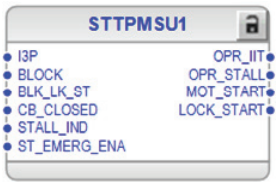

Figure 613: Function block

4.10.3 Functionality

The motor start-up supervision function STTPMSU is designed for protection against excessive starting time and locked rotor conditions of the motor during starting. For a good and reliable operation of the motor, the thermal stress during the motor starting is maintained within the allowed limits.

The starting of the motor is supervised by monitoring the TRMS magnitude of all the phase currents or by monitoring the status of the circuit breaker connected to the motor.

During the start-up period of the motor, STTPMSU calculates the integral of the I^2t value. If the calculated value exceeds the set value, the operate signal is activated.

STTPMSU has the provision to check the locked rotor condition of the motor using the speed switch, which means checking if the rotor is able to rotate or not. This feature operates after a predefined operating time.

STTPMSU also protects the motor from an excessive number of start-ups. Upon exceeding the specified number of start-ups within certain duration, STTPMSU blocks further starts. The restart of the motor is also inhibited after each start and continues to be inhibited for a set duration. When the lock of start of motor is enabled, STTPMSU gives the time remaining until the restart of the motor.

STTPMSU contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

4.10.4 Analog input configuration

STTPMSU has one analog group input which must be properly configured.

Table 1035: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing

blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.10.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of STTPMSU can be described with a module diagram. All the modules in the diagram are explained in the next sections.

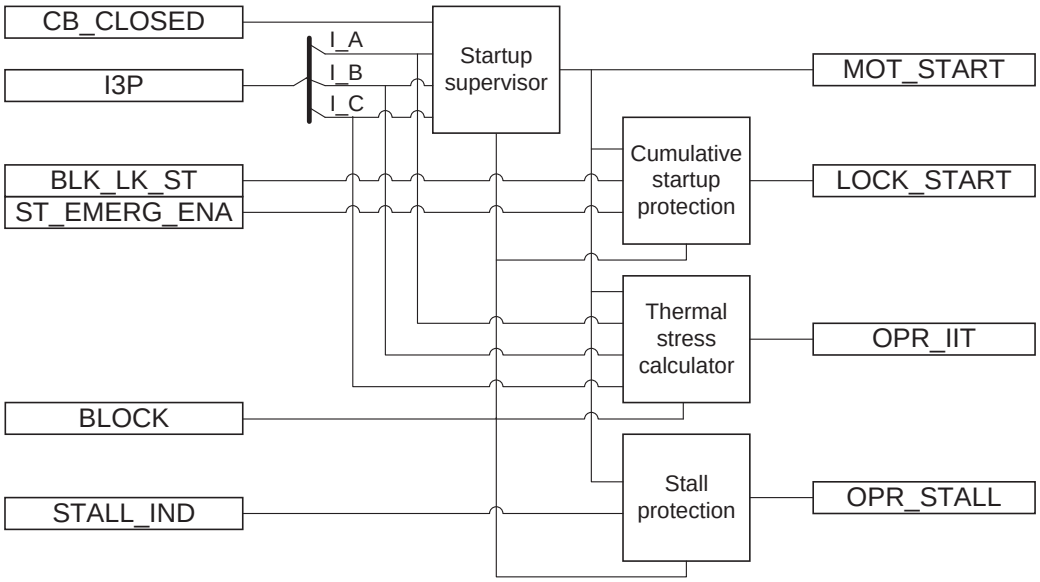

Figure 614: Functional module diagram

Startup supervisor

This module detects the starting of the motor. The starting and stalling motor conditions are detected in four different modes of operation. This is done through the *Operation mode* setting.

When the *Operation mode* setting is operated in the "IIt" mode, the function calculates the value of the thermal stress of the motor during the start-up condition. In this mode, the start-up condition is detected by monitoring the TRMS currents.

The *Operation mode* setting in the "IIt, CB" mode enables the function to calculate the value of the thermal stress when a start-up is monitored in addition to the `CB_CLOSED` input.

In the "IIt & stall" mode, the function calculates the thermal stress of the motor during the start-up condition. The start-up condition is detected by monitoring the TRMS currents.

In the "IIt & stall, CB" mode, the function calculates the thermal stress of the motor during the start-up condition but the start-up condition is detected by monitoring the TRMS current as well as the circuit breaker status.

In both the "IIt & stall" and "IIt & stall, CB" mode, the function also checks for motor stalling by monitoring the speed switch.

When the measured current value is used for start-up supervision in the "IIt" and "IIt & stall" modes, the module initially recognizes the de-energized condition of the motor when the values of all three phase currents are less than *Motor standstill A* for longer than 100 milliseconds. If any of the phase currents of the de-energized condition rises to a value equal to or greater than *Start detection A*, the MOT_START output signal is activated indicating that the motor start-up is in progress. The MOT_START output remains active until the values of all three phase currents drop below 90 percent of the set value of *Start detection A* and remain below that level for a time of *Str over delay time*, that is, until the start-up situation is over.

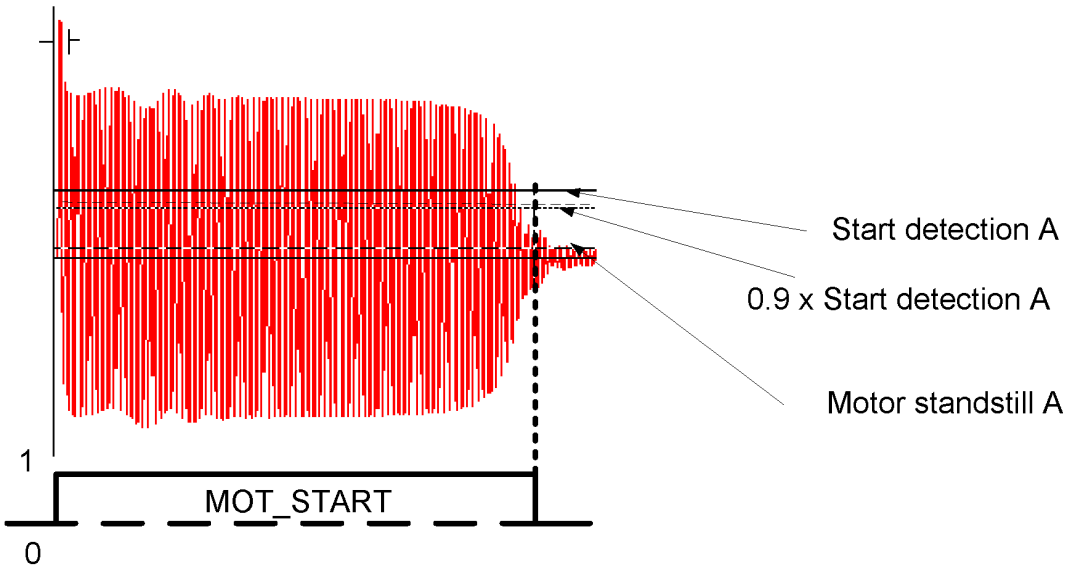

Figure 615: Functionality of start-up supervision in the "IIt and IIt&stall" mode

In case of the "IIt, CB" or "IIt & stall, CB" modes, the function initially recognizes the de-energized condition of the motor when the value of all three phase currents is below the value of the *Motor standstill A* setting for 100 milliseconds. The beginning of the motor start-up is recognized when CB is closed, that is, when the CB_CLOSED input is activated and at least one phase current value exceeds the *Motor standstill A* setting.

These two events do not take place at the same instant, that is, the CB main contact is closed first, in which case the phase current value rises above 0.1 pu and after some delay the CB auxiliary contact gives the information of the CB_CLOSED input. In some cases, the CB_CLOSED input can be active but the value of current may not be greater than the value of the *Motor standstill A* setting. To allow both possibilities, a time slot of 200 milliseconds is provided for current and the CB_CLOSED input. If both events occur during this time, the motor start-up is recognized.

The motor start-up ends either within the value of the *Str over delay time* setting from the beginning of the start-up or the opening of CB or when the CB_CLOSED input is deactivated. The operation of the MOT_START output signal in this operation mode is as illustrated in *Figure 616*.

This CB mode can be used in soft-started or slip ring motors for protection against a high starting current, that is, a problem in starting and so on.

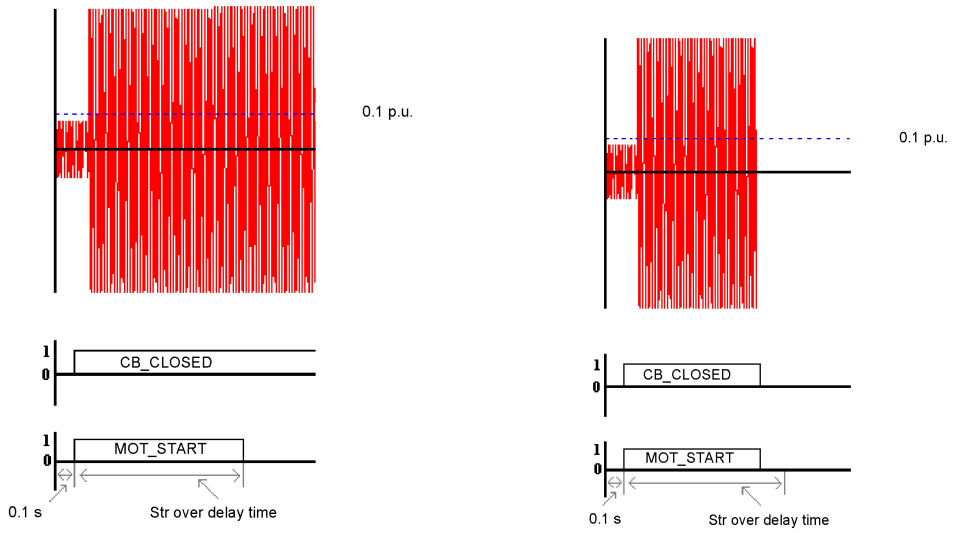

Figure 616: Functionality of start-up supervision in the "IIt, CB" mode and the "IIt and stall, CB" mode

The *Str over delay time* setting has different purposes in different modes of operation.

- In the “IIt” or “IIt & stall” modes, the aim of this setting is to check for the completion of the motor start-up period. The purpose of this time delay setting is to allow for short interruptions in the current without changing the state of the MOT_START output. In this mode of operation, the value of the setting is in the range of around 100 milliseconds.
- In the “IIt, CB” or “IIt & stall, CB” modes, the purpose of this setting is to check for the life of the protection scheme after the CB_CLOSED input has been activated. Based on the values of the phase currents, the completion of the start-up period cannot be judged. So in this mode of operation, the value of the time delay setting can even be as high as within the range of seconds, for example around 30 seconds.

The activation of the BLOCK input signal deactivates the MOT_START output.

Thermal stress calculator

Because of the high current surges during the start-up period, a thermal stress is imposed on the rotor. With less air circulation in the ventilation of the rotor before it reaches its full speed, the situation becomes even worse. Consequently, a long start-up causes a rapid heating of the rotor.

This module calculates the thermal stress developed in the motor during start-up. The heat developed during the starting can be calculated with the equation.

$$W = R_s \int_0^t i_s^2(t)\,dt$$

(Equation 282)

R_s	combined rotor and stator resistance
i_s	starting current of the motor
t	starting time of the motor

This equation is normally represented as the integral of I^2t. It is a commonly used method in protective protection relays to protect the motor from thermal stress during starting. The advantage of this method over the traditional definite time overcurrent protection is that when the motor is started with a reduced voltage as in the star-delta starting method, the starting current is lower. This allows more starting time for the motor since the module is monitoring the integral of I^2t.

The module calculates the accumulated heat continuously and compares it to the limiting value obtained from the product of the square of the values of the *Motor start-up A* and *Motor start-up time* settings. When the calculated value of the thermal stress exceeds this limit, the OPR_IIT output is activated.

The module also measures the time START_TIME required by the motor to attain the rated speed and the relative thermal stress IIT_RL. The values are available in the Monitored data view.

The activation of the BLOCK input signal resets the thermal stress calculator and deactivates the OPR_IIT output.

Stall protection

This module is activated only when the selected *Operation mode* setting value is "IIt & stall" or "IIt & stall, CB".

The start-up current is specific to each motor and depends on the start-up method used, such as direct online, autotransformer and rotor resistance insertion. The start-up time is dependent on the load connected to the motor.

Based on the motor characteristics supplied by the manufacturer, this module is required if the stalling time is shorter than or too close to the starting time. In such cases, a speed switch must be used to indicate whether a motor is accelerating during start-up or not.

At motor standstill, the STALL_IND input is active. It indicates that the rotor is not rotating. When the motor is started, at certain revolution the deactivation of the STALL_IND by the speed switch indicates that the rotor is rotating. If the input is not deactivated within *Lock rotor time*, the OPR_STALL output is activated.

The module calculates the duration of the motor in stalling condition, the STALL_RL output indicating the percent ratio of the start situation and the set value of *Lock rotor time*. The value is available in the Monitored data view.

The activation of the BLOCK input signal resets the operation time and deactivates the OPR_STALL output.

Cumulative start-up protection

This module protects the motor from an excessive number of start-ups.

Whenever the motor is started, the latest value of START_TIME is added to the existing value of T_ST_CNT and the updated cumulative start-up time is available at T_ST_CNT. If the value of T_ST_CNT is greater than the value of *Cumulative time Lim*, the LOCK_START output is activated and lockout condition for the restart of motor is enabled during the time the output is active. The LOCK_START output remains high until the T_ST_CNT value reduces to a value less than the value of

Cumulative time Lim. The start time counter reduces at the rate of the value of *Counter Red rate*.

The LOCK_START output becomes activated at the start of MOT_START. The output remains active for a period of *Restart inhibit time*.

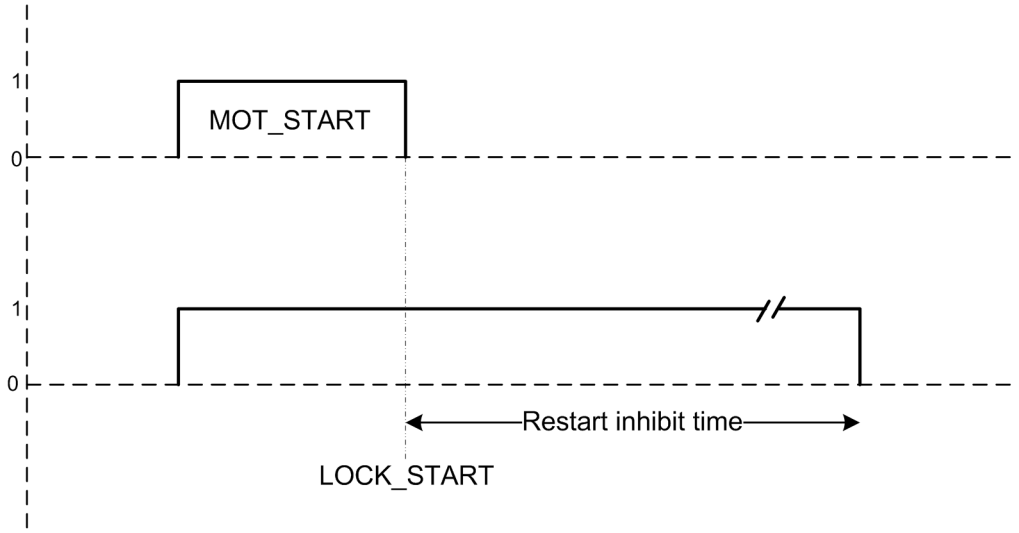

Figure 617: Time delay for cumulative start

This module also protects the motor from consecutive start-ups. When the LOCK_START output is active, T_RST_ENA shows the possible time for next restart. The value of T_RST_ENA is calculated by the difference of *Restart inhibit time* and the elapsed time from the instant LOCK_START is enabled.

When the ST_EMERG_ENA emergency start is set high, the value of the cumulative start-up time counter is set to *Cumulative time Lim* - 60s · *Emg start Red rate*. This disables LOCK_START and in turn makes the restart of the motor possible.

This module also calculates the total number of start-ups occurred, START_CNT. The value can be reset from the Clear menu.

The old *Number of motor start-ups occurred* counter value (START_CNT) can be taken into use by writing the value to the *Ini start up counter* parameter and resetting the value via the Clear menu from WHMI or LHMI.

The calculated values of T_RST_ENA, T_ST_CNT and START_CNT are available in the Monitored data view.

The activation of the BLK_LK_ST input signal deactivates the LOCK_START output. The activation of the BLOCK input signal resets the cumulative start-up counter module.

4.10.6 Application

When a motor is started, it draws a current well in excess of the motor's full-load rating throughout the period it takes for the motor to run up to the rated speed. The motor starting current decreases as the motor speed increases and the value of current remains close to the rotor-locked value for most of the acceleration period.

The full-voltage starting or the direct-on-line starting method is used out of the many methods used for starting the induction motor. If there is either an electrical

or mechanical constraint, this starting method is not suitable. The full-voltage starting produces the highest starting torque. A high starting torque is generally required to start a high-inertia load to limit the acceleration time. In this method, full voltage is applied to the motor when the switch is in the "On" position. This method of starting results in a great initial current surge, which is typically four to eight times that of the full-load current drawn by the motor. If a star-delta starter is used, the value of the line current will only be about one-third of the direct-on-line starting current.

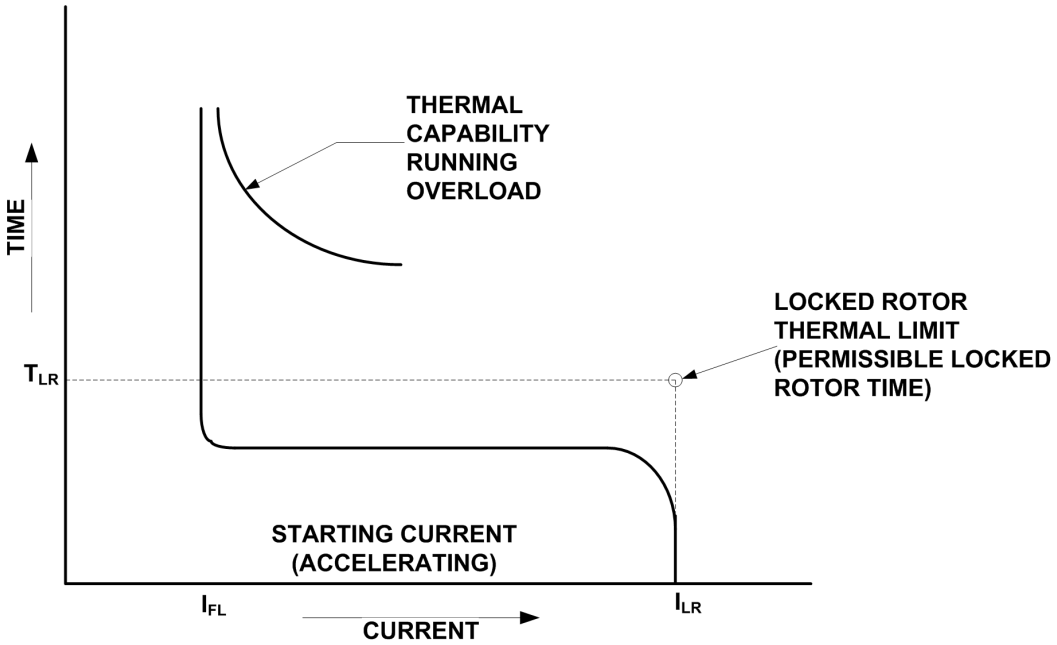

Figure 618: Typical motor starting and capability curves

The start-up supervision of a motor is an important function because of the higher thermal stress developed during starting. During the start-up, the current surge imposes a thermal strain on the rotor. This is exaggerated as the air flow for cooling is less because the fans do not rotate in their full speed. Moreover, the difference of speed between the rotating magnetic field and the rotor during the start-up time induces a high magnitude of slip current in the rotor at frequencies higher than when the motor is at full speed. The skin effect is stronger at higher frequencies and all these factors increase the losses and the generated heat. This is worse when the rotor is locked.

The starting current for slip-ring motors is less than the full load current and therefore it is advisable to use the circuit breaker in the closed position to indicate the starting for such type of motors.

The starting times vary depending on motor design and load torque characteristics. The time taken may vary from less than two seconds to more than 60 seconds. The starting time is determined for each application.

When the permissible stall time is less than the starting time of the motor, the stalling protection is used and the value of the time delay setting should be set slightly less than the permissible stall time. The speed switch on the motor shaft must be used for detecting whether the motor begins to accelerate or not. However, if the safe stall time is longer than the start-up time of the motor, the speed switch is not required.

The failure of a motor to accelerate or to reach its full nominal speed in an acceptable time when the stator is energized is caused by several types of abnormal conditions, including a mechanical failure of the motor or load bearings, low supply voltage, open circuit in one phase of a three-phase voltage supply or too high starting voltage. All these abnormal conditions result in overheating.

Repeated starts increase the temperature to a high value in the stator or rotor windings, or both, unless enough time is allowed for the heat to dissipate. To ensure a safe operation it is necessary to provide a fixed-time interval between starts or limit the number of starts within a period of time. This is why the motor manufacturers have restrictions on how many starts are allowed in a defined time interval. This function does not allow starting of the motor if the number of starts exceeds the set level in the register that calculates them. This insures that the thermal effects on the motor for consecutive starts stay within permissible levels.

For example, the motor manufacturer may state that three starts at the maximum are allowed within 4 hours and the start-up situation time is 60 seconds. By initiating three successive starts we reach the situation as illustrated. As a result, the value of the register adds up to a total of 180 seconds. Right after the third start has been initiated, the output lock of start of motor is activated and the fourth start will not be allowed, provided the time limit has been set to 121 seconds.

Furthermore, a maximum of three starts in 4 hours means that the value of the register should reach the set start time counter limit within 4 hours to allow a new start. Accordingly, the start time counter reduction should be 60 seconds in 4 hours and should thus be set to 60 s / 4 h = 15 s / h.

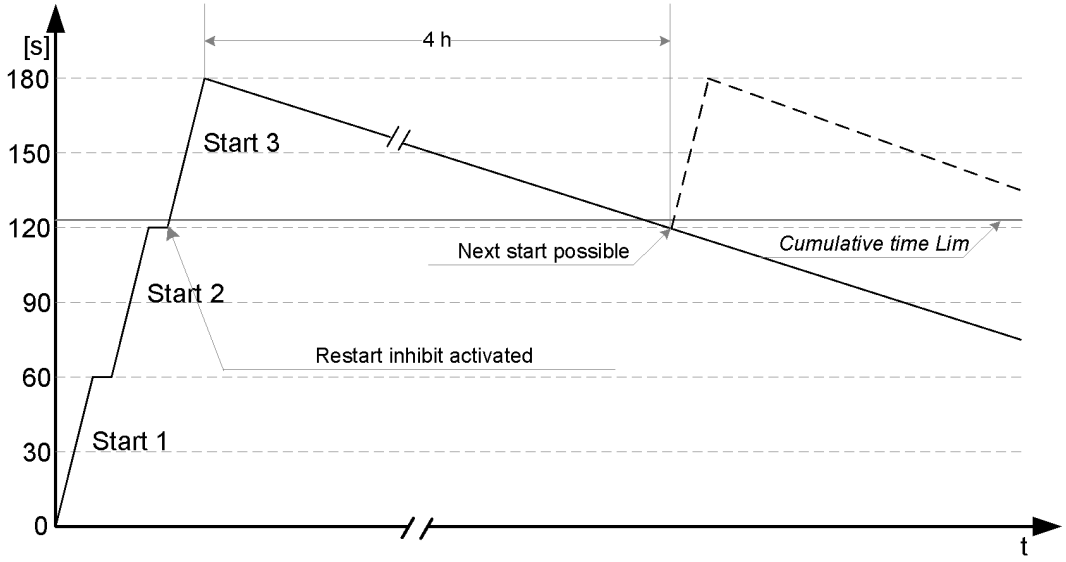

Figure 619: Typical motor-starting and capability curves

Setting of *Cumulative time Lim*

Cumulative time Lim is calculated by

$$\sum t_{si} = (n-1) \times t + margin$$

(Equation 283)

n	specified maximum allowed number of motor start-ups
t	start-up time of the motor (in seconds)
margin	safety margin (~10...20 percent)

Setting of *Counter Red rate*

Counter Red rate is calculated by

$$\Delta\sum t_s = \frac{t}{t_{reset}}$$

(Equation 284)

t	specified start time of the motor in seconds
t_{reset}	duration during which the maximum number of motor start-ups stated by the manufacturer can be made; time in hours

4.11.2 Function block

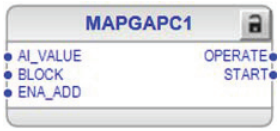

Figure 620: Function block

4.11.3 Functionality

The multipurpose protection function MAPGAPC is used as a general protection with many possible application areas as it has flexible measuring and setting facilities. The function can be used as an under- or overprotection with a settable absolute hysteresis limit. The function operates with the definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.11.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of MAPGAPC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

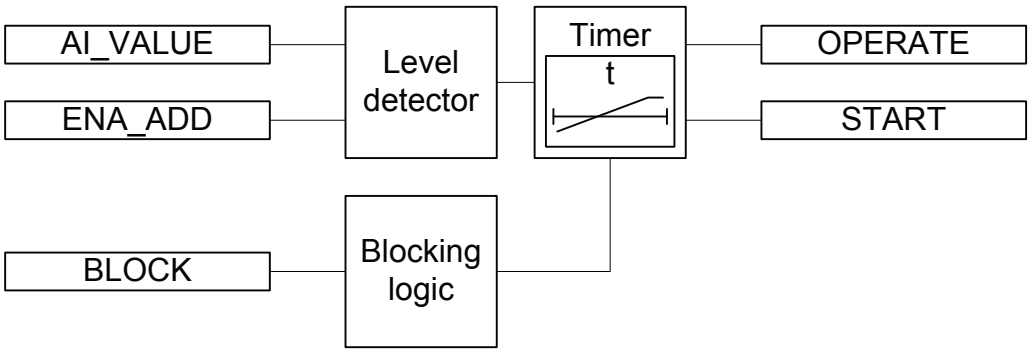

Figure 621: Functional module diagram

Level detector

The level detector compares `AI_VALUE` to the *Start value* setting. The *Operation mode* setting defines the direction of the level detector.

Table 1045: *Operation mode* types

Operation Mode	Description
"Under"	If the input signal AI_VALUE is lower than the set value of the "Start value" setting, the level detector enables the timer module.
"Over"	If the input signal AI_VALUE exceeds the set value of the *Start value* setting, the level detector enables the timer module.

The *Absolute hysteresis* setting can be used for preventing unnecessary oscillations if the input signal is slightly above or below the *Start value* setting. After leaving the hysteresis area, the start condition has to be fulfilled again and it is not sufficient for the signal to only return to the hysteresis area. If the ENA_ADD input is activated, the threshold value of the internal comparator is the sum of the *Start value Add* and *Start value* settings. The resulting threshold value for the comparator can be increased or decreased depending on the sign and value of the *Start value Add* setting.

Timer

Once activated, the timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated. If the starting condition disappears before the module operates, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

The timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, the function operates normally but the OPERATE output is not activated.

4.11.5 Application

The function block can be used for any general analog signal protection, either underprotection or overprotection. The setting range is wide, allowing various protection schemes for the function. Thus, the absolute hysteresis can be set to a value that suits the application.

The temperature protection using the RTD sensors can be done using the function block. The measured temperature can be fed from the RTD sensor to the function input that detects too high temperatures in the motor bearings or windings, for example. When the ENA_ADD input is enabled, the threshold value of the internal comparator is the sum of the *Start value Add* and *Start value* settings. This allows a temporal increase or decrease of the level detector depending on the sign and value of the *Start value Add* setting, for example, when the emergency start is activated. If, for example, *Start value* is 100, *Start value Add* is 20 and the ENA_ADD input is active, the input signal needs to rise above 120 before MAPGAPC operates.

4.11.6 Signals

4.12 Capacitor bank protection

4.12.1 Three-phase overload protection for shunt capacitor banks COLPTOC (ANSI 51,37,86C)

4.12.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase overload protection for shunt capacitor banks	COLPTOC	3I> 3I<	51,37,86C

4.12.1.2 Function block

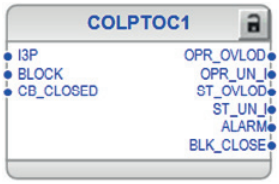

Figure 622: Function block symbol

4.12.1.3 Functionality

The three-phase overload protection for shunt capacitor banks function COLPTOC provides single-phase, two-phase and three-phase protection against overloads caused by harmonic currents and overvoltages in shunt capacitor banks. The operation of overload and alarm is based on the peak value of the integrated current which is proportional to the voltage across the capacitor.

The overload function operates with IDMT characteristic and an alarm function operates with DT characteristic.

COLPTOC provides undercurrent protection to detect disconnection of the capacitor. COLPTOC has breaker reclosing inhibit feature to enable complete capacitor discharging before breaker reclosing after it has operated.

COLPTOC contains blocking functionality. It is possible to block the function outputs, timers or the function itself.

4.12.1.4 Analog channel configuration

COLPTOC has one analog group input which must be properly configured.

Table 1053: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.12.1.5 Operation principle

The function can be enabled and disabled with the Operation setting. The corresponding parameter values are “On” and “Off”.

The operation of COLPTOC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

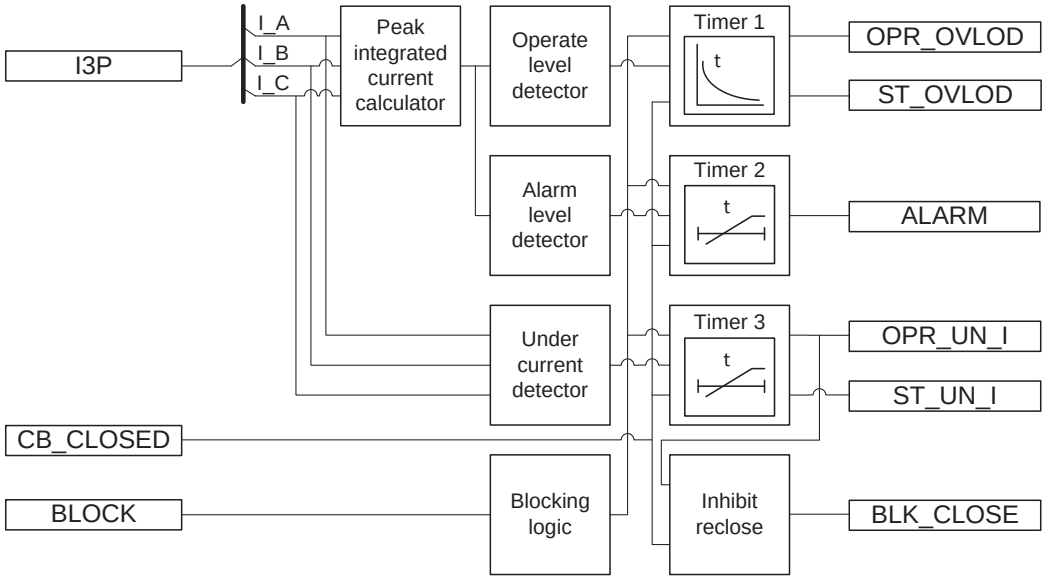

Figure 623: Functional module diagram

Peak integrated current calculator

The peak integrated current calculator calculates peak value of integrated current (`I_PEAK_INT_A`, `I_PEAK_INT_B` and `I_PEAK_INT_C`) which is proportional to the voltage over capacitor. The `I_PEAK_INT_A`, `I_PEAK_INT_B` and `I_PEAK_INT_C` values are available in monitored data view. The frequency response of the peak integrated current calculator can be seen in *Figure 624*.

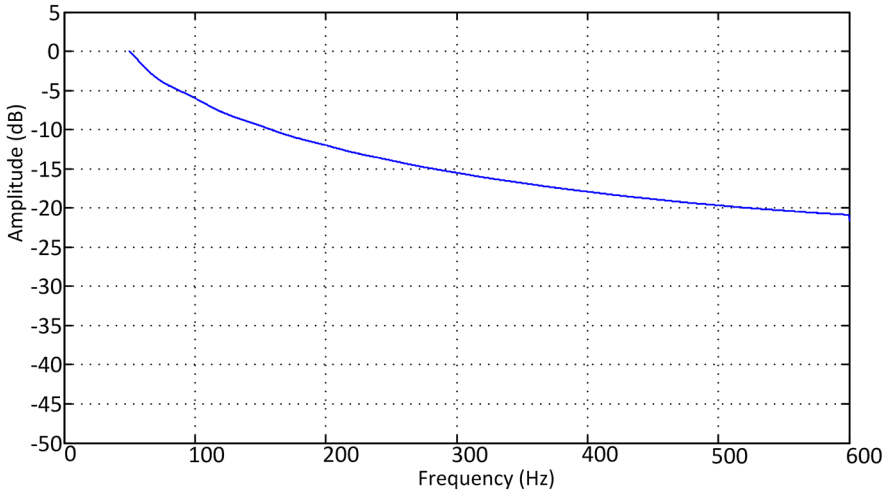

Figure 624: Frequency response of the peak integrated current calculator

Operate level detector

The Operate level detector compares `I_PEAK_INT_x` value to *Start value overload*. If the phase or phases in which `I_PEAK_INT_x` exceeds the setting matches the *Num of start phases* setting, the Operate level detector module activates the Timer 1 module.

Timer 1

Once activated, the Timer 1 module activates the ST_OVLOD output. The operation time depends on the overload level and *Time multiplier*. The operation time under standard characteristics is based on ANSI/IEEE 37.99 and IEC 60871-1 recommendations.

Table 1054: Standard Curve characteristics for IDMT Curve

Overload value	IED operate time(s) with k = 1	Standard
1.10	43200	IEC60871-1
1.15	1800	IEC60871-1
1.20	300	IEC60871-1
1.30	60	ANSI/IEEE37.99,IEC60871-1
1.40	15	ANSI/IEEE37.99
1.70	1	ANSI/IEEE37.99
2.20	0.120	ANSI/IEEE37.99

Operate time is based on maximum value of I_PEAK_INT_A, I_PEAK_INT_B and I_PEAK_INT_C. From maximum value calculated , operate time between any two consecutive points in the standard table is based on logarithmic interpolation.

The operate time can be scaled using the *Time multiplier* setting. The OPR_OVLOD output is activated if the overload situation lasts long enough to exceed the operation time.

The operate time for the operation overload stage is limited between 0.1 s to 43200 s (12 hours) if *Time multiplier* is used.

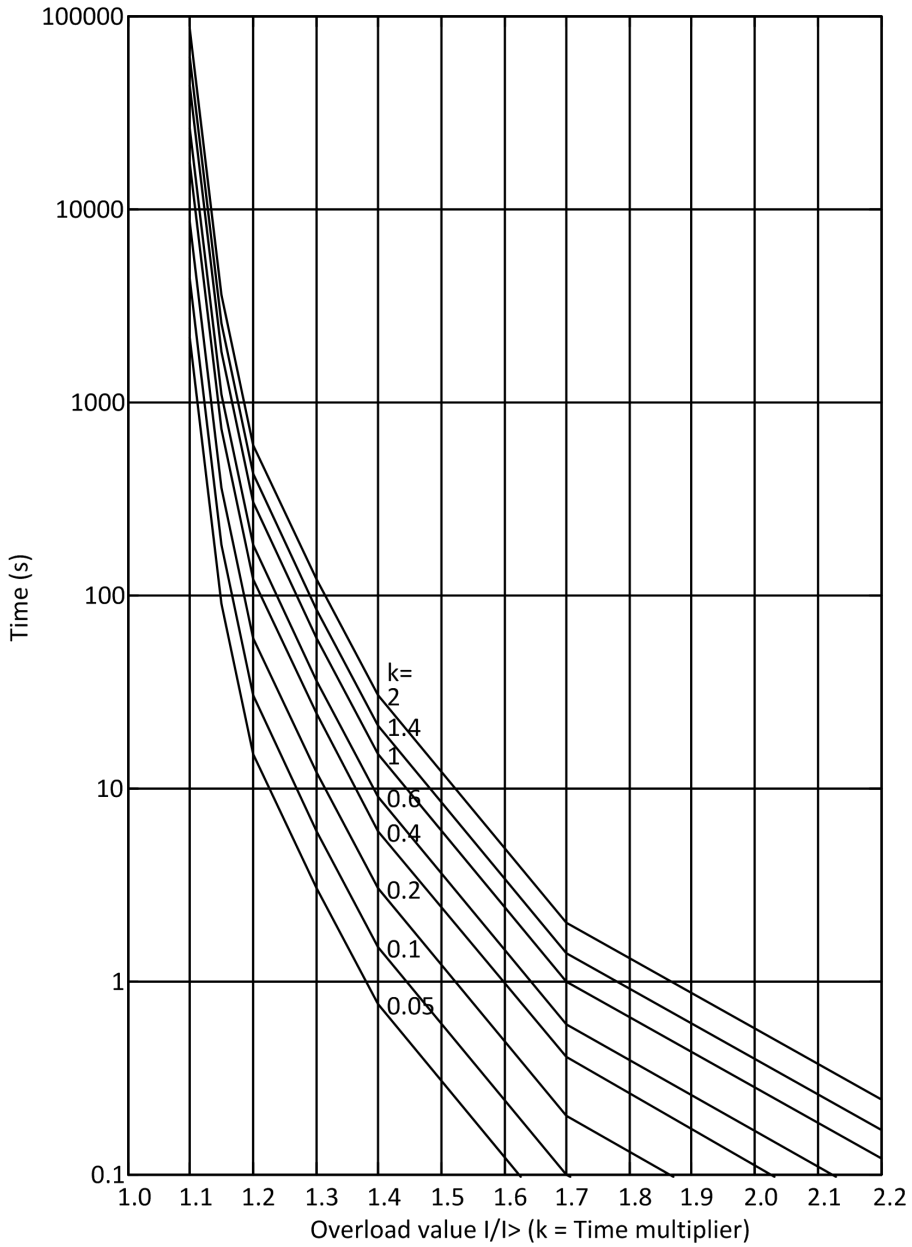

Figure 625: Inverse-time characteristic curves for overload stage

If the integrated current exceeds 1.1 times the setting *Start value overload* for a short period but does not operate as the current decreases within *Start value overload*, the output `ST_OVLOD` is kept active but the operation timer is frozen. However, if the integrated current exceeds 1.1 times the *Start value overload* setting value again, the operation timer continue from the freezing point. Thus, the operation timer is cumulative. If the integrated current exceeds 1.1 times the setting *Start value overload* only once and remains within the *Start value overload* area for 24 hours, the operation timer and the output `ST_OVLOD` are reset.

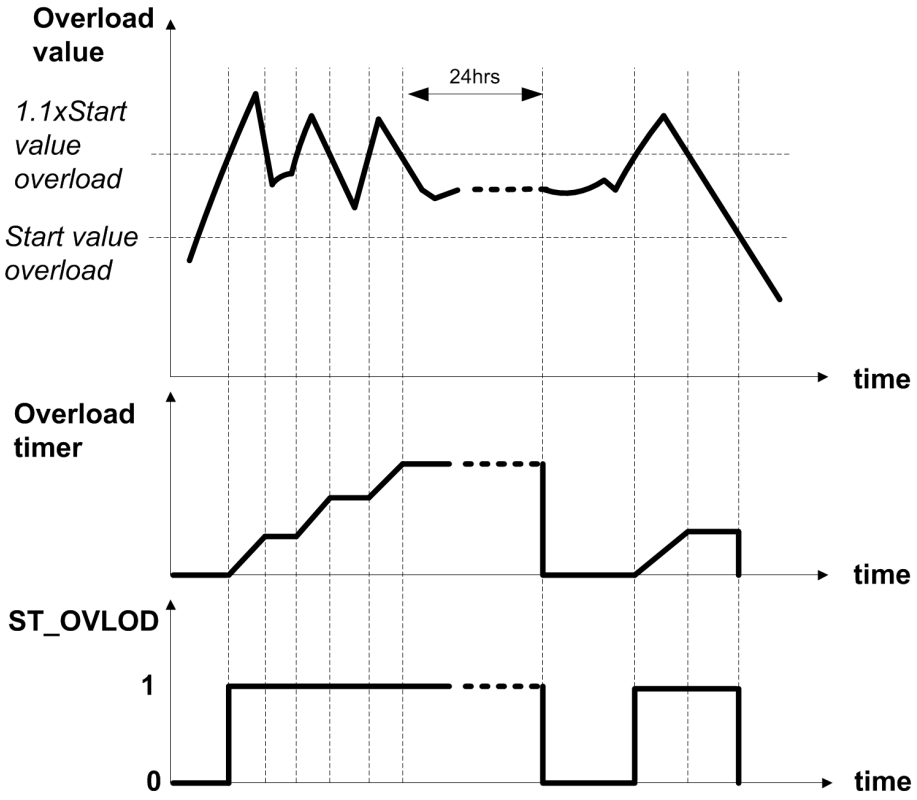

Figure 626: The behavior of the IDMT timer and the output ST_OVLOD

The ST_DUR_OVLOD output indicates the percentage ratio of the start situation and the operation time in the Timer 1 module and is available in the monitored data view.

The Timer 1 module is internally blocked for one second after the capacitor bank is connected by detecting the rising edge of the CB_CLOSED signal. The CB_CLOSED signal is True when the CB position is closed.

Alarm level detector

The Alarm level detector compares I_PEAK_INT_x value to *Alarm start value*. If the phase or phases in which I_PEAK_INT_x exceeds the setting matches the *Num of start phases* setting, the Alarm level detector module activates the Timer 2 module.

The *Num of start phases* setting is a common setting for both Operate level detector and Alarm level detector.

Timer 2

The Timer 2 characteristics are according to Definite Time (DT) .When the operation timer has reached the value of *Alarm delay time*, the ALARM output is activated.

If a drop-off situation happens, the timer is reset.

The Timer 2 module is internally blocked for one second after the capacitor bank is connected by detecting the rising edge of the

CB_CLOSED signal. The CB_CLOSED signal is True when the CB position is closed.

Under current detector

The Under current detector module can be enabled by setting *Enable under current* to “Enable” and disabled by setting it to “Disable”. The Under current detector module is also disabled when CB_CLOSED is FALSE, that is, when circuit breaker is open.

The fundamental frequency component of phase currents is compared to the setting *Start value Un Cur*. If all the three-phase currents are below the setting *Start value Un Cur*, the Under current detector module enables the Timer 3 module.

Timer 3

Once activated, the Timer 3 module activates the ST_UN_I output. The operation is based on DT characteristics. When the operation timer has reached the value of *Un Cur delay time*, the OPR_UN_I output is activated.

If the undercurrent situation disappears, the operation timer is reset. The ST_DUR_UN_I output indicates the percentage ratio of the undercurrent start situation and the set operation time in the Timer 3 module and is available in the monitored data view.

The OPR_UN_I output is of pulse type and remains TRUE for 150 ms. After that, ST_DUR_UN_I and OPR_UN_I are deactivated and ST_DUR_UN_I is reset.

If the circuit breaker closed status signal is not detected, the constant value TRUE has to be connected to CB_CLOSED input to enable the undercurrent detector.

If the circuit breaker status signal is not connected to CB_CLOSED input, the OPR_UN_I output is activated even if the circuit breaker is open and undercurrent is detected.

Inhibit reclose

When the output OPR_UN_I becomes active or when the CB_CLOSED state changes from TRUE to FALSE, that is, when circuit breaker opens, the reclosing inhibition module activates output BLK_CLOSE.

If *Enable under current* is set to “Disable”, the reclosing inhibition operation is based purely on the CB_CLOSED input.

When the relay powers up after a reboot or software reset, or if the Operation of COLPTOC function is switched from off to on, the BLK_CLOSE output is activated defined by the *Reclose inhibit time*, regardless the *Reclose inhibit mode*.

The behavior of the BLK_CLOSE output depends on *Reclose inhibit mode*. If *Reclose inhibit mode* is set to “Lockout”, the BLK_CLOSE output needs to be reset manually from the clearing menu parameter *COLPTOC inhibit recl*. If *Reclose inhibit mode* is set to “Non-latched”, the BLK_CLOSE output resets after the set *Reclose inhibit time* has elapsed.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** >

Blocking mode which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, COLPTOC is executed normally but the OPR_OVLOD and OPR_UN_I outputs are not allowed to activate.

The BLOCK input does not block the BLK_CLOSE signal.

4.12.1.6 Application

The application area for three-phase overload protection function of shunt capacitor bank is the protection of power capacitor banks intended for reactive power compensation and filtering of the harmonics. Shunt capacitor banks provide a low-impedance path to harmonic currents and hence attract harmonic currents flowing in the system. Increased harmonic currents result in excessive voltage stress across the capacitor bank. According to the standards, a high-voltage capacitor shall be able to withstand 10% overload. Loading beyond that can cause damage to the capacitor bank and in turn to the system. Hence, COLPTOC is specially designed for the protection against overloads produced by harmonic currents and overvoltage.

Undercurrent protection is used to disconnect the capacitor bank from the rest of the power system when the voltage at the capacitor bank terminals is too low for too long a period of time. To avoid an undercurrent trip operation when the capacitor bank is disconnected from the power system, the undercurrent functionality is blocked by using the capacitor bank circuit breaker status signal.

Furthermore, the reclosing inhibition feature provides protection against the reconnection of a charged capacitor to a live network. Whenever the capacitor bank circuit breaker is opened, the reclosing is inhibited for the duration of the discharge time of the capacitor. The reclosing inhibition functionality can be disabled manually or automatically. In the manual mode, the inhibition reclosing has to be manually reset and in automatic mode, the reclosing inhibitionl resets automatically after the set time.

4.12.1.7 Signals

COLPTOC Input signals

Table 1055: COLPTOC Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents

4.12.2.2 Function block

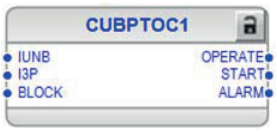

Figure 627: Function block symbol

4.12.2.3 Functionality

The current unbalance protection for shunt capacitor banks function CUBPTOC is used to protect the double-Y-connected capacitor banks from internal faults. CUBPTOC is suitable for the protection of internally fused, externally fused and fuseless applications.

CUBPTOC has two stages of operation, that is, operation stage and alarm stage. In the operating stage, CUBPTOC starts when the measured unbalance current

[1] Harmonics current before fault = 0.5 × I_n, harmonics fault current 1.5 × *Start value*, results based on statistical distribution of 1000 measurements
[2] Includes the delay of the signal output contact
[3] Harmonics current before fault = 1.2 × I_n, harmonics fault current 0.8 × *Start value*, results based on statistical distribution of 1000 measurements

exceeds the set limit. The operation time characteristics can be selected to be either definite time (DT) or inverse definite minimum time (IDMT). The operation under alarm stage is either based on the DT characteristics or the faulty element counter of a capacitor bank.

CUBPTOC has a blocking functionality. It is possible to block the function outputs, timers or the function itself.

4.12.2.4 Analog channel configuration

CUBPTOC has two analog group inputs which must be properly configured.

Table 1064: Analog inputs

Input	Description
IUNB	Unbalance current (measured)
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1065: Special conditions

Condition	Description
IUNB measurement	The function requires that the unbalance current measurement is connected via the RESTCTR function block.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.12.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”. The current unbalance protection for shunt capacitor banks operates on the DFT measurement mode.

The operation of CUBPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

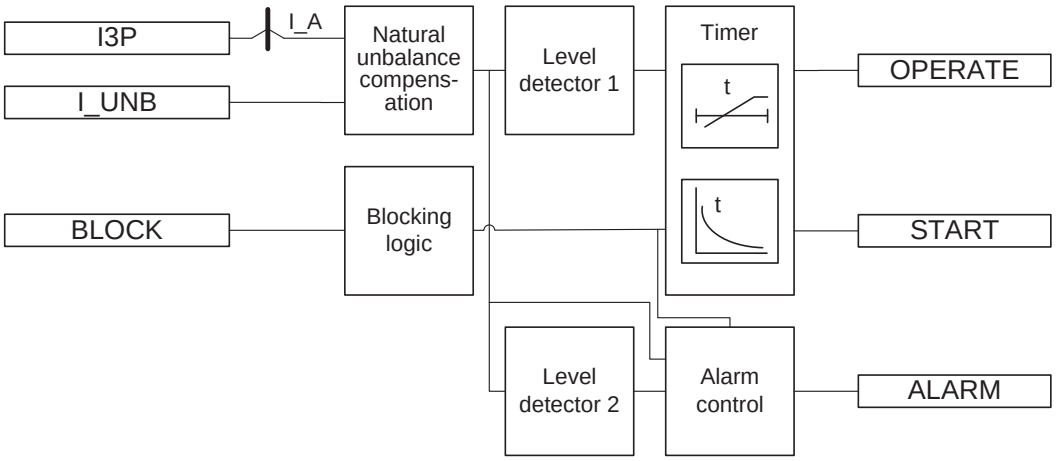

Figure 628: Functional module diagram

Natural unbalance Compensation

A standard double-Y-connected shunt capacitor bank configuration is shown in *Figure 629*. The fundamental frequency component of an unbalance current is measured on the common neutral connecting the two balanced parts of a shunt capacitor bank, that is, between star point 1 and star point 2.

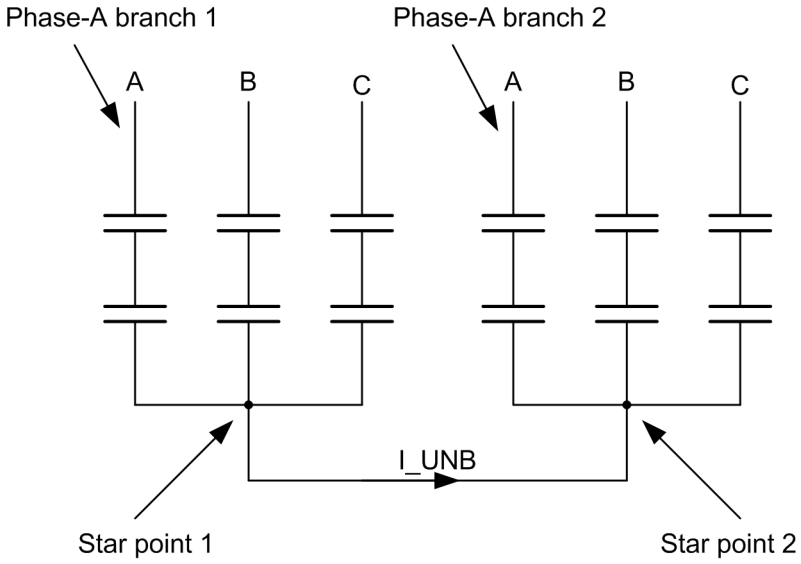

Figure 629: Double-Y-connected capacitor bank

The phase angle of the measured fundamental frequency component of the unbalance current I_UNB is synchronized by using the phase current I_A as a reference.

$$\angle\overline{I_{unb}} = \angle\overline{I_UNB} - \angle\overline{I_A}$$

(Equation 285)

In a three-phase star-connected capacitor bank circuit, there may be some amount of natural unbalance current flowing through the neutral, which is primarily due

to capacitor manufacturing tolerances. The natural unbalance current must be compensated for before using the measured unbalance current for the function operation. The natural unbalance current needs to be recorded when there is no fault in the capacitor banks, and it is initiated through the command *Record unbalance*, available under menu path **Control** > **CUBPTOC**. By selecting *Record unbalance* with value “Record”, the measured unbalance current $\bar{I}_{Unb}$ is considered as the natural unbalance current $\bar{I}_{NatUnb}$ and is stored as a reference. The amplitude and angle of the recorded natural unbalance current I_AMPL_NAT and I_ANGL_NAT are available in the monitored data view.

Once the natural unbalance current is recorded during further executions of the function, the natural unbalance current is subtracted from the measured unbalance current $\bar{I}_{Unb}$ to obtain the compensated unbalance current $\bar{I}_{CompUnb}$ as shown in *Figure 630*.

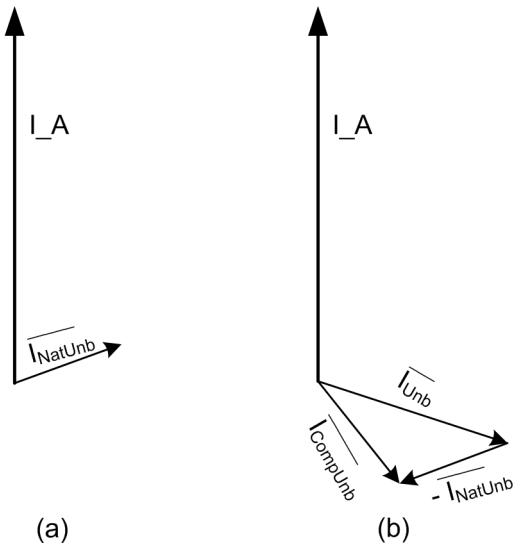

Figure 630: Natural unbalance compensation. (a) Healthy condition when the natural unbalance is recorded (b) Unbalance compensation during faulty conditions

The natural unbalance current compensation is enabled using the setting *Natural Comp Enable*. If *Natural Comp Enable* is set to “FALSE”, the unbalance current is not compensated. If *Natural Comp Enable* is set to “TRUE”, the compensated unbalance current is calculated based on the equation.

$$\bar{I}_{CompUnb} = \bar{I}_{Unb} - \bar{I}_{NatUnb}$$

(Equation 286)

The amplitude I_AMPL_COMP and the angle I_ANGL_COMP of the compensated unbalance current $\bar{I}_{CompUnb}$ are available in the monitored data view.

Level detector 1

The calculated compensated unbalance current I_AMPL_COMP is compared to the set "Start value". If I_AMPL_COMP exceeds the set "Start value", the Level detector 1 sends an enabling signal to the Timer 1 module.

Timer 1

Once activated, the Timer 1 module activates the START output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the OPERATE output is activated. When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C* and *Curve parameter E*.

In a drop-off situation, that is when a fault suddenly disappears before the operate delay is exceeded, the Timer 1 reset state is activated. The functionality of the Timer 1 in the reset state depends on the combination of the Operating curve type and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves are selected, an immediate reset occurs. The START output is deactivated when the reset timer has elapsed.

The setting *Time multiplier* is used for scaling the IDMT operation and reset times.

The setting parameter *Minimum operate time* defines the minimum desired operation time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve but always at least the value of the *Minimum operate time* setting.

The Timer 1 module calculates the start duration value START_DUR, which indicates the percentile ratio of the start situation and the set operation time. The value is available in the monitored data view.

In a typical double-Y-connected configuration (*Figure 629*), there are two branches in every phase and hence six individual counters COUNT_BR1_A, COUNT_BR2_A, COUNT_BR1_B, COUNT_BR2_B, COUNT_BR1_C and COUNT_BR2_C are maintained. Based on the phase angle of the compensated unbalance current I_ANGL_COMP, the phase and the branch of the element failure location is detected. However, the element failure location also depends on the type of capacitor banks, that is, whether internal or external fuses are used. The setting *Fuse location* is used to set the capacitor bank type as “External” or “Internal”.

For an external fuse capacitor bank, the element failure location and corresponding counters to be incremented are determined based on the phase angle of the compensated unbalance current.

Table 1066: Element failure location and counters to be incremented for external fuse case

Phase angle of the compensated unbalance current (degrees)	Phase and branch of the element failure	Counters to be incremented
-15...+15	Phase-A branch 1	COUNT_BR1_A
-15...-45	Phase-A branch 1 Phase-C branch 2	COUNT_BR1_A COUNT_BR2_C
-45...-75	Phase-C branch 2	COUNT_BR2_C
-75...-105	Phase-B branch 1 Phase-C branch 2	COUNT_BR1_B COUNT_BR2_C
-105...-135	Phase-B branch 1	COUNT_BR1_B
-135...-165	Phase-B branch 1 Phase-A branch 2	COUNT_BR1_B COUNT_BR2_A
-165...-180	Phase-A branch 2	COUNT_BR2_A
+165...+180	Phase-A branch2	COUNT_BR2_A
+135...+165	Phase-C branch 1 Phase-A branch 2	COUNT_BR1_C COUNT_BR2_A
+105...+135	Phase-C branch 1	COUNT_BR1_C
+75...+105	Phase-C branch1 Phase-B branch2	COUNT_BR1_C COUNT_BR2_B
+45...+75	Phase-B branch2	COUNT_BR2_B
+15...+45	Phase-A branch1 Phase-B branch2	COUNT_BR1_A COUNT_BR2_B

If the capacitor bank is fuseless, then the setting *Fuse location* should be set to “External” and *Table 1066* can be used to determine the element failure location.

If the compensated unbalance current I_AMPL_COMP is greater than three times the set *Alarm value*, it is considered to be a case of blown external fuse. For the internal fuse and blown fuse cases, the element failure location and corresponding counters to be incremented are determined based on the phase angle of the compensated unbalance current.

Table 1067: Element failure location and counters to be incremented for internal fuse and blown fuse case

Phase angle of the compensated unbalance current (degrees)	Phase and branch of the element failure	Counters to be incremented
-15...+15	Phase-A branch 2	COUNT_BR2_A
-15... -45	Phase-A branch 2	COUNT_BR2_A

Table continues on the next page

Phase angle of the compensated unbalance current (degrees)	Phase and branch of the element failure	Counters to be incremented
	Phase-C branch 1	COUNT_BR1_C
-45...-75	Phase-C branch 1	COUNT_BR1_C
-75...-105	Phase-B branch 2 Phase-C branch 1	COUNT_BR2_B COUNT_BR1_C
-105...-135	Phase-B branch 2	COUNT_BR2_B

+105...+135	Phase-C branch 2	COUNT_BR2_C
+75...+105	Phase-C branch 2 Phase-B branch 1	COUNT_BR2_C COUNT_BR1_B
+45...+75	Phase-B branch 1	COUNT_BR1_B
+15...+45	Phase-A branch 2 Phase-B branch 1	COUNT_BR2_A COUNT_BR1_B

After *Alarm delay time* has elapsed, the corresponding counter value is incremented based on the magnitude of the unbalance current. If I_AMPL_COMP is less than 1.5 times the set *Alarm value*, the counter is incremented by one. Furthermore, if I_AMPL_COMP is between 1.5 and 2.5 times the set *Alarm value*, the counter is incremented by two and so on.

Normally, the setting *Alarm value* is about 0.1 percent lower than the value of the unbalance current which is caused by one faulty element. This setting value has to be chosen carefully because a slightly lower value may lead to a situation where the counters show more failures than the actual. Too high setting leads to a situation where a fault is not detected.

The counter values COUNT_BR1_A, COUNT_BR2_A, COUNT_BR1_B, COUNT_BR2_B, COUNT_BR1_C and COUNT_BR2_C are available in the monitoring data view. The total number of element failures in double-Y-connected capacitor banks, FAIL_COUNT, is available in the monitored data view.

The ALARM output is activated, when the value of FAIL_COUNT exceeds the setting *Element failure limit*.

The counter values can be reset via *CUBPTOC counters* which is located under the Clear menu.

Level detector 2

The calculated compensated unbalance current I_AMPL_COMP is compared to the set *Alarm start value*. If the I_AMPL_COMP exceeds the set *Alarm value* the Level detector *2* sends enabling signal to the Alarm control module.

Alarm control

Depending on the *Alarm mode* setting, the alarm stage operation is according to “Normal mode” or “Element counter mode”.

In the “Normal mode” the time characteristic is according to DT. When the alarm timer has reached the value set by *Alarm delay time*, the ALARM output is activated. If the fault disappears before the alarm activates, the alarm timer is reset immediately.

The “Element counter mode” is used to detect faulty elements of the capacitor bank and count the number of element failures in each branch and line. On activation, this module increments the corresponding element failure counters after the set *Alarm delay time* has elapsed.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode**, which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the IED program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the "Freeze timers" mode, the operation timer is frozen to the prevailing value. In the "Block all" mode, the whole function is blocked and the timers are reset. In the "Block OPERATE output" mode, CUBPTOC operates normally but the OPERATE output is not activated.

4.12.2.6 Application

CUBPTOC is designed for the protection against internal faults in double-Y-connected capacitor banks. This unbalance protection detects an asymmetry in the capacitor bank caused by blown fuses or short circuits across bushings or between capacitor units and the racks in which they are mounted.

Normally, the capacitor units are designed to withstand 110 percent of the nominal voltage continuously. When an element inside a capacitor bank fails, the remaining healthier elements experience an increase in voltage across them. If the voltage exceeds the 110 percent value of the nominal voltage, it can lead to a failure of the healthier elements of the bank and in turn fail the entire capacitor bank. Since the capacitor unbalance current is directly proportional to the element failures, unbalance protection is an effective way of detecting capacitor element failures. The current unbalance protection function is usually used with the three-phase capacitor bank overload protection function to increase the sensitivity of protection for capacitor banks.

Due to the two-stage (operation and alarm stage) unbalance protection and the natural unbalance compensation facility, the protection of capacitor banks with internal fuses can be implemented with a very high degree of sensitivity.

Furthermore, CUBPTOC provides a sophisticated method of detecting the number of faulty elements in each phase by calculating the differential unbalance current.

The unbalance protection function can be used for internally fused, externally fused and fuseless shunt capacitor banks. Since a fuseless capacitor bank lacks the individual capacitor unit fuses, current unbalance protection becomes even more critical for fuseless applications.

When an individual element fails, it causes unbalance current. With an increasing number of element failures, the unbalance current increases and CUBPTOC gives an alarm. The alarm level is normally set to 50 percent of the maximum permitted level. The capacitor bank needs to be taken out of service to replace the faulty units. If this is not done, the capacitor bank is tripped when the maximum allowed unbalance current level is exceeded.

If two simultaneous faults occur in the same phase but in different branches, there is no change in the unbalance current and CUBPTOC does not detect this type of faults.

If two simultaneous faults occur in the same branch but in different phases, it may cause a phase angle equal to a situation where there is only one fault in the branch. Therefore, the element failure counters show only one fault instead of two.

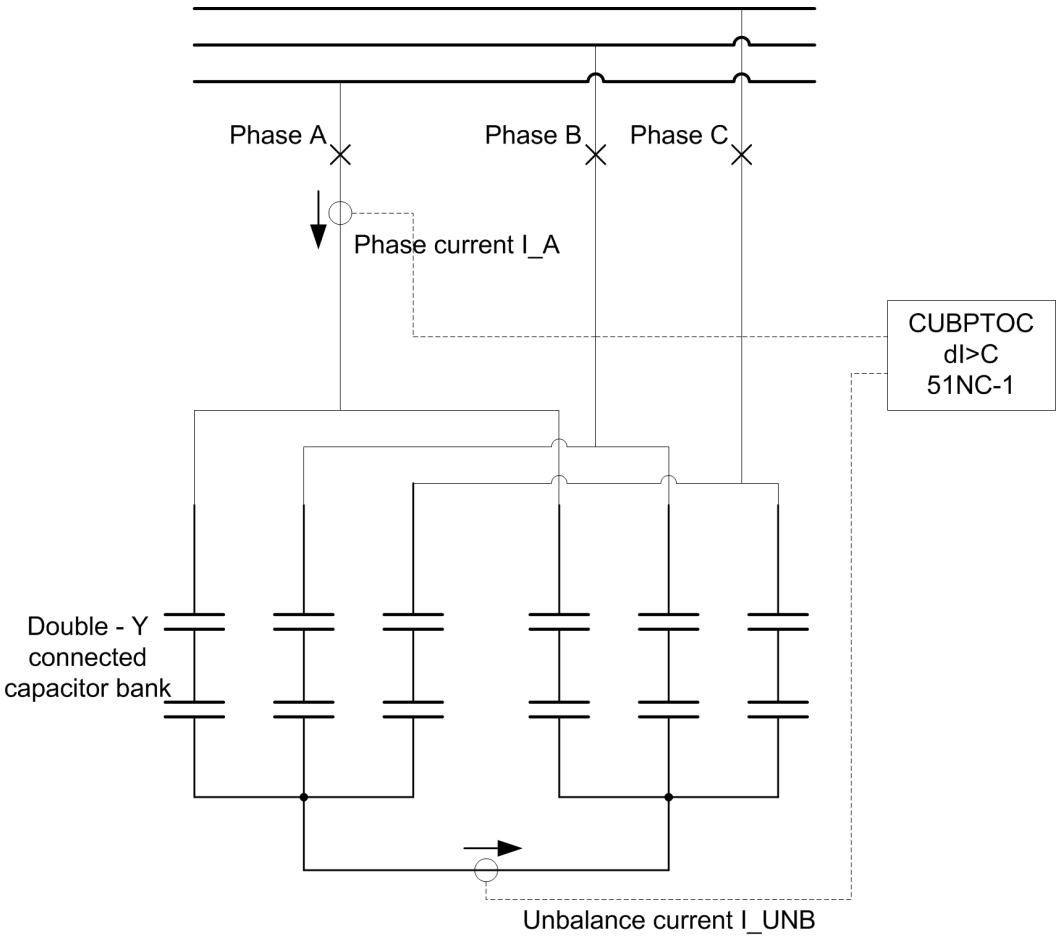

Figure 631: Example of double-Y-connected shunt capacitor bank unbalance protection

Connect the phase current analog input I_A and unbalance current I_UNB to the protection relay for the CUBPTOC function to start working.

Steps to measure natural unbalance current

1. The setting *Natural Comp Enable* must be set to “TRUE”.
2. The capacitor bank must be energized.
3. The capacitor bank compensated unbalance current I_COM_AMPL is observed from Monitored data.
4. The command *Record unbalance* must be activated by selecting the value “Record” which stores the unbalance reference for future unbalance calculations.
5. The compensated unbalance current (I_COM_AMPL) is re-checked to be approximately zero.

The natural unbalance recording should be made only during the steady-state condition and when all the capacitor bank elements are assumed to be in service.

4.12.3.2 Function block

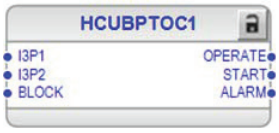

Figure 632: Function block symbol

4.12.3.3 Functionality

The three-phase current unbalance protection function for shunt capacitor banks HCUBPTOC is used to protect the H-bridge capacitor banks against internal faults. HCUBPTOC is suitable for protection of internally fused, externally fused and fuseless capacitor bank applications.

HCUBPTOC has two stages of operation, the operation stage and alarm stage. In the operation stage, HCUBPTOC starts when the measured unbalance current exceeds the set limit. The operating time characteristics can be selected to be either definite time (DT) or inverse definite minimum time (IDMT). In the alarm stage, the alarm starts when the measured unbalance current exceeds the set alarm limit. The alarm time characteristics are based on DT.

HCUBPTOC contains blocking functionality. It is possible to block the function outputs, timers or the function itself.

[1] Fundamental frequency current = 1.0 × I_n, current before fault = 0.0 × I_n, fault current = 2.0 × *Start value*, results based on statistical distribution of 1000 measurements

[2] Includes the delay of the signal output contact

4.12.3.4 Analog channel configuration

HCUBPTOC has two analog group inputs which must be properly configured.

Table 1076: Analog inputs

Input	Description
I3P1	Three-phase currents
I3P2	Three-phase unbalance currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.12.3.5 Operation principle

The function can be enabled and disabled with the Operation setting. The corresponding parameter values are “On” and “Off”.

The three-phase current unbalance protection for shunt capacitor banks operates on the DFT measurement mode. The operation of HCUBPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

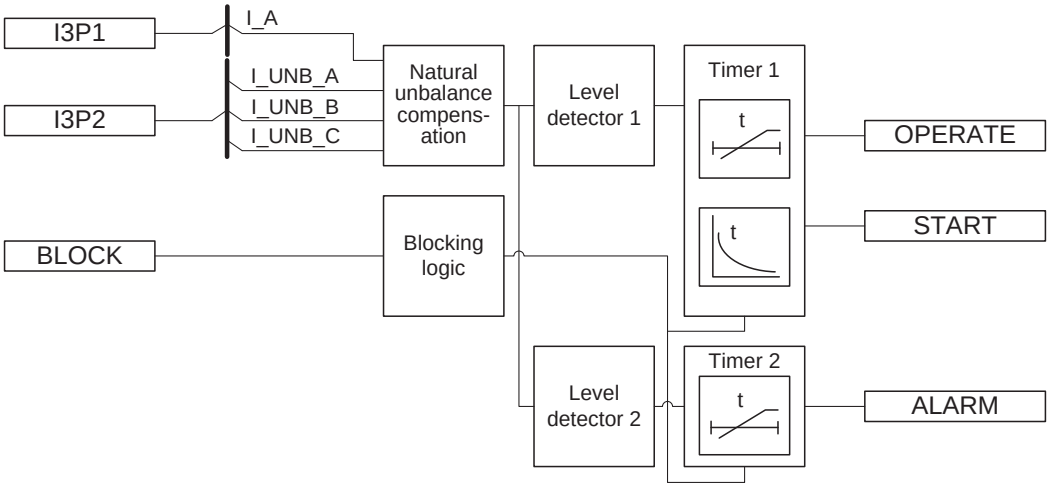

Figure 633: Function module diagram

Natural unbalance compensation

In the three-phase H-bridge-connected shunt capacitor bank configuration, the unbalance currents `I_UNB_A`, `I_UNB_B` and `I_UNB_C` are measured at the common points of the H-bridge.

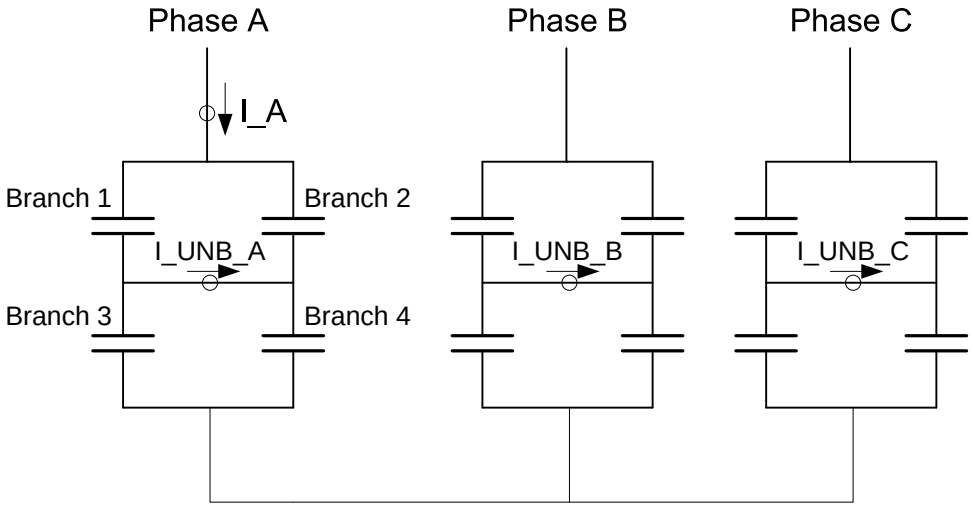

Figure 634: H-Bridge-connected capacitor bank

The phase angles of three-phase measured unbalance currents are synchronized using the phase current I_A as reference. The phase-A unbalance current phase angle can be calculated with the equation.

$$\angle\overline{I_{Unb_A}} = \angle\overline{I_UNB_A} - \angle\overline{I_A}$$

(Equation 287)

A three-phase H-bridge-connected capacitor bank circuit may have some amount of natural unbalance current flowing through the common points of H-bridge, which may primarily be due to capacitor manufacturing tolerances. Therefore, the natural unbalance current must be compensated for before using the measured unbalance current for function operation.

The natural unbalance current needs to be recorded when there is no fault in the capacitor banks, and it is initiated through the command *Record unbalance* available under menu path **Control** > **HCUBPTOC**. The natural unbalance currents are recorded for all the phases at the same time by setting command *Record unbalance* to “Record all phases” or each natural unbalance current can be recorded separately for individual phases by setting command *Record unbalance* to “Record phase A” or “Record phase B” or “Record phase C”. By selecting *Record unbalance* with value “Record”, the measured three-phase unbalance currents ($\overline{I_{Unb_A}}, \overline{I_{Unb_B}}, \overline{I_{Unb_C}}$,) are considered the natural unbalance currents for each phase respectively and stored as a reference. The amplitude and angle of the phasewise-recorded natural unbalance currents `I_NAT_AMPL_A`, `I_NAT_ANGL_A`, `I_NAT_AMPL_B`, `I_NAT_ANGL_B`, `I_NAT_AMPL_C` and `I_NAT_ANGL_C` are available in the monitored data view.

Once a natural unbalance current is recorded, the phasewise natural unbalance current is subtracted from the corresponding phase-measured unbalance current ($\overline{I_{Unb}}$) during further executions of the function to obtain the compensated unbalance current ($\overline{I_{CompUnb}}$) .

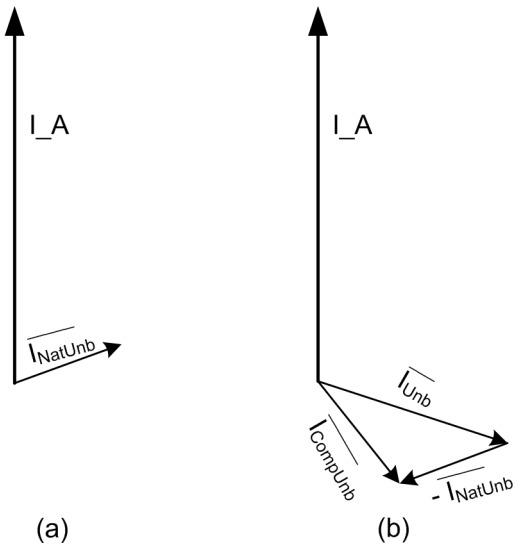

Figure 635: Natural unbalance compensation. (a) Healthy condition when the natural unbalance is recorded (b) Unbalance compensation during faulty conditions

The natural unbalance compensation for each phase is enabled based on the settings *Natural Comp Ena PhA*, *Natural Comp Ena PhB* and *Natural Comp Ena PhC* respectively. For example, if *Natural Comp Ena PhA* is set to “FALSE”, the unbalance current is not compensated. If *Natural Comp Ena PhA* is set to “TRUE”, the compensated unbalance current for phase A is calculated based on the equation.

$$\overline{I_{CompUnb_A}} = \overline{I_{Unb_A}} - \overline{I_{NatUnb_A}}$$

(Equation 288)

$I_{CompUnb_A}$	Phase A-compensated unbalance current
I_{Urb_A}	Phase A-measured unbalance current
I_{NatUnb_A}	Phase A-recorded natural unbalance current

The phasewise-compensated unbalance current amplitudes and angles `I_COM_AMPL_A`, `I_COM_ANGL_A`, `I_COM_AMPL_B`, `I_COM_ANGL_B`, `I_COM_AMPL_C` and `I_COM_ANGL_C` are available in the monitored data view.

The phase angles of the unbalance currents indicate the branch of a faulty element in a capacitor bank. For an internal fuse capacitor bank, the element failure branch location is determined based on the phase angle of the compensated unbalance current.

Table 1077: Detection of element failure location for internal fuse capacitor bank

Name of the phase angle	Phase angle of unbalance current	Element failure branch location *Figure 634*
I_COM_ANGL_A	~+180°	Phase A - Branch 1 or Phase A - Branch 4
I_COM_ANGL_A	~0°	Phase A - Branch 2 or Phase A - Branch 3

Table continues on the next page

I_COM_ANGL_B	~+60°	Phase B - Branch 1 or Phase B - Branch 4
I_COM_ANGL_B	~–120°	Phase B - Branch 2 or Phase B - Branch 3
I_COM_ANGL_C	~–60°	Phase C - Branch 1 or Phase C - Branch 4
I_COM_ANGL_C	~+120°	Phase C - Branch 2 or Phase C - Branch 3

If external fuses are used, the direction of an unbalance current is opposite to that of the bank where internal fuses are in use.

Table 1078: Detection of element failure location for external fuse capacitor bank

Name of the phase angle	Phase angle of unbalance current	Element failure branch location *Figure 634*
I_COM_ANGL_A	~0°	Phase A - Branch 1 or Phase A - Branch 4
I_COM_ANGL_A	~+180°	Phase A - Branch 2 or Phase A - Branch 3
I_COM_ANGL_B	~–120°	Phase B - Branch 1 or Phase B - Branch 4
I_COM_ANGL_B	~+60°	Phase B - Branch 2 or Phase B - Branch 3

I_COM_ANGL_C	~–60°	Phase C - Branch 2 or Phase C - Branch 3

Level detector 1

The phasewise-compensated unbalance currents `I_COM_AMPL_A`, `I_COM_AMPL_B` and `I_COM_AMPL_C` are compared to the set *Start value*. If the compensated unbalance current in one or more phases exceeds the set *Start value*, the Level detector 1 module sends the enabling signal to the Timer 1 module.

Timer 1

Once activated, the Timer 1 module activates the `START` output. Depending on the value of the *Operating curve type* setting, the time characteristics are according to DT or IDMT. When the operation timer has reached the value of *Operate delay time* in the DT mode or the maximum value defined by the inverse time curve, the `OPERATE` output is activated.

When the user-programmable IDMT curve is selected, the operation time characteristics are defined by the parameters *Curve parameter A*, *Curve parameter B*, *Curve parameter C* and *Curve parameter E*.

In a drop-off situation, that is, when a fault suddenly disappears before the operation delay is exceeded, the Timer 1 reset state is activated. The functionality of Timer 1 in the reset state depends on the combination of the *Operating curve type* and *Reset delay time* settings. When the DT characteristic is selected, the reset timer runs until the set *Reset delay time* value is exceeded. When the IDMT curves

are selected, an immediate reset occurs. The START output is deactivated when the reset timer has elapsed.

The setting *Time multiplier* is used for scaling the IDMT operation times.

The setting parameter *Minimum operate time* defines the minimum desired operation time for IDMT. The setting is applicable only when the IDMT curves are used.

The *Minimum operate time* setting should be used with great care because the operation time is according to the IDMT curve, but always at least the value of the *Minimum operate time* setting.

Timer 1 calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the monitored data view.

Level detector 2

The phasewise-compensated unbalance currents I_COM_AMPL_A, I_COM_AMPL_B and I_COM_AMPL_C are compared to the set *Alarm start value*. If the compensated unbalance current in one or more phases exceeds the set *Alarm start value*, the Level detector 2 module sends the enabling signal to the Timer 2 module.

Timer 2

Once activated, the timer activates the alarm timer. The timer characteristic is according to DT. When the alarm timer has reached the value set by *Alarm delay time*, the ALARM output is activated.

If the fault disappears before the alarm activates, the alarm timer is reset immediately.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, HCUBPTOC operates normally but the OPERATE output is not activated.

4.12.3.6 Application

Shunt capacitor banks (SCBs) are widely used in transmission and distribution networks to produce reactive power support. Located in relevant places such as in the vicinity of load centers, SCBs have beneficial effects on power system performance: increased power factor, reduced losses, improved system capacity and better voltage level at load points.

The capacitor bank terminology ‘Bank’, ‘Unit’ and ‘Element’ is shown in *Figure 636*.

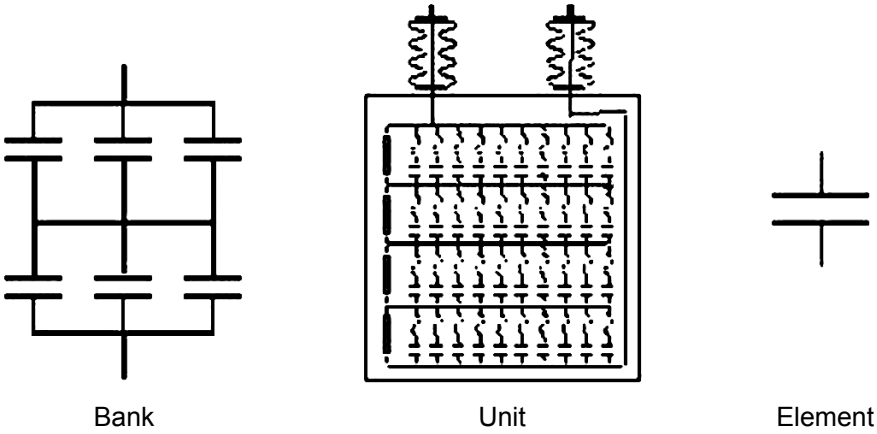

Figure 636: Bank, unit and element of a capacitor bank

HCUBPTOC is designed for the protection against internal faults in H-bridge-connected capacitor banks. This unbalance protection detects an asymmetry in the capacitor bank, caused by blown fuses or short-circuits across bushings, or between capacitor units and the racks in which they are mounted.

Normally, the capacitor units are designed to withstand 110% of the nominal voltage continuously. When an element inside a capacitor bank fails, the remaining healthy elements experience an increase in voltage across them. If the voltage exceeds 110% of the nominal voltage, it can lead to a failure of the healthy elements of the bank and in turn fail the entire capacitor bank. Since the capacitor unbalance current is directly proportional to element failures, unbalance protection is an effective way of detecting capacitor element failures. The current unbalance protection function is usually used along with the three-phase capacitor bank overload protection function to increase the sensitivity of protection for capacitor banks.

Due to the two-stage (operation and alarm stage) unbalance protection and the natural unbalance compensation facility, the protection of capacitor banks with internal fuses can be implemented with a very high degree of sensitivity.

The unbalance protection function can be used for internally fused, externally fused and fuseless shunt capacitor banks. Since a fuseless capacitor bank lacks the individual capacitor unit fuses, current unbalance protection becomes even more critical for fuseless applications.

When an individual element fails, it creates current unbalance. With an increasing number of element failures, the unbalance current increases and HCUBPTOC gives an alarm. The alarm level is normally set to 50% of the maximum permitted level. The capacitor bank then should be taken out of service to replace the faulty units. If not, the capacitor bank is tripped when the maximum allowed unbalance current level is exceeded.

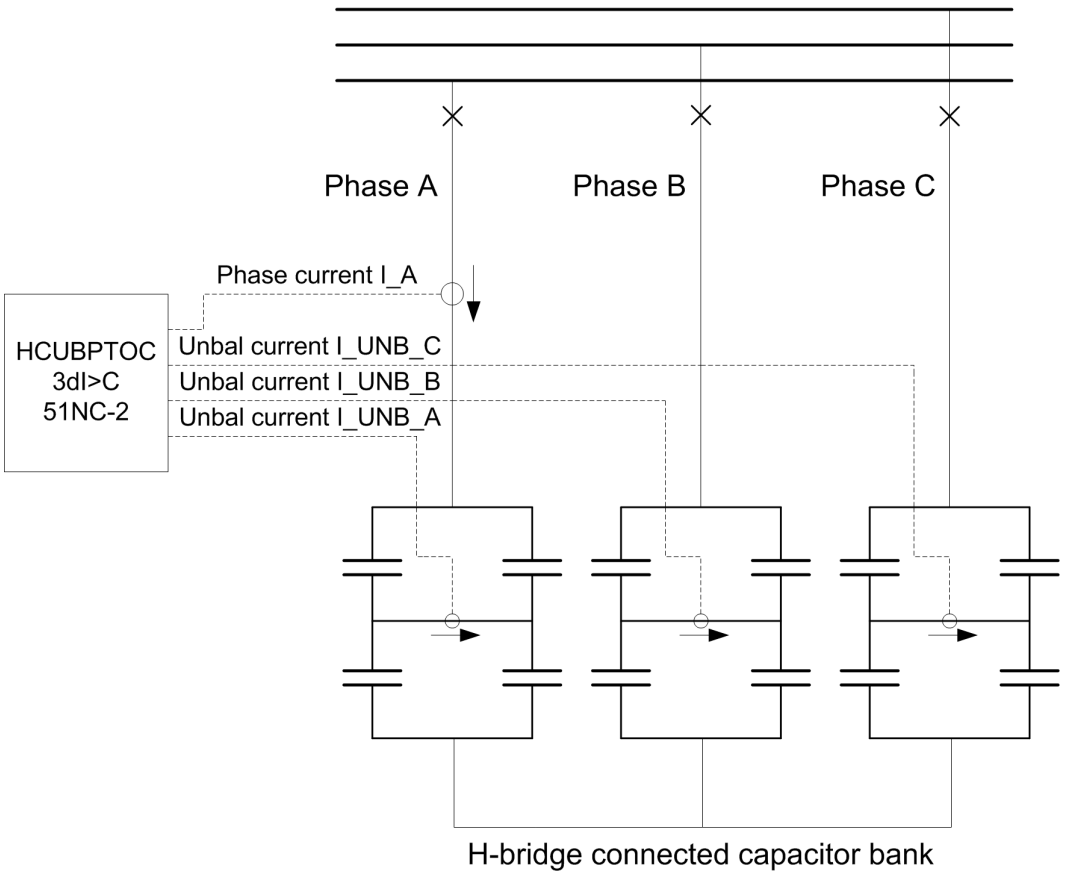

Figure 637: Application example of capacitor bank unbalance protection

The phase current analog input I_A and at least one unbalance current must be connected to the protection relay for the HCUBPTOC function to start working.

Steps to measure natural unbalance current

1. The setting *Natural Comp Enable* must be set to “TRUE”.
2. The capacitor bank must be energized.
3. The capacitor bank compensated unbalance current `I_COM_AMPL` is observed from Monitored data.
4. The command *Record unbalance* must be activated by selecting the value “Record” which stores the unbalance reference for future unbalance calculations.
5. The compensated unbalance current (`I_COM_AMPL`) is re-checked to be approximately zero.

The natural unbalance recording should be made only during the steady-state condition and when all the capacitor bank elements are assumed to be in service.

Shunt capacitor bank switching resonance protection, current based	SRCPTOC	TD>	55ITHD

4.12.4.2 Function block

Figure 638: Function block symbol

4.12.4.3 Functionality

The shunt capacitor bank switching resonance protection, current based, function SRCPTOC is used for detecting three-phase resonance caused by capacitor switching or topology changes in the network. The operating characteristic is a definite time (DT).

SRCPTOC contains a blocking functionality. It is possible to block function outputs, timers or the function itself.

4.12.4.4 Analog input configuration

SRCPTOC has one analog group input which must be properly configured.

Table 1087: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.12.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”.

The operation of SRCPTOC can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

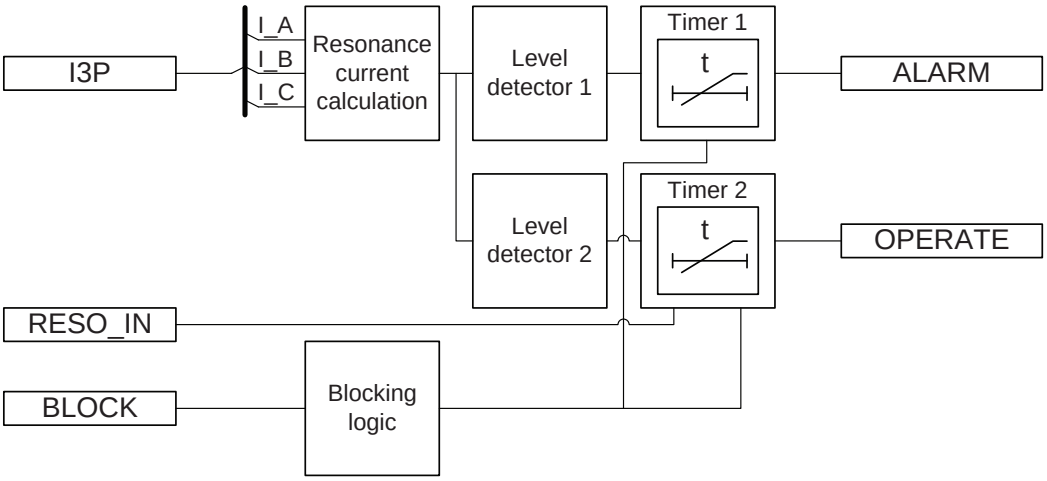

Figure 639: Functional module diagram

Resonance current calculation

This module calculates the resonance current per phase set as per setting *Tuning harmonic Num*. The resonance current for phase A is calculated with the equation.

$$I_RESO_A = \sqrt{I^2_{RMS_A} - I^2_{1_A} - I^2_{DC_A} - I^2_{K_A}}$$

(Equation 289)

I_{RMS_A}	RMS value of current in phase A (contains up to 11 th harmonic)
I_{DC_A}	DC-component in phase A current
I_{1_A}	Fundamental component in phase A current
I_{K_A}	K th harmonic component in phase A current, K is defined by setting *Tuning harmonic Num*
I_RESO_A	Calculated resonance current for phase A

The resonance current is calculated through the filter implementation. The DC and fundamental components are removed by passing the total RMS current through the High pass filter. The K th harmonic component is removed by passing the High pass filter output through the K th harmonic Band stop filter. The magnitude

response of the High pass filter and all the harmonic Band stop filters are shown in *Figure 640*.

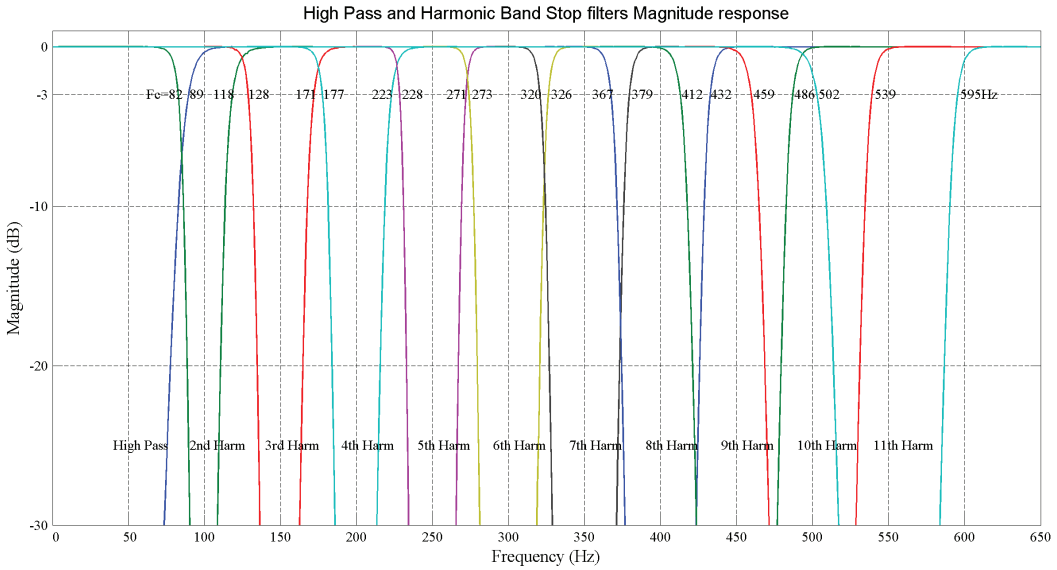

Figure 640: Magnitude response of High pass and all the harmonic Band stop filters

Similarly resonance current is calculated in the same way for phase B and phase C. Resonance currents `I_RESO_A`, `I_RESO_B` and `I_RESO_C` are available in the monitored data view.

The maximum of the three calculated resonance currents is further considered for calculation.

$$I_RESONANCE = Max(I_RESO_A, I_RESO_B, I_RESO_C)$$

(Equation 290)

If a capacitor bank is used only for reactive power compensation and there is no series reactor in a filter branch, the resonance protection is very important. In this case, the setting *Tuning harmonic Num* should be set to 1 because the capacitor branch is not tuned for a special frequency as in tuned filter applications. Even though *Tuning harmonic Num* is set to 1, the fundamental component is subtracted only once from I_{RMS}.

Level detector 1

The maximum calculated resonance current is compared to the set *Alarm start value*. If the calculated `I_RESONANCE` exceeds the set *Alarm start value*, the module sends the enabling signal to the Timer 1 module.

Level detector 2

The maximum calculated resonance current is compared to the set *Start value*. If the calculated `I_RESONANCE` exceeds the set *Start value*, this module sends the enabling signal to the Timer 2 module.

Timer 1

Once activated, the timer activates the alarm timer. The timer characteristic is according to DT. When the alarm timer has reached the value set by *Alarm delay time*, the ALARM output is activated.

If the fault disappears before the alarm activates, the alarm timer is reset immediately.

Timer 2

Once activated, the timer activates the operation timer. The timer characteristic is according to DT. When the operation timer has reached the value set by *Operate delay time*, the OPERATE output is activated.

If the fault disappears before the operate activates, the operation timer is reset immediately.

If the input RESO_IN becomes active, the OPERATE output is activated immediately. If the resonance protection at a higher-order filter branch has already operated, the function in lower-order filter branches can be tripped immediately using this feature.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the IED program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, SRCPTOC operates normally but the OPERATE output is not activated.

4.12.4.6 Application

Switched shunt capacitor banks are widely used by utilities and customers in industrial distribution systems to provide voltage support and to improve the power factor of a load. Capacitor steps may be switched in and out of circuits routinely as the demand for capacitive VAR compensation of a load fluctuates. Normally, automatic power factor controllers are employed which automatically switch on or off the capacitors of the capacitor bank, depending upon the prevalent reactive power requirement in the system.

One potential problem for the application of automatic power factor controllers is that it may cause harmonic resonance under certain system conditions. Capacitor switching changes the parameters of the system, which may cause the resonance frequency of the circuit to be equal to one of the frequencies of the harmonic sources prevalent in the system. Harmonic resonance, when it occurs, may result in severe voltage and current distortions, which increases losses and causes overheating of other equipment in the circuit.

A traditional way of solving the problem is to conduct a detailed system study for each individual installation and use the results to properly size the capacitors and determine the right operating range of capacitors to avoid harmonic resonance

with other system components. However, this method is not economical but more time-consuming.

The capacitor switching-resonance protection function can be used as a solution to the above mentioned problem. The basis for the harmonic resonance protection is the detection of a current harmonic resonance condition caused by capacitor switching. A prolonged increase of the harmonic distortion level after a switching operation is a clear indication of such condition. When a resonant condition caused by capacitor switching occurs in a circuit, SRCPTOC detunes the circuit by taking the reverse action, that is, switching the capacitor bank off if switching it on causes resonance. If the resonance situation has been detected and SRCPTOC has switched off a capacitor bank, power factor controller should not try to switch on the capacitor bank until the switching resonance function reset.

The capacitor switching-resonance protection function can also be used to protect harmonic filters. In harmonic filter bank applications, the SRCPTOC function can be tuned to harmonic frequency for which the harmonic filter is designed to ensure that the function does not include thr tuned harmonic frequency current into the calculation of the resonance current. If there is more than one harmonic filter bank involved, each SRCPTOC tunes to the harmonic frequency of its corresponding filter bank. The interlinking between the functions can be done in such a way that if resonance occurs in a higher harmonic frequency filter bank, all the lower harmonic frequency filter banks can be tripped immediately by activating the function input `RESO_IN`.

The settings *Alarm start value* and *Start value* determine the portion of the total harmonic current (excluding the harmonic defined by the setting *Tuning harmonic Num*) in relation to the CT nominal value required for SRCPTOC to give alarm and operate respectively.

For power factor correction application

- *Tuning harmonic Num* must be set to 1.
- *Alarm start value* and *Start value* must be set according to the standard IEEE519 -1992.

For harmonic filter application

- *Tuning harmonic Num* must be set to the filter design tuning frequency.
- *Alarm start value* and *Start value* must be set according to the standard IEEE519 -1992.

Settings *Alarm start value* and *Start value* should be selected as such that in normal operation SRCPTOC should not operate.

4.12.5 Compensated neutral unbalance voltage protection CNUPTOV (ANSI 59NU)

4.12.5.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Compensated neutral unbalance voltage protection	CNUPTOV	CNU>	59NU

4.12.5.2 Function block

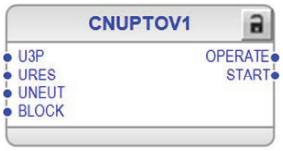

Figure 641: Function block

4.12.5.3 Functionality

The compensated neutral unbalance voltage protection function CNUPTOV detects overvoltage at the neutral point of the shunt capacitor. A blown fuse or a shortcircuited capacitor element results in unbalance in the shunt capacitor bank causing increase in neutral point voltage. With CNUPTOV, an inherent capacitor bank unbalance which results in non-zero neutral point voltage can be compensated automatically on a continuous basis.

The function starts when the fundamental (DFT) component of the compensated neutral unbalance voltage exceeds the set limit. CNUPTOV operates with the definite time (DT) characteristics.

The function contains a blocking functionality. It is possible to block function outputs, the definite timer or the function itself.

4.12.5.4 Analog channel configuration

CNUPTOV has three analog group inputs which must be properly configured.

Table 1094: Analog inputs

Input	Description
U3P	Three phase voltages
URES	Residual voltage (measured or calculated)
UNEUT	Measured neutral voltage

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1095: Special conditions

Condition	Description
U3P connected real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.
URES calculated	The function requires that all three voltage channels from terminal side are connected to calculate residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. Check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

4.12.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of CNUPTOV can be described with a module diagram. All the modules in the diagram are explained in the next sections.

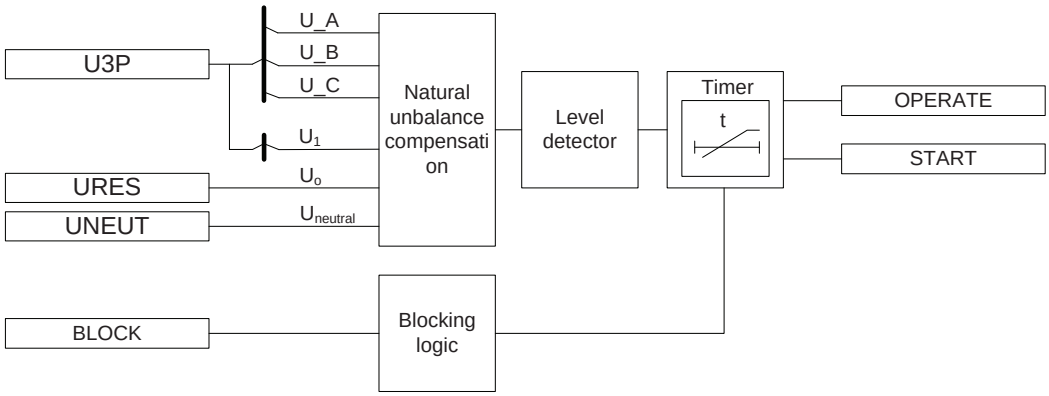

Figure 642: Functional module diagram

Natural unbalance compensation

This module calculates the natural unbalance compensation. Calculation for compensation is initiated through the command Record unbalance, available under the menu path **Control** > **CNUPTOV**. The function equates the operating signal to zero and calculates $\overline{U_{unb}}$ from the available known quantities. $\overline{U_{unb}}$ is memorized as $\overline{U_{unb}}(m)$. This memorized value is then used when calculating the operating quantity. For more information, see the *Chapter 4.12.5.6 Operating quantity* section in this manual.

If the positive-sequence voltage is available at the time of memorizing the $\overline{U_{unb}}(m)$ value, the positive-sequence voltage is also memorized as $\overline{U_1}(m)$. The function then applies the revised compensation voltage to account for change in bus voltages between the moment of memorizing the compensation voltage and the time of applying it.

$$\overline{U_{unb}} = \overline{U_{unb}}(m) \cdot \frac{\overline{U_1}}{\overline{U_1}(m)}$$

Figure 643: Equation

Level detect

The operating signal is compared to the set *Start value*. If the operating signal exceeds the set *Start value*, Level detector sends an enabling signal to the Timer module.

Timer

Once activated, Timer activates the START output. The time characteristic is according to DT. When the operation timer has reached the value set by *Operate delay* time, the OPERATE output is activated if the operating signal persists. If a drop-off situation happens, that is, the fault disappears before the operate delay is exceeded, the timer reset state is activated. If the reset timer reaches the value set by *Reset delay time*, the operation timer resets and the START output is deactivated.

Timer calculates the start duration value START_DUR, which indicates the percentage ratio of the start situation and the set operation time. The value is available in the Monitored data view.

Blocking logic

There are three operation modes in the blocking function. The operation modes are controlled by the BLOCK input and the global setting in **Configuration** > **System** > **Blocking mode** which selects the blocking mode. The BLOCK input can be controlled by a binary input, a horizontal communication input or an internal signal of the protection relay's program. The influence of the BLOCK signal activation is preselected with the global setting *Blocking mode*.

The *Blocking mode* setting has three blocking methods. In the “Freeze timers” mode, the operation timer is frozen to the prevailing value, but the OPERATE output is not deactivated when blocking is activated. In the “Block all” mode, the whole function is blocked and the timers are reset. In the “Block OPERATE output” mode, the function operates normally but the OPERATE output is not activated.

4.12.5.6 Operating quantity

Operating quantity in ungrounded SCB

Consider a case of a standard ungrounded shunt capacitor bank as shown in *Figure 644*.

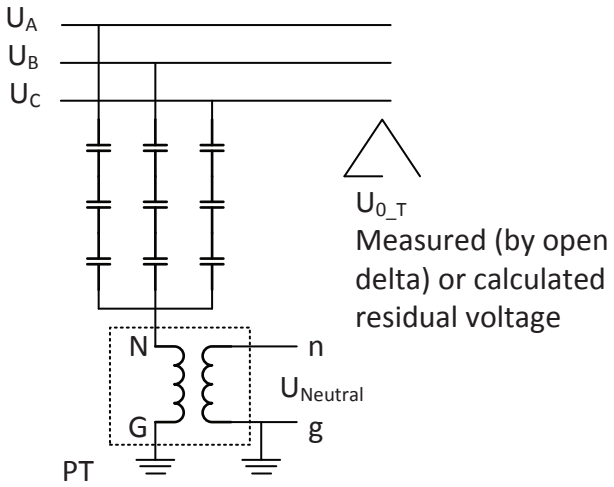

Figure 644: Ungrounded SCB

The operating signal for the compensated neutral voltage unbalance in per unit with reference to the neutral side of an ungrounded SCB is as indicated in *Figure 645*.

$$Operating\ signal = \left| \frac{\overline{U}_{Neutral}}{U_{N_sr}} - \frac{n_{Uo}}{U_{N_pr}} \cdot \overline{U}_o - \overline{U}_{unb} \right|$$

Figure 645: Equation

$U_{Neutral}$	Measured shunt capacitor neutral voltage
U_o	Measured open delta voltage
U_{unb}	Natural unbalance compensation component
n_{Uo}	Voltage ratio of open delta VT
U_{N_sr}	Rated secondary voltage of neutral connected VT
U_{N_pr}	Rated primary voltage of neutral connected VT

The rated *Primary voltage* and *Secondary voltage* for the neutral voltage channel $U_{Neutral}$, and for U_{N_pr} and U_{N_sr} are set in the global setting under **Configuration** > **Analog inputs** > **Voltage (Uo,VT)**.

The operating signal setting is given as multiple of the neutral VT rated voltage.

In monitored data, xUn refers to neutral VT rated voltage.

4.12.5.7 Application

Shunt capacitor banks are provided with an unbalance protection function which is mainly used to detect problems within capacitor units using the presumed symmetry in the impedances of the protected bank. The unbalance protection responds to unbalances in the measured signals caused by changes in the impedance of the capacitor bank.

In compensating unbalance protection, the operating signal compensates both the inherent capacitor bank unbalance and the system unbalance. The method involves measuring the residual voltage at the capacitor terminal side and at the neutral

side. The terminal side's residual voltage component is obtained directly by VTs connected in open delta or by deriving open delta voltage using all three terminal side phase voltages. The neutral side's residual voltage is measured directly by connecting a VT between the neutral point and earth. It is advisable to block the function with the fuse failure function.

Example 1, ungrounded SCB

Figure 646 illustrates how much the neutral voltage changes in case of failure of some phase elements of the ungrounded SCB.

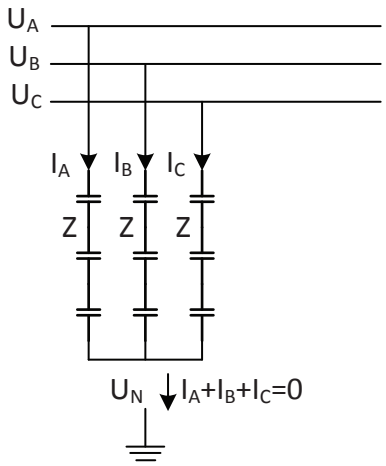

Figure 646: Ungrounded SCB

In a healthy ungrounded capacitor bank, the sum of the phase currents is

$$\bar{I}_A + \bar{I}_B + \bar{I}_C = 0$$

Figure 647: Equation

If the capacitor bank is symmetrical, that is, there is equal impedance in each phase, the equation can be

$$\left(\frac{\bar{U}_A - \bar{U}_N}{Z}\right) + \left(\frac{\bar{U}_B - \bar{U}_N}{Z}\right) + \left(\frac{\bar{U}_C - \bar{U}_N}{Z}\right) = 0$$

Figure 648: Equation

If the fault in the capacitor bank changes the phase A impedance to kZ

$$\left(\frac{\bar{U}_A - \bar{U}_N}{kZ}\right) + \left(\frac{\bar{U}_B - \bar{U}_N}{Z}\right) + \left(\frac{\bar{U}_C - \bar{U}_N}{Z}\right) = 0$$

Figure 649: Equation

$$\frac{\bar{U}_A}{kZ} + \frac{\bar{U}_B}{Z} + \frac{\bar{U}_C}{Z} = \bar{U}_N \cdot \left(\frac{1}{kZ} + \frac{2}{Z}\right)$$

Figure 650: Equation

$$\overline{U}_A + k \cdot \left(\overline{U}_B + \overline{U}_C\right) = \overline{U}_N \cdot \left(1 + 2 \cdot k\right)$$

Figure 651: Equation

If the system is symmetrical, that is, the system is healthy without any fault

$$\overline{U}_A + \overline{U}_B + \overline{U}_C = 0$$

Figure 652: Equation

Combining *Figure 651* and *Figure 652* results in

$$\overline{U}_A + k \cdot \left(-\overline{U}_A\right) = \overline{U}_N \cdot \left(1 + 2 \cdot k\right)$$

Figure 653: Equation

$$\overline{U}_N = \overline{U}_A \cdot \frac{\left(1 - k\right)}{\left(1 + 2 \cdot k\right)}$$

Figure 654: Equation

Considering the neutral VT ratio, per unit voltage referred to the neutral side is given by

$$\overline{U}_N = \frac{\overline{U}_A \cdot \frac{\left(1 - k\right)}{\left(1 + 2 \cdot k\right)}}{U_{N_pr}}$$

Figure 655: Equation

For example, if the impedance of the 20 kV system (U_A = 11.547 kV) capacitance drops by 5 percent, that is, k = 0.95, the neutral voltage is around 200 V according to *Figure 654*. If the voltage rating of a neutral VT is 20 kV/100 V, then in per unit terms refer to neutral side, the neutral voltage is around 0.01 · Un, that is, *Start value* should be set around 0.01.

In addition, assume that residual voltage (terminal side) is measured directly using an open-delta VT having ratio of $\frac{20kV}{\sqrt{3}} / \frac{100V}{\sqrt{3}} / \frac{100V}{3}$. Also, the *Primary voltage* and *Secondary voltage* settings under **Configuration** > **Analog inputs** > **Voltage (UoB,VT)** in a grounded system are set as 11.547 kV and 100 V, respectively. Similarly, if the VT connected at the neutral point has a ratio of $\frac{20kV}{\sqrt{3}} / \frac{100V}{\sqrt{3}}$, the *Primary voltage* and *Secondary voltage* settings under **Configuration** > **Analog inputs** > **Voltage (UoB,VT)** must be set as 20 kV and 100 V, respectively.

5 Protection related functions

5.1 Three-phase inrush detector INRPHAR (ANSI 68HB)

5.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase inrush detector	INRPHAR	3I2f>	68HB

5.1.2 Function block

Figure 656: Function block

5.1.3 Functionality

The three-phase inrush detector function INRPHAR is used to detect transformer inrush situations in distribution networks.

Transformer inrush detection is based on the following principle: the output signal BLK2H is activated once the numerically derived ratio of second harmonic current I_2H and the fundamental frequency current I_1H exceeds the set value.

The operate time characteristic for the function is of definite time (DT) type.

The function contains a blocking functionality. Blocking deactivates all outputs and resets timers.

5.1.4 Analog channel configuration

INRPHAR has one analog group input which must be properly configured.

Table 1103: Analog signals

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.1.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of INRPHAR can be described using a module diagram. All the modules in the diagram are explained in the next sections.

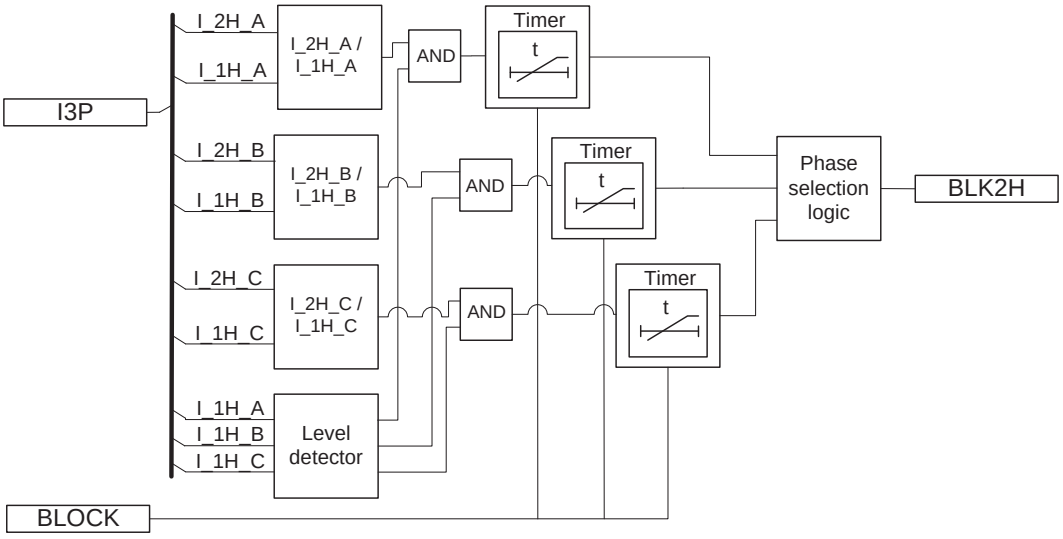

Figure 657: Functional module diagram

I_2H/I_1H

These modules calculate the ratio of the second harmonic (I_2H) and fundamental frequency (I_1H) of the phase currents. The calculated value is compared to the set *Start value*. If the calculated value exceeds the set *Start value*, the module output is activated.

Level detector

The output of the phase-specific level detector is activated when the fundamental frequency current I_1H exceeds the set *Min operate current* of the nominal current.

Timer

Once activated, Timer runs until the set *Operate delay time* value is exceeded. The time characteristics is according to DT. When the operation timer has reached the *Operate delay time* value, the Timer module output is activated. If the timer has

elapsed and the inrush situation still exists, the Timer module output remains active until the I_2H/I_1H ratio drops below the set *Start value* , that is, until the inrush situation is over. If the drop-off situation occurs within the operate time up counting, the reset timer is activated. If the drop-off time exceeds *Reset delay time* , the operate timer is reset.

The BLOCK input can be controlled with a binary input, a horizontal communication input or an internal signal of the relay program. The activation of the BLOCK input prevents the BLK2H output from being activated.

Phase selection logic

This module determines the number of phases used for activating the BLK2H output. If Num of start phases = "1 out of 3", an inrush on any of the phases activates output BLK2H. If the set value equals "2 out of 3", an inrush or at least two phases are required to activate output BLK2H.

5.1.6 Application

Transformer protections require high stability to avoid tripping during magnetizing inrush conditions. A typical example of an inrush detector application is doubling the start value of an overcurrent protection during inrush detection.

The inrush detection function can be used to selectively block overcurrent and earth-fault function stages when the ratio of the second harmonic component to the fundamental component exceeds the set value.

Other applications of this function include the detection of inrush in lines connected to a transformer.

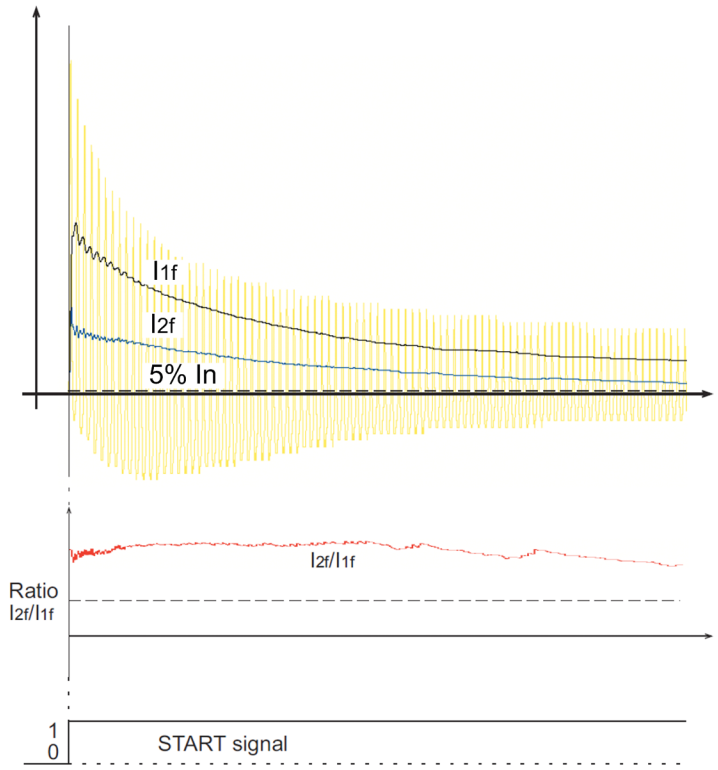

Figure 658: Inrush current in transformer

It is recommended to use the second harmonic and the waveform based inrush blocking from the transformer differential protection function TR2PTDF, if available.

5.2 Circuit breaker failure protection CCBRBRF (ANSI 50BF)

5.2.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Circuit breaker failure protection	CCBRBRF	3I>/Io>BF	50BF

5.2.2 Function block

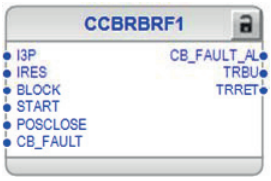

Figure 659: Function block

5.2.3 Functionality

The circuit breaker failure protection function CCBRBRF is activated by trip commands from the protection functions. The commands are either internal commands to the terminal or external commands through binary inputs. The start command is always a default for three-phase operation. CCBRBRF includes a three-phase conditional or unconditional retrip function, and also a three-phase conditional back-up trip function.

CCBRBRF uses the same levels of current detection for both retrip and back-up trip. The operating values of the current measuring elements can be set within a predefined setting range. The function has two independent timers for trip purposes: a retrip timer for the repeated tripping of its own breaker and a back-up timer for the trip logic operation for upstream breakers. A minimum trip pulse length can be set independently for the trip output.

The function contains a blocking functionality which can be used to block the function outputs.

5.2.4 Analog channel configuration

CCBRBRF has two analog group inputs which must be properly configured.

Table 1112: Analog inputs

Input	Description
I3P [1]	Three-phase currents, necessary when *CB failure mode* is set other than "Breaker status"
IRES [1]	Residual current (measured or calculated), necessary when *CB failure mode* is set other than "Breaker status"

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of CCBRBRF can be described using a module diagram. All the modules in the diagram are explained in the next sections. Also further information on the retrip and backup trip logics is given in sub-module diagrams.

[1] Can be connected to GRPOFF if *CB failure mode* is set to "Breaker status" and *CB fail retrip mode* is not set to "Current check".

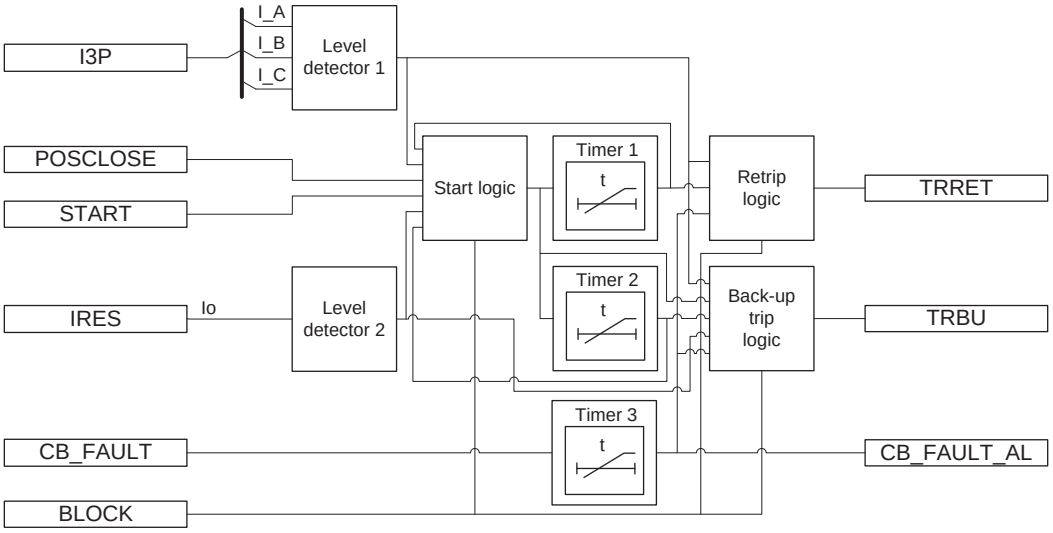

Figure 660: Functional module diagram

Level detector 1

The measured phase currents are compared phasewise to the set *Current value*. If the measured value exceeds the set *Current value*, the level detector reports the exceeding of the value to the start, retrip and backup trip logics. The parameter should be set low enough so that breaker failure situations with small fault current or high load current can be detected. The setting can be chosen in accordance with the most sensitive protection function to start the breaker failure protection.

Level detector 2

The measured residual current is compared to the set *Current value Res*. If the measured value exceeds the set *Current value Res*, the level detector reports the exceeding of the value to the start and backup trip logics. In high-impedance earthed systems, the residual current at phase-to-earth faults is normally much smaller than the short circuit currents. To detect a breaker failure at single-phase earth faults in these systems, it is necessary to measure the residual current separately. In effectively earthed systems, also the setting of the earth-fault current protection can be chosen at a relatively low current level. The current setting should be chosen in accordance with the setting of the sensitive earth-fault protection.

Start logic

Start logic is used to manage the starting of Timer 1 and Timer 2. It also resets the function after the circuit breaker failure is handled. On the rising edge of the `START` input, the enabling signal is sent to Timer 1 and Timer 2. Typically, the `START` input is activated when any protection function operates and trips the circuit breaker.

The Start logic module is reset depending on the settings *CB failure mode* and *CB failure trip mode* as shown in *Table 1113*. In all cases in *Table 1113*, however, the resetting is possible only after 150 ms from the activation of Start logic. This time is for ensuring correct operation in case of oscillation in the starting signal.

Table 1113: Start logic operation

Value of setting CB failure mode	Value of setting CB failure trip mode	Start logic reset condition
Current	1 out of 3	All phase currents drop below *Current value* setting.
	1 out of 4	All phase currents drop below *Current value* setting and the residual current drops below *Current value Res* setting.
	2 out of 4	Either of the following is true: • All phase currents drop below *Current value* setting. • The residual current drops below *Current value Res* setting and (at least) two phases are below *Current value* setting.
Breaker status	1 out of 3 1 out of 4 2 out of 4	CB is in open position.
Both(AND)	1 out of 3	Either of the following is true: • CB is in open position. • All phase currents drop below *Current value* setting.
	1 out of 4	Either of the following is true: • CB is in open position. • All phase currents drop below *Current value* setting and the residual current drops below *Current value Res* setting.
	2 out of 4	One of the following is true: • CB is in open position. • All phase currents drop below *Current value* setting. • The residual current drops below *Current value Res* setting and (at least) two phases are below *Current value* setting.
Both(OR)	1 out of 3	CB is in open position and all phase currents drop below *Current value* setting.
	1 out of 4	CB is in open position and all phase currents drop below *Current value* setting and the residual current drops below *Current value Res* setting.
	2 out of 4	CB is in open position and either of the following is true: • All phase currents drop below *Current value* setting.

Value of setting CB failure mode	Value of setting CB failure trip mode	Start logic reset condition
		• The residual current drops below *Current value Res* setting and (at least) two phases are below *Current value* setting.

In addition, the function is immediately reset if:

- *Start latching mode* is set to "Level sensitive", and the START signal is deactivated. The recommended setting value is "Rising edge".
- The BLOCK input is activated.

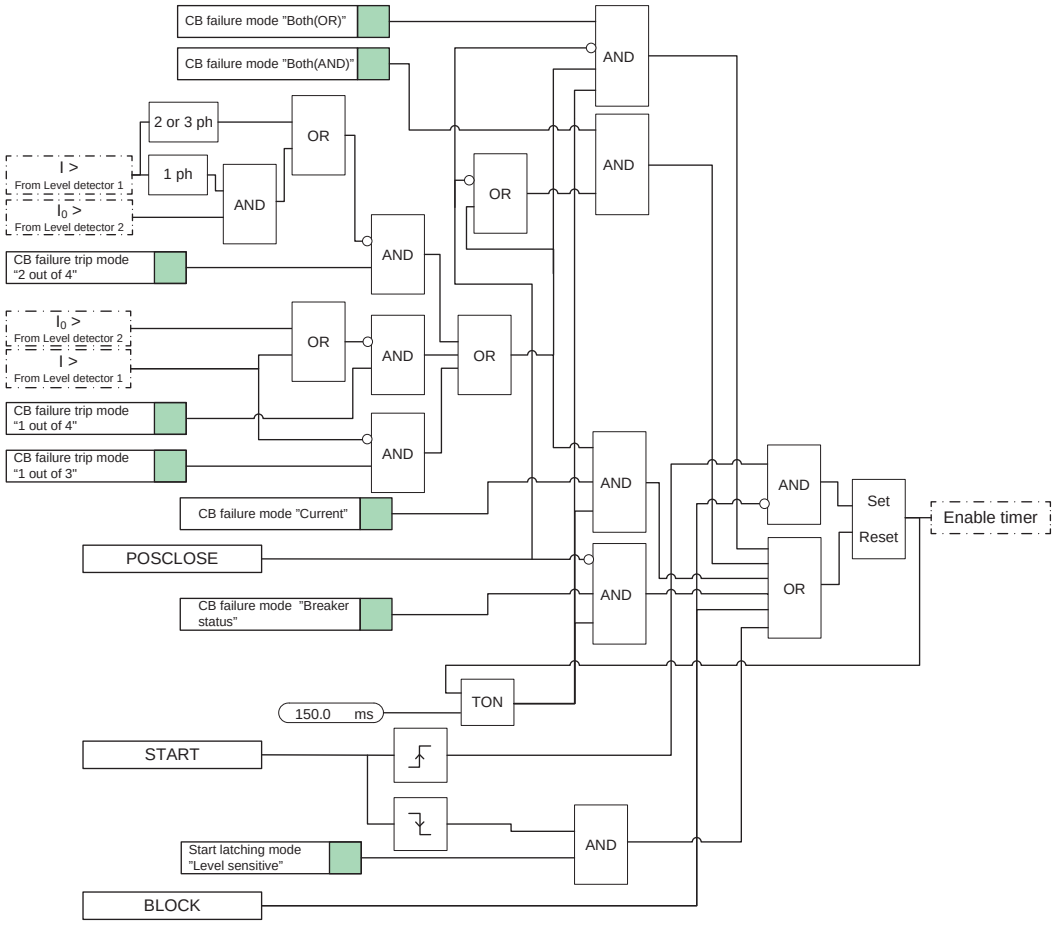

Figure 661: Start logic

Timer 1

Once activated, the timer runs until the set *Retrip time* value has elapsed. The time characteristic is according to DT. When the operation timer has reached the value set with *Retrip time*, the retrip logic is activated. A typical setting is 0...50 ms.

Timer 2

Once activated, the timer runs until the set *CB failure delay* value has elapsed. The time characteristic is according to DT. When the operation timer has reached the set maximum time value *CB failure delay*, the backup trip logic is activated. The value of

this setting is made as low as possible at the same time as any unwanted operation is avoided. A typical setting is 90 - 150 ms, which is also dependent on the retrip timer.

The minimum time delay for the CB failure delay can be estimated as:

$$CBfailuredelay \geq Retriptime + t_{cbopen} + t_{BFP_reset} + t_{margin}$$

(Equation 291)

t_{cbopen}	Maximum opening time for the circuit breaker
t_{BFP_reset}	Maximum time for the breaker failure protection to detect the correct breaker function (the current criteria reset)
t_{margin}	Safety margin

It is often required that the total fault clearance time is less than the given critical time. This time often depends on the ability to maintain transient stability in case of a fault close to a power plant.

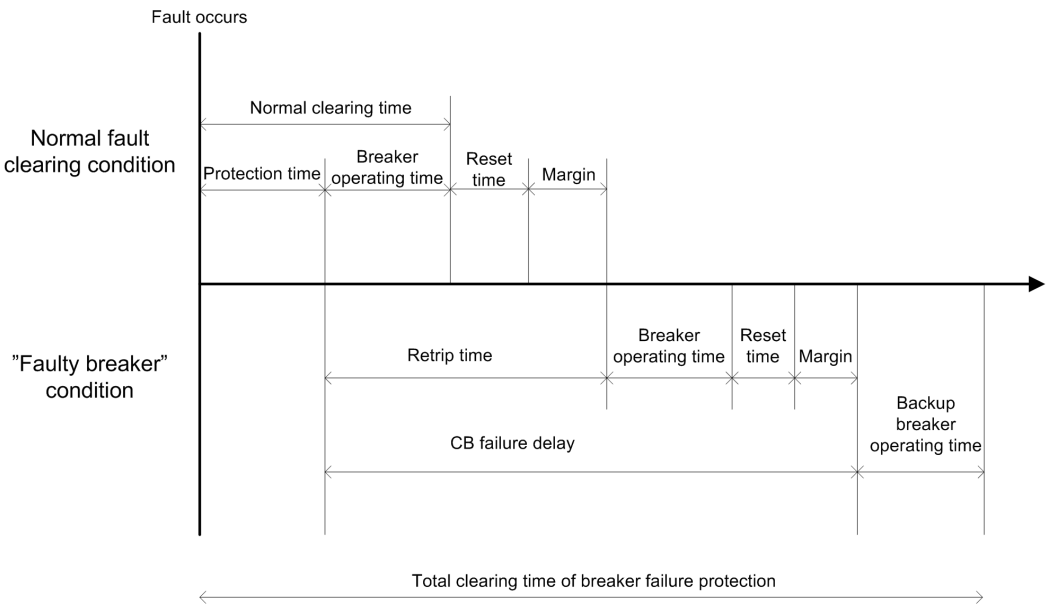

Figure 662: Timeline of the breaker failure protection

Timer 3

This module is activated by the CB_FAULT signal. Once activated, the timer runs until the set *CB fault delay* value has elapsed. The time characteristic is according to DT. When the operation timer has reached the maximum time value *CB fault delay*, the CB_FAULT_AL output is activated. After the set time, an alarm is given so that the circuit breaker can be repaired. A typical value is 5 s.

Retrip logic

Timer 1 activates Retrip logic, which can be used to give a retrip signal TRRET for the main circuit breaker. The operation of Retrip logic depends on the settings *CB failure mode* and *CB fail retrip mode* as shown in *Table 1114*.

Table 1114: Retrip logic operation

Value of setting CB fail retrip mode	Value of setting CB failure mode	Retrip functionality
Off	Current Breaker status Both(AND) Both(OR	Retrip functionality switched off. TRRET is not activated.
Without Check	Current Breaker status Both(AND) Both(OR	TRRET is activated after Timer 1 elapses.
Current check	Current	TRRET is activated after Timer 1 elapses and any phase current exceeds *Current value* setting.
	Breaker status	TRRET is activated after Timer 1 elapses and CB is in closed position.
	Both(AND)	TRRET is activated after Timer 1 elapses and CB is in closed position and any phase current exceeds *Current value* setting.
	Both(OR)	TRRET is activated after Timer 1 elapses and either of the following is true: • CB is in closed position. • Any phase current exceeds *Current value* setting.

TRRET activation is blocked if either CB_FAULT_AL output (from Timer 3) is active or the BLOCK input is activated.

Once activated, TRRET remains active for the set *Trip pulse time* or until the reasons for activation are reset. TRRET is also reset if CB_FAULT_AL or BLOCK is activated.

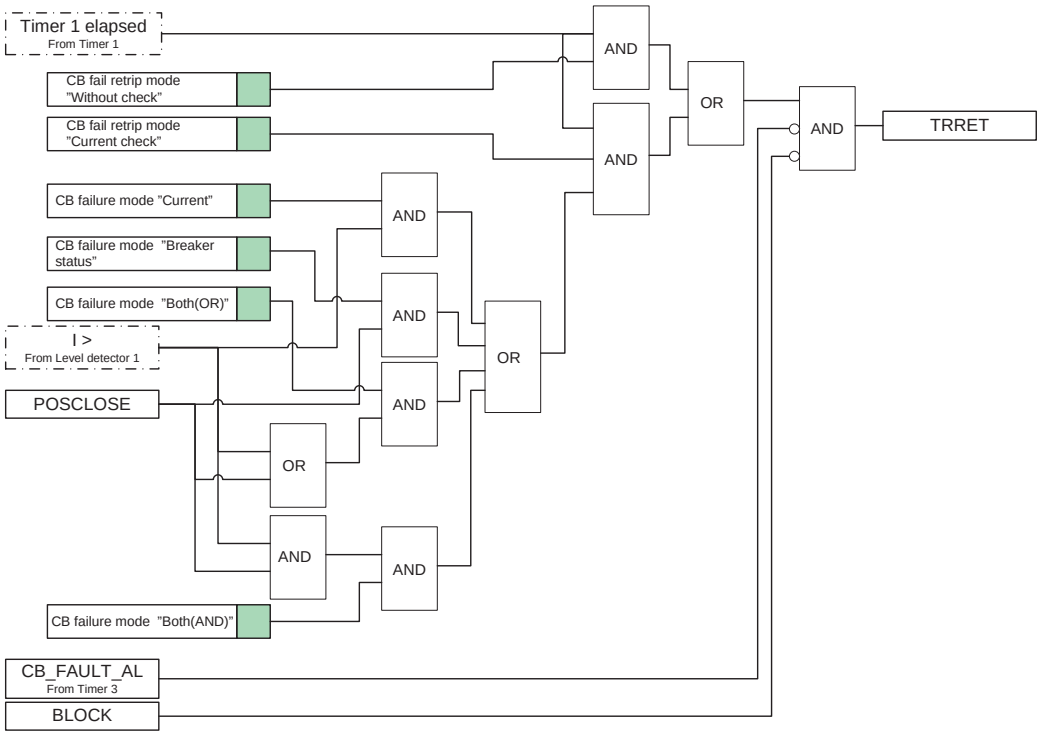

Figure 663: Retrip logic

Backup trip logic

Timer 2 activates Backup trip logic, which gives a backup trip TRBU for the upstream circuit breaker if the main circuit breaker fails to clear the fault. Backup trip logic is also activated if the timer-enabling signal from the Start logic module (rising edge of the START input detected) and CB_FAULT_AL are both active.

The operation of Backup trip logic depends on the settings *CB failure mode* and *CB failure trip* mode as shown in *Table 1115*.

Table 1115: Backup trip logic operation

Value of setting CB failure mode	Value of setting CB failure trip mode	Conditions for activating Backup trip logic
Current	1 out of 3	Any phase current exceeds *Current value* setting.
	1 out of 4	Either of the following is true: • Any phase current exceeds *Current value* setting. • The residual current exceeds *Current value Res* setting.
	2 out of 4	Either of the following is true: • Any phase current exceeds *Current value* setting and the residual current exceeds *Current value Res* setting.

Table continues on the next page

Value of setting CB failure mode	Value of setting CB failure trip mode	Conditions for activating Backup trip logic
		• Two or three phase currents exceed *Current value* setting.
Breaker status	1 out of 3 1 out of 4 2 out of 4	CB is in closed position.
Both(AND)	1 out of 3	CB is in closed position and any phase current exceeds *Current value* setting.
	1 out of 4	CB is in closed position and either of the following is true: • Any phase current exceeds *Current value* setting. • The residual current exceeds *Current value Res* setting.
	2 out of 4	CB is in closed position and either of the following is true: • Any phase current exceeds *Current value* setting and the residual current exceeds *Current value Res* setting. • Two or three phase currents exceed *Current value* setting.
Both(OR)	1 out of 3	Either of the following is true: • CB is in closed position. • Any phase current exceeds *Current value* setting.
	1 out of 4	One of the following is true: • CB is in closed position. • Any phase current exceeds *Current value* setting. • The residual current exceeds *Current value Res* setting.
	2 out of 4	One of the following is true: • CB is in closed position. • Any phase current exceeds *Current value* setting and the residual current exceeds *Current value Res* setting. • Two or three phase currents exceed *Current value* setting.

Once activated, TRBU remains active until the set *Trip pulse time* or until the reasons for activation are reset. TRRET is also reset if BLOCK is activated.

In most applications, "1 out of 3" is sufficient.

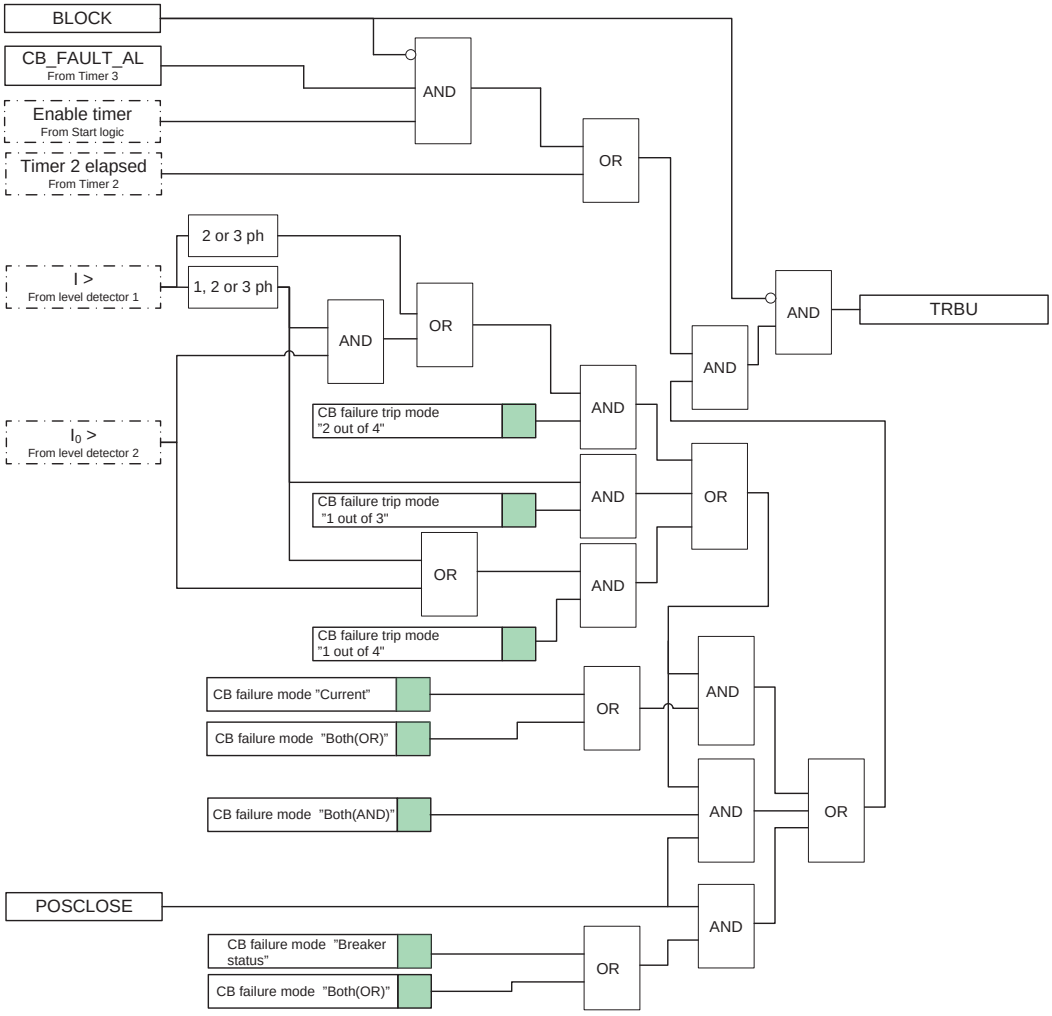

Figure 664: Backup trip logic

5.2.6 Application

The n-1 criterion is often used in the design of a fault clearance system. This means that the fault is cleared even if some component in the fault clearance system is faulty. A circuit breaker is a necessary component in the fault clearance system. For practical and economical reasons, it is not feasible to duplicate the circuit breaker for the protected component, but breaker failure protection is used instead.

The breaker failure function issues a backup trip command to up-stream circuit breakers in case the original circuit breaker fails to trip for the protected component. The detection of a failure to break the current through the breaker is made by measuring the current or by detecting the remaining trip signal (unconditional).

CCBRBRF can also retrip. This means that a second trip signal is sent to the protected circuit breaker. The retrip function is used to increase the operational reliability of the breaker. The function can also be used to avoid backup tripping of several breakers in case mistakes occur during protection relay maintenance and tests.

CCBRBRF is initiated by operating different protection functions or digital logics inside the protection relay. It is also possible to initiate the function externally through a binary input.

CCBRBRF can be blocked by using an internally assigned signal or an external signal from a binary input. This signal blocks the function of the breaker failure protection even when the timers have started or the timers are reset.

The retrip timer is initiated after the start input is set to true. When the pre-defined time setting is exceeded, CCBRBRF issues the retrip and sends a trip command, for example, to the circuit breaker's second trip coil. Both a retrip with current check and an unconditional retrip are available. When a retrip with current check is chosen, the retrip is performed only if there is a current flow through the circuit breaker.

The backup trip timer is also initiated at the same time as the retrip timer. If CCBRBRF detects a failure in tripping the fault within the set backup delay time, which is longer than the retrip time, it sends a backup trip signal to the chosen backup breakers. The circuit breakers are normally upstream breakers which feed fault current to a faulty feeder.

The backup trip always includes a current check criterion. This means that the criterion for a breaker failure is that there is a current flow through the circuit breaker after the set backup delay time.

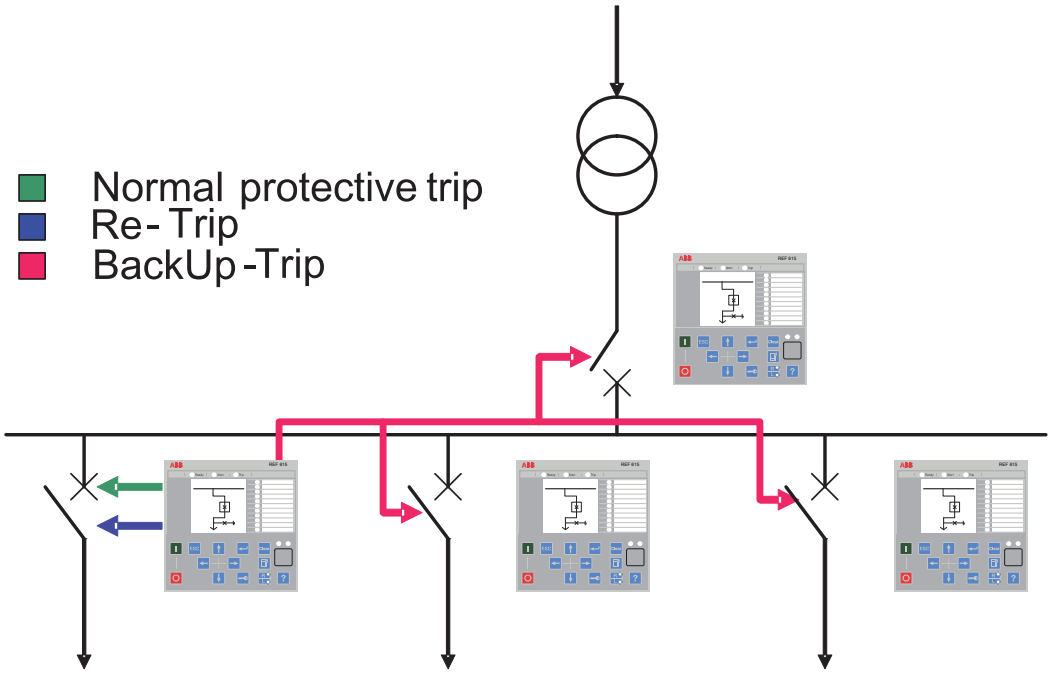

Figure 665: Typical breaker failure protection scheme in distribution substations

5.3 Master trip TRPPTRC (ANSI 94/86)

5.3.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Master trip	TRPPTRC	Master Trip	94/86

5.3.2 Function block

Figure 666: Function block

5.3.3 Functionality

The master trip function TRPPTRC is used as a trip command collector and handler after the protection functions. The features of this function influence the trip signal behavior of the circuit breaker. The minimum trip pulse length can be set when the non-latched mode is selected. It is also possible to select the latched or lockout mode for the trip signal.

5.3.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

When the TRPPTRC function is disabled, all trip outputs intended to go through the function to the circuit breaker trip coil are blocked.

The operation of TRPPTRC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

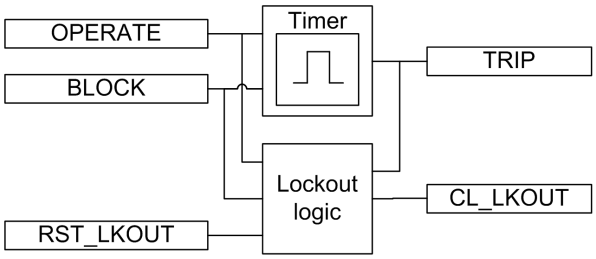

Figure 667: Functional module diagram

Timer

The duration of the TRIP output signal from TRPPTRC can be adjusted with the *Trip pulse time* setting when the "Non-latched" operation mode is used. The pulse length should be long enough to secure the opening of the breaker. For three-pole tripping, TRPPTRC has a single input OPERATE, through which all trip output signals are routed from the protection functions within the protection relay, or from external protection functions via one or more of the protection relay's binary inputs. The function has a single trip output TRIP for connecting the function to one or more of the protection relay's binary outputs, and also to other functions within the protection relay requiring this signal.

The BLOCK input blocks the TRIP output and resets the timer.

Lockout logic

TRPPTRC is provided with possibilities to activate a lockout. When activated, the lockout can be manually reset after checking the primary fault by activating the RST_LKOUT input or from the LHMI clear menu parameter. When using the "Latched" mode, the resetting of the TRIP output can be done similarly as when using the "Lockout" mode. It is also possible to reset the "Latched" mode remotely through a separate communication parameter.

The minimum pulse trip function is not active when using the "Lockout" or "Latched" modes but only when the "Non-latched" mode is selected.

The CL_LKOUT and TRIP outputs can be blocked with the BLOCK input.

Table 1123: Operation modes for the TRPPTRC trip output

Mode	Operation
Non-latched	The *Trip pulse length* parameter gives the minimum pulse length for TRIP
Latched	TRIP is latched ; both local and remote clearing is possible.
Lockout	TRIP is locked and can be cleared only locally via menu or the RST_LKOUT input.

5.3.5 Application

All trip signals from different protection functions are routed through the trip logic. The most simplified application of the logic function is linking the trip signal and ensuring that the signal is long enough.

The tripping logic in the protection relay is intended to be used in the three-phase tripping for all fault types (3ph operating). To prevent the closing of a circuit breaker after a trip, TRPPTRC can block the CBXCBR closing.

TRPPTRC is intended to be connected to one trip coil of the corresponding circuit breaker. If tripping is needed for another trip coil or another circuit breaker which needs, for example, different trip pulse time, another trip logic function can be used. The two instances of the PTRC function are identical, only the names of the functions, TRPPTRC1 and TRPPTRC2, are different. Therefore, even if all references are made only to TRPPTRC1, they also apply to TRPPTRC2.

The inputs from the protection functions are connected to the `OPERATE` input. Usually, a logic block OR is required to combine the different function outputs to this input. The `TRIP` output is connected to the binary outputs on the IO board. This signal can also be used for other purposes within the protection relay, for example when starting the breaker failure protection.

TRPPTRC is used for simple three-phase tripping applications.

5.4 High-impedance fault detection PHIZ (ANSI HIZ)

5.4.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
High-impedance fault detection	PHIZ	HIF	HIZ

5.4.2 Function block

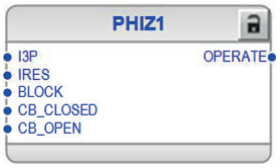

Figure 669: Function block

5.4.3 Functionality

A small percentage of earth faults have a very large impedance. They are comparable to load impedance and consequently have very little fault current. These high-impedance faults do not pose imminent danger to power system equipment. However, they are a substantial threat to humans and properties; people can touch or get close to conductors carrying large amounts of energy.

ABB has developed a patented technology (US Patent 7,069,116 B2 June 27, 2006, US Patent 7,085,659 B2 August 1, 2006) to detect a high-impedance fault.

The high-impedance fault detection function PHIZ also contains a blocking functionality. It is possible to block function outputs, if desired.

5.4.4 Analog channel configuration

PHIZ has two analog group inputs which must be properly configured.

Table 1128: Analog inputs

Input	Description
I3P	Three-phase currents
IRES	Residual current (measured or calculated)

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.4.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

PHIZ uses a multi-algorithm approach. Each algorithm uses various features of earth currents to detect a high-impedance fault.

Although the PHIZ algorithm is very sophisticated, the setting required to operate the function is simple. The *Security Level* setting, with the setting range of 1 to 10, is set to strike a balance between the extremes of security and dependability which together constitute the reliability of any system. The setting value “10” is more secure than “1”.

The higher the *Security Level* setting, the lower the probability of false detection, but the system might miss out some genuine fault. On the other hand, a lower setting would make the system operate more dependably for high-impedance faults in the line, but the operation is more likely for other transients in the system. There are events in electrical networks which can cause similar current waveforms like high-impedance faults. These events could then be detected by the PHIZ algorithm causing unnecessary detections. Normally, electrical network operator does not know the existence of these events well and those can also be happening very randomly. The effect is also always dependent on event location compared to protection relay measurement location. All these facts make the PHIZ algorithm operation in certain electrical networks quite hard to measure and forecast beforehand. There is not any direct formula which can calculate the exact right setting based on known electrical network parameters.

It is hence recommended to set the value midway to “5” initially. Based on experience and confidence gained in a particular application, the setting can be moved either side. In many cases, it would be a good practice to use PHIZ as an indicative function during a piloting phase, until enough experience has been gathered and a suitable setting found.

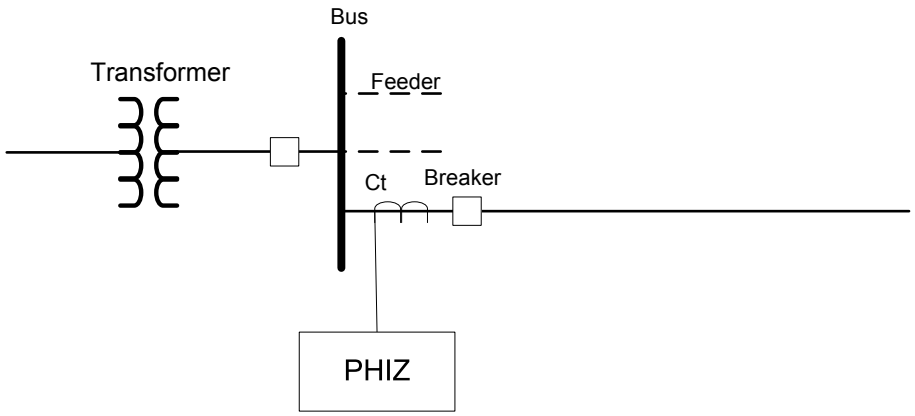

Figure 670: Electrical power system equipped with PHIZ

Power system signals are acquired, filtered and then processed by individual high-impedance fault detection algorithm. The results of these individual algorithms are further processed by a decision logic to provide the detection decision. The decision logic can be modified depending on the application requirement.

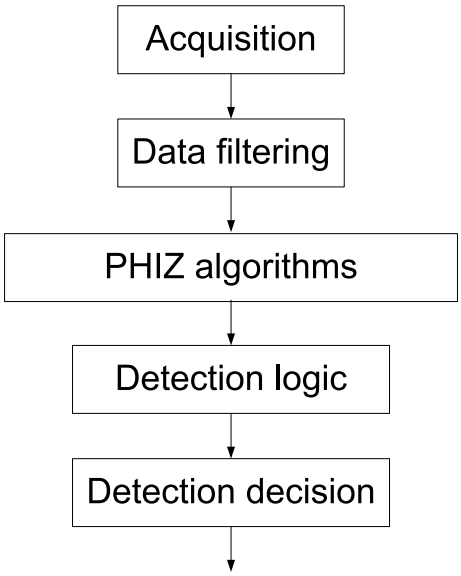

Figure 671: Block diagram of PHIZ

PHIZ is based on algorithms that use earth current signatures which are considered non-stationary, temporally volatile and of various burst duration. All harmonic and non-harmonic components within the available data window can play a vital role in the high-impedance fault detection. A major challenge is to develop a data model that acknowledges that high-impedance faults could take place at any time within the observation window of the signal and could be delayed randomly and attenuated substantially. The model is motivated by extensive research, actual experimental observations in the laboratory, field testing and what traditionally represents an accurate depiction of a non-stationary signal with a time-dependent spectrum.

Figure 672: Validation of PHIZ on gravel

Figure 673: Validation of PHIZ on concrete

Figure 674: Validation of PHIZ on sand

Figure 675: Validation of PHIZ on grass

5.4.6 Application

PHIZ is used to detect a downed conductor dropping to a very resistive ground, causing an earth fault which is very difficult to detect by a conventional protection relay functionality. PHIZ is then targeted to be used with overhead lines. PHIZ must be used in electrical networks with efficiently grounded or isolated neutral.

Electric power lines experience faults for many reasons. In most cases, electrical faults manifest in mechanical damage, which must be repaired before returning the line to service.

Most of the electrical network faults are earth faults. Conventional protection systems based on overcurrent, impedance or other principles are suitable for detecting relatively low-impedance faults which have a relatively high fault current.

However, a small percentage of the earth faults have a very large impedance. They are comparable to load impedance and consequently have very little fault current. These high-impedance faults do not pose imminent danger to power system equipment. However, they are a considerable threat to people and property. The IEEE Power System Relay Committee working group on High Impedance Fault Detection Technology defines High Impedance Faults as those that 'do not produce enough fault current to be detectable by conventional overcurrent relays or fuses.

PHIZ always needs sensitive Io measurement.

High-impedance fault (PHIZ) detection requires a different approach than that for conventional low-impedance faults. Reliable detection of PHIZ provides safety to humans and animals. ABB has developed innovative technology for highimpedance fault detection with over ten years of research resulting in many successful field tests.

5.5 Binary signal transfer BSTGAPC (ANSI BST)

5.5.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Binary signal transfer	BSTGAPC	BST	BST

5.5.2 Function block

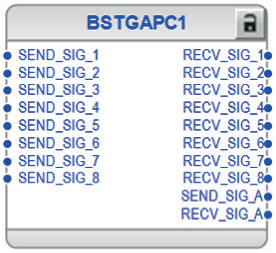

Figure 676: Function block

5.5.3 Functionality

The binary signal transfer function BSTGAPC is used for transferring binary signals between the local and remote end line differential protection relays. The function includes eight binary signals that are transferred in the protection communication telegram and can be freely configured and used for any purpose in the line differential application.

BSTGAPC transfers binary data continuously over the protection communication channel between the terminals. Each of the eight signals are bidirectional and the binary data sent locally is available remotely as a received signal.

BSTGAPC includes a minimum pulse time functionality for the received binary signals. Each received signal has its own minimum pulse time setting parameter.

BSTGAPC includes two alarm output signals. The SEND_SIG_A output signal is updated according to the status of the sent binary signals. The RECV_SIG_A output signal is updated according to the status of the received binary signals. Each signal can be separately included or excluded from the alarm logic with a setting parameter.

5.5.4 Operation principle

The *Signal 1...8 mode* setting can be used for changing the operation of the bidirectional signal channel. The signal channel can be disabled by setting the corresponding parameter value to “Not in use”. When the signal channel is disabled locally or remotely, the corresponding RECV_SIG_1...8 signal status is always false on both ends.

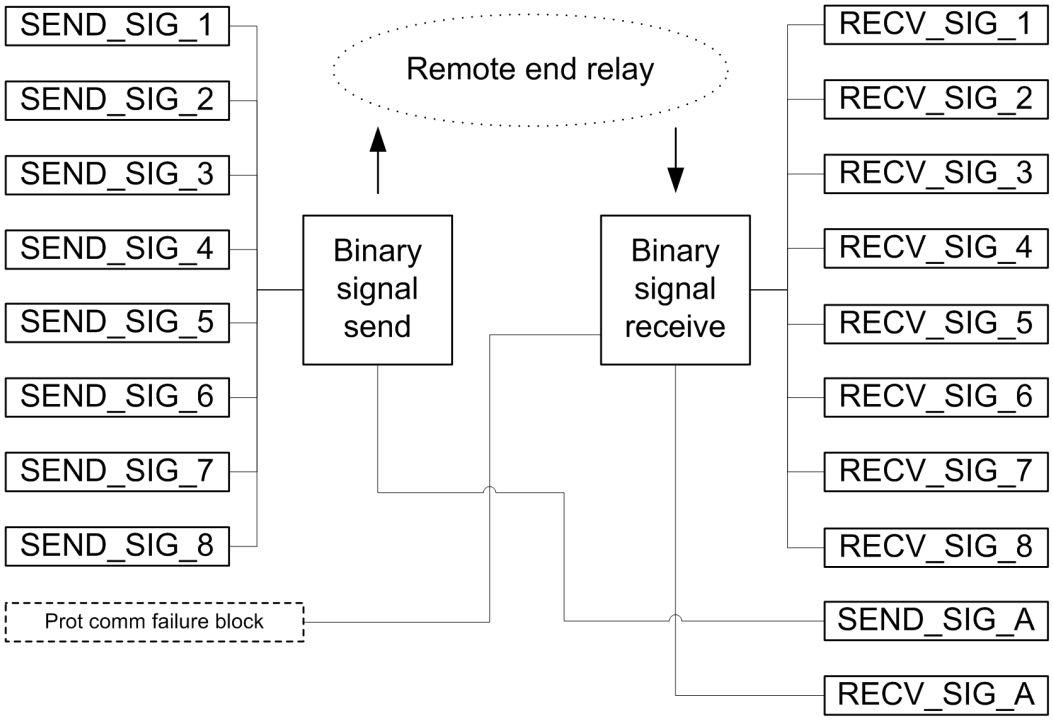

Figure 677: Functional module diagram

Binary signal send

The status of the inputs is continuously sent in the line differential protection telegrams. SEND_SIG_A can be used for alarming based on the status of SEND_SIG_1...8. By selecting the signal mode as "In use, alarm sel.", the sending status of the corresponding signal affects also the activation criteria of SEND_SIG_A. Further, in case more than one signal channels are selected into the alarm logic, the activation criteria can be defined according to "Any of selected" (OR) or "All of selected" (AND).

Binary signal receive

The function receives continuous binary data within the protection telegrams from the remote end protection relay. This received binary data status is then available as the RECV_SIG_1...8 outputs on the local end protection relay. RECV_SIG_A

can be used for alarming based on the status of RECV_SIG_1...8. By selecting the signal mode as "In use, alarm sel.", the received status of the corresponding signal affects the activation criteria of RECV_SIG_A. Further, in case more than one signal channels are selected into the alarm logic, the activation criteria can be defined according to "Any of selected" (OR) or "All of selected" (AND). Each signal has also the *Pulse time 1...8* setting that defines the minimum pulse length for RECV_SIG_1...8. Also, in case the protection communication supervision detects a failure in the communication, the RECV_SIG_1...8 outputs are not set to false sooner than the minimum pulse length defined is first ensured for each signal.

5.5.5 Application

Among with the analog data, the binary data can also be exchanged with the line differential protection relays. The usage of the binary data is application specific and can vary in each separate case. The demands for the speed of the binary signals vary depending on the usage of the data. When the binary data is used as blocking signals for the line differential protection, the transfer response is extremely high. Binary signal interchange can be used in applications such as:

- Remote position indications
- Inter-tripping of the circuit breakers on both line ends
- Blocking of the line differential protection during transformer inrush or current circuit supervision failure
- Protection schemes; blocking or permissive
- Remote alarming

The figure shows the overall chain to transfer binary data in an example application. The position indication of the local circuit breaker is connected to the protection relay's input interface and is then available for the relay configuration. The circuit breaker position indication is connected to the first input of BSTGAPC which is used to send information to the remote end via communication. In the remote end, this information is handled as a remote circuit breaker open position and it is available from the first output of BSTGAPC. This way the information can be exchanged.

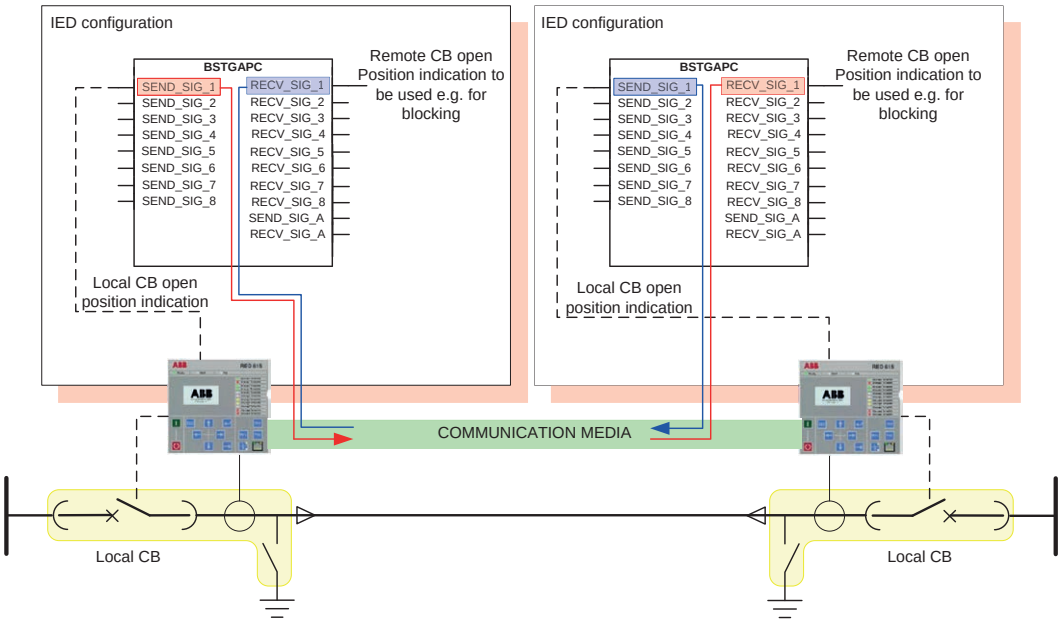

Figure 678: Example of usage of binary signal transfer for position indication change

Additional dedicated channel can be used to transfer binary signal infor-mation quickly without the need to configure GOOSE. This minimizes the configuration effort since configuration templates can be directly used when signal transfer is required only for point to point instead of multipoint.

In addition to X6 Ethernet port which is tied to PCSITPC1 and BSTGAPC1-2, X3 Ethernet port can be configured to dedicated channel mode. It also requires PCSITPC2 block for supervision and one of the BSTGAPC3-4 for signal connections. Analog signals are not available for this channel.

Dedicated channel	Functions	Description
Ethernet Port X6	BSTGAPC1-2, PCSITPC1, LNPLDF1	Includes analog data and can be used for line differential application as well as for binary signal transfer.
Ethernet Port X3	BSTGAPC3-4, PCSITPC2	Analog data cannot be either send or received. Only used for binary signal transfer. Ethernet port must be set to dedicated channel mode.

Relay pairs exchanging only binary signals can be connected to either port. However, one must verify that connector types match especially when X3 is connected to X6 (SFP module).

5.6 Emergency start-up ESMGAPC (ANSI EST,62)

5.6.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Emergency start-up	ESMGAPC	ESTART	EST,62

5.6.2 Function block

Figure 679: Function block

5.6.3 Functionality

An emergency condition can arise in cases where the motor needs to be started despite knowing that this can increase the temperature above limits or cause a thermal overload that can damage the motor. The emergency start-up function ESMGAPC allows motor start-ups during such emergency conditions. ESMGAPC is only to force the protection relay to allow the restarting of the motor. After the emergency start input is activated, the motor can be started normally. ESMGAPC itself does not actually restart the motor.

The function contains a blocking functionality. It is possible to block function outputs, timer or the function itself.

5.6.4 Analog channel configuration

ESMGAPC has one analog group input which must be properly configured.

Table 1139: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing

blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.6.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of ESMGAPC can be described using a module diagram. All the modules in the diagram are explained in the next sections.

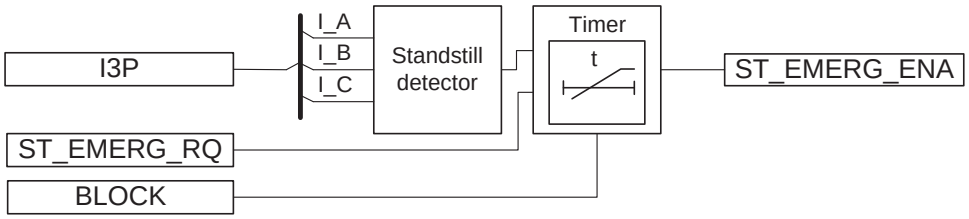

Figure 680: Functional module diagram

Standstill detector

The module detects if the motor is in a standstill condition. The standstill condition can be detected based on the phase current values. If all three phase currents are below the set value of *Motor standstill A*, the motor is considered to be in a standstill condition.

Timer

The timer is a fixed 10-minute timer that is activated when the ST_EMERG_RQ input is activated and motor standstill condition is fulfilled. Thus, the activation of the ST_EMERG_RQ input activates the ST_EMERG_ENA output, provided that the motor is in a standstill condition. The ST_EMERG_ENA output remains active for 10 minutes or as long as the ST_EMERG_RQ input is high, whichever takes longer.

The activation of the BLOCK input blocks and also resets the timer.

The function also provides the ST_EMERG_ENA output change date and time, T_ST_EMERG. The information is available in the monitored data view.

5.6.6 Application

If the motor needs to be started in an emergency condition at the risk of damaging the motor, all the external restart inhibits are ignored, allowing the motor to be restarted. Furthermore, if the calculated thermal level is higher than the restart inhibit level at an emergency start condition, the calculated thermal level is set slightly below the restart inhibit level. Also, if the register value of the cumulative start-up time counter exceeds the restart inhibit level, the value is set slightly below the restart disable value to allow at least one motor start-up.

The activation of the ST_EMERG_RQ digital input allows to perform emergency start. The protection relay is forced to a state which allows the restart of motor, and the operator can now restart the motor. A new emergency start cannot be made

until the 10 minute time-out has passed or until the emergency start is released, whichever takes longer.

The last change of the emergency start output signal is recorded.

5.7 Fault locator SCEFRFLO (ANSI FLOC)

5.7.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Fault locator	SCEFRFLO	FLOC	FLOC

5.7.2 Function block

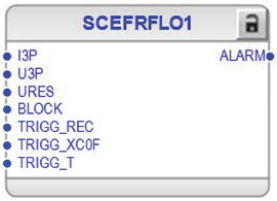

Figure 681: Function block

5.7.3 Functionality

The fault locator function SCEFRFLO provides impedance-based fault location. It is designed for radially operated distribution systems, and it can locate short circuits in all kinds of distribution networks. Earth faults can be located in effectively earthed and in low-resistance or low-reactance earthed networks. With certain limitations, SCEFRFLO can also be used for locating an earth fault in unearthed distribution networks. Moreover, SCEFRFLO can be applied to compensated (resonant earthed) networks where an earth-fault current raising resistor is connected in parallel with the arc suppression coil. The location of the continuous low-ohmic earth fault can be determined by using the switching of the parallel resistor of the coil during an earth fault.

The fault distance calculation is based on the locally measured fundamental frequency current and voltage phasors. The full operation of SCEFRFLO requires all phase currents and phase-to-earth voltages to be measured.

The fault distance estimate is obtained when SCEFRFLO is externally or internally triggered.

5.7.4 Analog channel configuration

SCEFRFLO has three analog group inputs which must be properly configured.

Table 1147: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages
URES [1]	Residual voltage (measured), necessary when the phase-to-phase voltages are measured and Phase voltage Meas is set to "Accurate"

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

[1] Can be connected to GRPOFF if *Phase voltage Meas* is set to "Ph-to-ph without Uo"

Table 1148: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.7.5 Operation principle

The function can be enabled or disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of SCEFRFLO can be described with a module diagram. All the modules in the diagram are explained in the next sections.

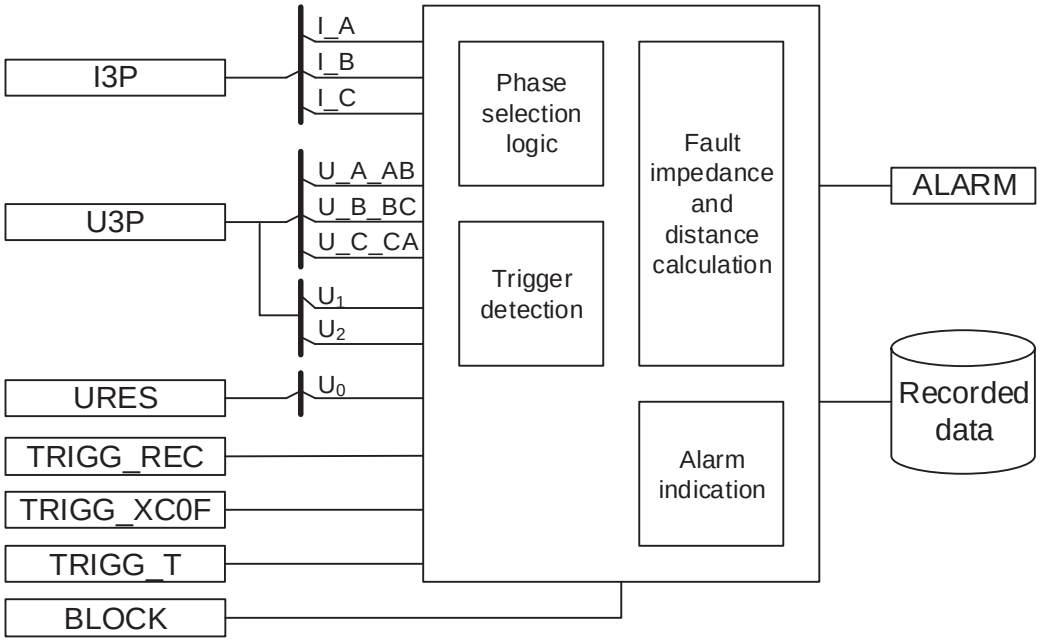

Figure 682: Functional module diagram

The fault distance calculation is done in two steps. First, the fault type is determined with the in-built Phase selection logic (PSL). Second, based on the selected impedance measuring element (fault loop) the fault distance from the measuring point to the fault location is calculated.

The phase current magnitude's minimum threshold value is 1 % xIn.

5.7.5.1 Phase selection logic

Phase selection logic identifies the faulty phases based on a combined impedance and current criterion. Phase selection logic is virtually setting-free and has only one parameter, *Z Max phase load*, for discriminating a heavy symmetrical load from a three-phase fault. The setting *Z Max phase load* can be calculated using the equation

$$Z\,Max\ phase\,load = 0.8 \cdot \frac{U_{xy}^2}{S_{max}}$$

(Equation 292)

U_{xy}	Nominal phase-to-phase voltage
S_{max}	Maximum three-phase load

For example, if U_{xy} = 20 kV and S_{max} = 1 MVA, then *Z Max phase load* = 320.0 Ω.

The identification of the faulty phases is compulsory for the correct operation of SCEFRFLO. This is because only one of the impedance-measuring elements (fault loops) provides the correct result for a specific fault type. A three-phase fault is an exception and theoretically it can be calculated with any of the fault loops. The fault loop used in the fault distance calculation is indicated in the recorded data Flt loop as specified in *Table 1149*.

Table 1149: Fault types and corresponding fault loops

Fault type	Description	Flt loop
-	No fault	No fault
A-E	Phase A-to-earth fault	AG Fault
B-E	Phase B-to-earth fault	BG Fault
C-E	Phase C-to-earth fault	CG Fault
A-B	Phase A-to-B short circuit fault	AB Fault
B-C	Phase B-to-C short circuit fault	BC Fault
C-A	Phase C-to-A short circuit fault	AC Fault
A-B-C-(E)	Three-phase short circuit	ABC Fault

In case of two-phase-to-earth-faults (A-B-E, B-C-E or C-A-E), the selected fault loop depends on the location of the earth faults. When the faults are located at the same feeder, the corresponding phase-to-phase loop (“AB Fault”, “BC Fault” or “CA Fault”) is used for calculation. When the faults are located at different feeders, the phase-to-earth loop (“AG Fault”, “BG Fault” or “CG Fault”) corresponding to the faulty phase at the protected feeder is used for calculation.

5.7.5.2 Fault impedance and distance calculation

As soon as a fault condition is recognized by Phase selection logic, the fault distance calculation is started with one of the seven impedance-measuring elements, that is, the fault loops. SCEFRFLO uses independent algorithms for each fault type to achieve optimal performance.

The inherent result from the fault distance calculation is the ohmic fault loop impedance value.

Table 1150: The calculated impedance values available in the recorded data

Impedance valule	Description
Flt phase reactance	Estimated positive sequence reactance from the substation to the fault location in primary ohms.
Flt point resistance	Fault resistance value in the fault spot in primary ohms. The composition of this term depends on the fault loop as described in the following subsections.
Flt loop resistance	The total fault loop resistance from the substation to the fault location in primary ohms. Fault point resistance is included in this value. The composition of this term is different for short-circuit and earth-fault loops as described in the following subsections.
Flt loop reactance	The total fault loop reactance from the substation to the fault location in primary ohms. The composition of this term is different for short-circuit and earth-faults loops as described in the following subsections.

These impedance values can be used as such or they can be further processed in system-level fault location applications, such as distribution management system (DMS).

5.7.5.3 Fault loops “AG Fault” or “BG Fault” or “CG Fault”

Fault loops “AG Fault”, “BG Fault” and “CG Fault” are used for single-phase-toearth faults. When the earth faults are located at different feeders, they are also applied in the case of two-phase-to-earth faults. In this case, the phase-to-earth loop (“AG Fault”, “BG Fault” or “CG Fault”) corresponding to the faulty phase at the protected feeder is used for calculation. *Figure 683* shows the phase-to-earth fault loop model. The following impedances are measured and stored in the recorded data of SCEFRFLO.

$$Flt\ point\ resistance = R_{fault}$$

(Equation 293)

$$Flt\ loop\ resistance = R_1 + R_N + R_{fault}$$

(Equation 294)

$$Flt\ loop\ reactance = X_1 + X_N$$

(Equation 295)

$$Flt\ phase\ reactance = X_1$$

(Equation 296)

R_1	Estimated positive-sequence resistance from the substation to the fault location
X_1	Estimated positive-sequence reactance from the substation to the fault location
R_0	Estimated zero-sequence resistance from the substation to the fault location
X_0	Estimated zero-sequence reactance from the substation to the fault location
R_N	Estimated the earth return path resistance (= (R0 – R1)/3) from the substation to the fault location
X_N	Estimated is the earth return path reactance (= (X0 – X1)/3) from the substation to the fault
R_{fault}	Estimated fault resistance at the fault location

The recorded data Flt phase reactance provides the estimated positive-sequence reactance from the substation to the fault location.

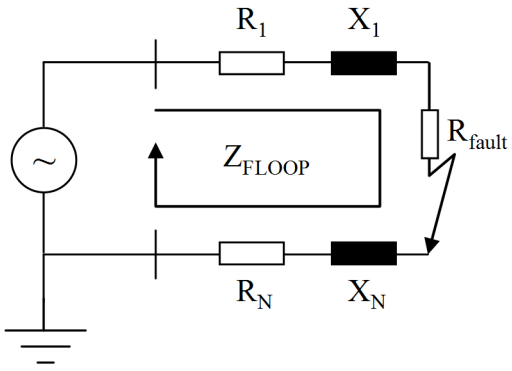

Figure 683: Fault loop impedance for phase-to-earth fault loops “AG Fault”, “BG Fault” or “CG Fault”

Setting *Flt Loc Det mode* is used for selecting between different algorithms for the calculation of the earth-fault distance. In case of compensated (resonant earthed) networks where an earth-fault current raising resistor is used, setting *Flt Loc Det mode* = "Comp, switched R" should be selected. In all other cases of system neutral point earthing (effectively earthed, low-resistance, low-reactance or unearthed networks), setting "Non-comp" should be selected.

Earth-fault distance calculation in case of non-compensated networks

In case of non-compensated networks (effectively earthed, low-resistance, lowreactance or unearthed networks), the setting *Flt Loc Det mode* is equal to "Noncomp". Furthermore, the earth-fault distance calculation algorithm is selected with setting *EF algorithm Sel*. Options for the selection are "Load compensation" and "Load modelling". For the correct operation of both algorithms, there should not be any zero-sequence current sources, for example, earthing transformers, in front of the protection relay.

The “Load compensation” algorithm uses symmetrical components to compensate for the effect of load on the measured voltages and currents. In case of radial feeders, this algorithm should be selected with low-impedance/effectively earthed systems where the fault current is fed from one side only and there are no in-feeds along the protected line.

The “Load modelling” algorithm takes into account the effect of the load in the measured currents and voltages by considering it in the fault loop model. In case

of radial feeders, this algorithm can be applied with low-impedance/effectively earthed systems where the fault current is fed from one side only. The “Load modelling” algorithm has been especially designed for unearthed systems.

The “Load modelling” algorithm requires the *Equivalent load Dis* setting, that is, an equivalent load distance, as an additional parameter. The derivation and meaning of this parameter is illustrated in *Figure 684*, where the load is assumed to be evenly distributed along the feeder, resulting in the actual voltage drop curve as seen in the middle part of *Figure 684*.

In case of evenly distributed load, *Equivalent load Dis* ~ 0.5. When the load is tapped at the end of the feeder, *Equivalent load Dis* = 1.0. If the load distribution is unknown, a default value of 0.5 can be used for *Equivalent load Dis*.

The maximum value of the voltage drop, denoted as U_{drop}(real), appears at the end of the feeder. The *Equivalent load Dis* setting is the distance at which a single load tap corresponding to the total load of the feeder results in a voltage drop equal to U_{drop}(real). The dashed curve shows the voltage drop profile in this case.

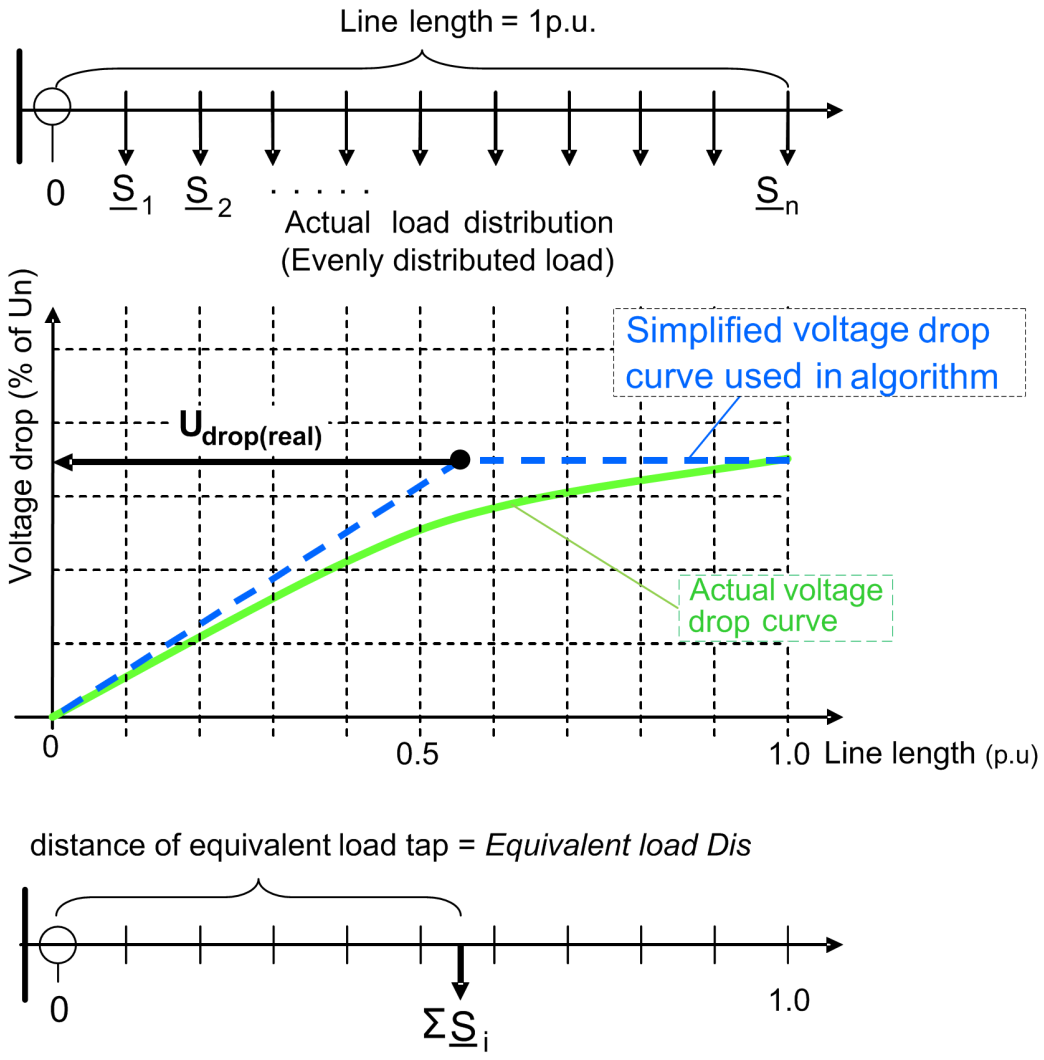

Figure 684: Description of the equivalent load distance

The exact value for *Equivalent load Dis* can be calculated based on the load flow and voltage drop calculations using data from DMS-system and the following equation.

$$Equivalent\ load\ Dis = \frac{U_{d(real)}}{U_{d(tap,d=1)}}$$

(Equation 297)

$U_{d(real)}$	The actual maximum voltage drop of the feeder
$U_{d(tap,d=1)}$	The fictional voltage drop, if the entire load would be tapped at the end (d=1) of the feeder (not drawn in *Figure 684*). The calculation of this value requires data from the DMS system.

Alternatively, the setting *Equivalent load Dis* can be determined by conducting a single-phase earth-fault test (R_{fault} = 0 Ω) at that point of the feeder where the maximum actual voltage drop takes place. This point is typically located at the end of the main line. As a result, the calculated value is stored in the recorded data Equivalent load Dis.

In addition, when the setting *EF algorithm Sel* is equal to "Load modelling", the *EF algorithm Cur Sel* setting determines whether the used algorithm is based on zero-sequence "Io based" or negative-sequence "I2 based" current. The difference between "Io based" and "I2 based" methods is that "I2 based" does not require the *Ph capacitive React* and *Ph leakage Ris* settings. In case of "Io based", these settings are needed to compensate for the influence of the line-charging capacitances of the protected feeder. This improves the accuracy of the fault location estimate when fault resistance is involved in the fault.

With certain restrictions, the “Load modelling” algorithm can also be applied to unearthed networks. In this case the *EF algorithm Cur Sel* setting should be set to “Io based” and thus *Ph capacitive React* and *Ph leakage Ris* settings must be determined.

The prerequisite for the operation of SCEFRFLO in earth faults in unearthed networks is that the earth-fault current of the network corresponding to a solid fault exceeds the pre-fault load current; that is the *Equation 298* is valid.

$$Flt\ to\ Lod\ Cur\ ratio = \frac{\left|I_{ef(Rfault=0)}\right|}{\left|I_{Load}\right|} \geq 1$$

(Equation 298)

This ratio is estimated by SCEFRFLO and stored in the recorded data Flt to Lod Cur ratio together with the fault distance estimate.

In case of an unearthed network, sufficient fault current magnitude resulting in Flt to Lod Cur ratio >1 can be achieved, for example, with proper switching operations in the background network, if possible, which increase the fault current. If the faulty feeder is re-energized after the switching operation, a new estimate for the fault distance can be obtained. Fault resistance decreases the fault location accuracy so the resistance should not be higher than a few hundred ohms. Also, a low value of Flt to Lod Cur ratio causes inaccuracy and affects the quality of the fault distance estimate. The inaccuracies affecting the calculated fault distance estimate are reported in the recorded result quality indicator value Flt Dist quality in *Table 93*.

Earth-fault distance calculation in case of compensated (resonant earthed) networks where an earth-fault current raising resistor is used

In case of compensated (resonant earthed) networks where an earth-fault current raising resistor is used, the setting *Flt Loc Det mode* is equal to "Comp, switched R". The algorithm for calculation of earth-fault distance requires a measurable change in the measured phase currents and phase-to-earth voltages during an earth fault. Such a change can be accomplished by switching on the resistor of the PAW winding (Power Auxiliary Winding) of the compensation coil during the fault.

The algorithm requires three independent time instances, which are assumed to be known by the algorithm:

- t_0 = time instance before the fault
- t_1 = time instance before the change during the earth fault
- t_2 = time instance after the change during the earth fault

The effect of loads is considered by applying “Load modelling” algorithm.

The required settings of the algorithm are:

- R1 = Positive-sequence resistance of the protected feeder [ohm, prim]
- X1 = Positive-sequence reactance of the protected feeder [ohm, prim]
- R0 = Zero-sequence resistance of the protected feeder [ohm, prim]
- X0 = Zero-sequence reactance of the protected feeder [ohm, prim]
- s = Equivalent load distance [pu]

Determining timings of changes: determination of earth fault occurrence and time instance t0

Timing t_0 is needed to store the current and voltage phasors right before the occurrence of the earth fault. Timing t_0 is common to both triggering types (*Calculation Trg mode* either “Internal” or “External”). Pre-fault (indicating healthy network) phasors are continuously updated and stored at intervals of 300 ms until the earth fault is indicated. When the earth fault is detected (internal detection), the pre-fault phasor is stored at least 300 ms before the detection of the earth fault. This time instance before the earth fault is noted as t_0 (see *Figure 685*).

Determining timings of changes: determination of changes during an earth fault due to parallel resistor switching, time instances t1 and t2

- Time instance t_1 equals the time during earth fault, right before the switching of the parallel resistor of the coil (see *Figure 685*)
- Time instance t_2 equals the time during earth fault, just after the switching of the parallel resistor of the coil (see *Figure 685*)

In case of external triggering, time instances t_1 and t_2 are determined using input `TRIGG_T` and delay setting *Time delay*. `TRIGG_T` input should be activated when the parallel resistor is switched ON. Time instance t_1 is taken at least one fundamental cycle before `TRIGG_T` rising edge. Time instance t_2 is taken according to the set *Time delay* after the rising edge of `TRIGG_T` signal. Setting *Time delay* should be few hundreds of ms and it is needed due to oscillations in currents and voltages after the switching of the parallel resistor.

`TRIGG_T` activation must be given after the initial earth-fault ignition transients. Only one activation of `TRIGG_T` is allowed during an earth fault. However, further activations are internally disabled.

Activation of input TRIGG_REC is required in case of external triggering to record the calculated estimates for fault distance. TRIGG_REC should be activated during the earth fault after the switching of the parallel resistor.

In case of internal triggering, time instances t_1 and t_2 are determined by monitoring the change of the resistive component of Io current using admittance calculation during the earth fault and comparing the magnitude of change to setting *Zero Ris Curr change*. Time instance t_1 is taken at least one fundamental cycle before and t_2 at least one fundamental cycle after the change in the resistive component of Io exceeding the start value (setting *Zero Ris Curr change*). The value for setting Zero Ris Curr change should be chosen based on the rated current value of the parallel resistor with proper margin:

Zero Ris Curr change < Ipar_rated [A] · q

where q = 0.5–0.7

For example, if the rated current value of the parallel resistor is 10A@20kV and In = 100 A for Io channel, then

Zero Ris Curr change < 0.05–0.07xIn

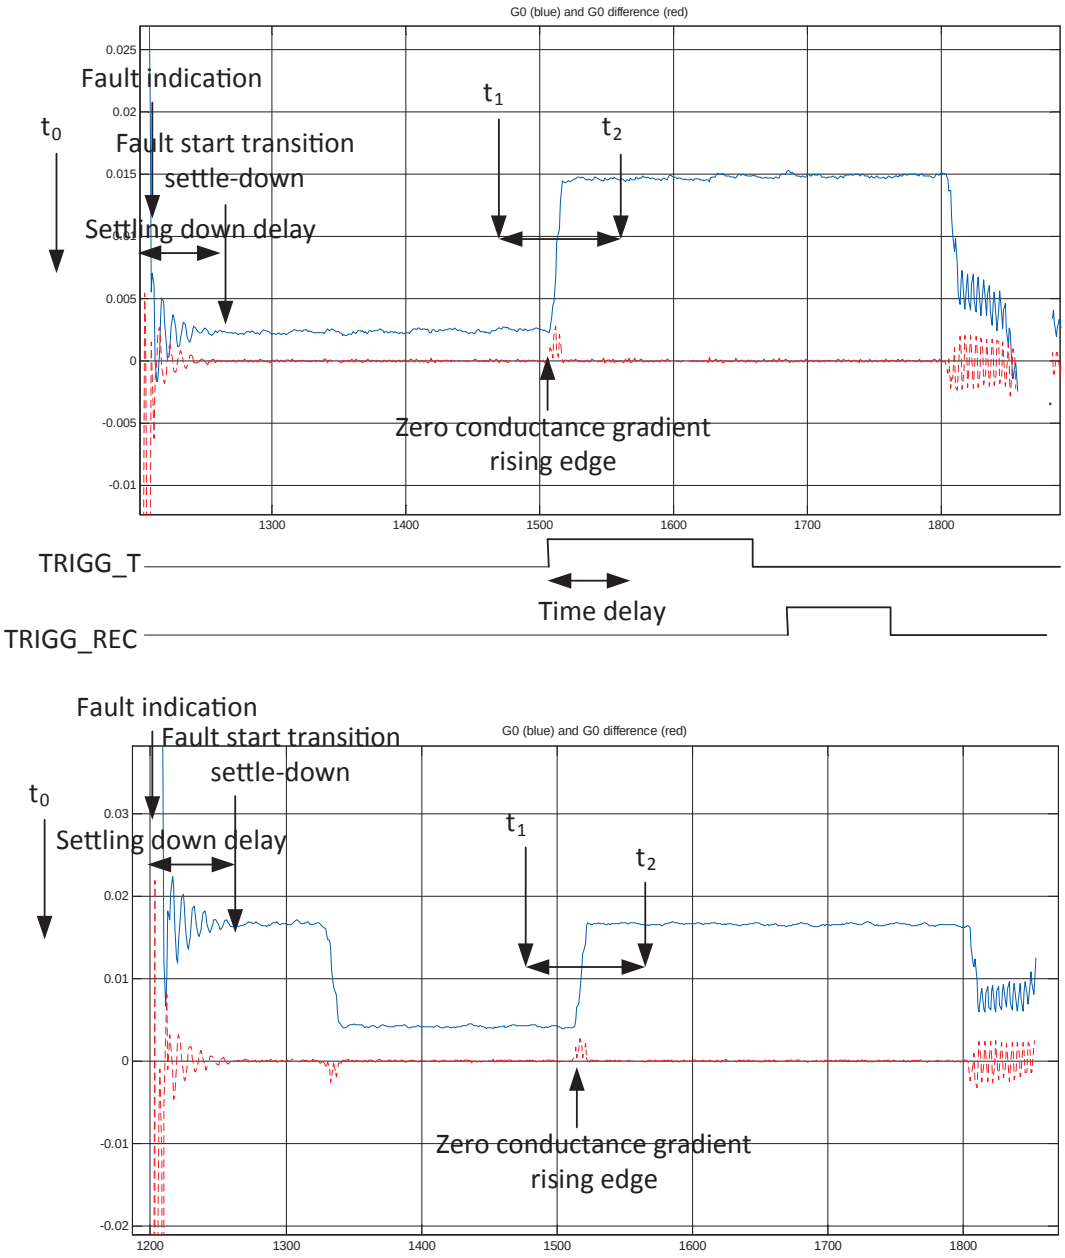

Figure 685: Fault distance estimate triggering moment definitions

Fault loops “AB Fault”, “BC Fault” or “CA Fault”

Fault loops “AB Fault”, “BC Fault” or “CA Fault” are used for phase-to-phase short circuit faults as well as in the case of a two-phase-to-earth fault if the individual earth faults are located at the same feeder. *Figure 686* shows the phase-to-phase fault loop model. The following impedances are measured and stored in the recorded data of SCEFRFLO.

$$Flt\ point\ resistance = \frac{R_{fault}}{2}$$

(Equation 299)

$$Flt\ loop\ resistance = R_1 + \frac{R_{fault}}{2}$$

(Equation 300)

$$Flt\ loop\ reactance = Flt\ phase\ reactance = X_1$$

(Equation 301)

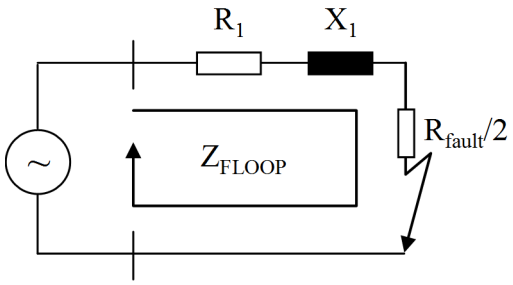

Figure 686: Fault loop impedance for phase-to-phase fault loops (either "AB Fault", "BC Fault" or "CA Fault")

The fault distance calculation algorithm for the phase-to-phase fault loops is defined by using settings *Load Com PP loops* and *Enable simple model*. Options for the selection are "Disabled" or "Enabled".

Load compensation can be enabled or disabled with setting *Load Com PP loops*. Load compensation should be disabled only if the ratio between the fault current and load current is high or when the value of the fault distance estimate for the short circuit fault is required from each shot of an autoreclosing sequence.

The fault distance calculation is most accurate when calculated with the fault loop model. This model requires positive-sequence impedances of the protected feeder to be given as settings. If these settings are not available, valid impedance values can be calculated also without the fault loop model with setting *Enable simple model* = "Enabled". However, a valid distance estimate, that is, the conversion of measured impedance ("electrical fault distance") into a physical fault distance requires accurate positive-sequence impedance settings.

Fault loop "ABC Fault"

Fault loop "ABC Fault" is used exclusively for the three-phase short circuit fault. *Figure 687* shows the three-phase fault loop model. The following impedances are measured and stored in the recorded data of SCEFRFLO.

$$Flt\ point\ resistance = R_{fault}$$

(Equation 302)

$$Flt\ loop\ resistance = R_1 + R_{fault}$$

(Equation 303)

$$Flt\ loop\ reactance = Flt\ phase\ reactance = X_1$$

(Equation 304)

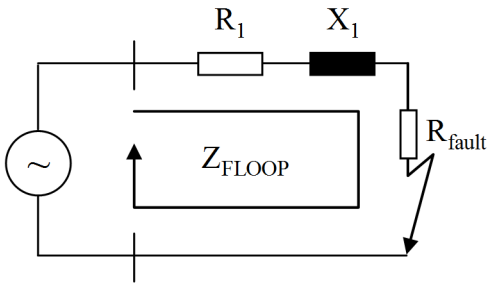

Figure 687: Fault loop impedance for a three-phase fault loop (“ABC Fault”)

The three-phase fault distance is calculated with a special measuring element using positive-sequence quantities. This is advantageous especially in case of non-transposed (asymmetric) lines, as the influence of line parameter asymmetry is reduced. If the line is non-transposed, all the phase-to-phase loops have different fault loop reactances. The use of positive-sequence quantities results in the average value of phase-to-phase loop reactances, that is, the most representative estimate in case of three-phase faults.

The fault distance calculation algorithm for the three-phase fault loop is defined with settings *Load Com PP loops* and *Enable simple model*. Options for the selection are "Disabled" or "Enabled".

Load compensation can be enabled or disabled with setting *Load Com PP loops*. The load compensation should be disabled only if the ratio between the fault current and load current is high or when the value of the fault distance estimate for the short circuit fault is required from each shot of an autoreclosing sequence.

The fault distance calculation is most accurate when the calculation is made with the fault loop model. This model requires positive sequence impedances of the protected feeder to be given as settings. If these settings are not available, valid impedance values can be calculated also without the fault loop model with setting *Enable simple model* = "Enabled". However, a valid distance estimate, that is, the conversion of measured impedance (“electrical fault distance”) into a physical fault distance requires accurate positive-sequence impedance settings.

Estimation of fault resistance in different fault loops

The fault point resistance value provided by the impedance calculation is available in recorded data Flt point resistance and it depends on the applied fault loop as shown in *Figure 688*. In case of earth faults, the estimated fault point resistance includes the total fault point resistance between the faulty phase and earth, for example, the arc and earthing resistances. In case of phase-to-phase faults, the estimated fault point resistance is half of the total fault point resistance between the phases. In case of a three-phase fault, the estimated fault point resistance equals the total fault point resistance per phase, for example, the arc resistance per phase.

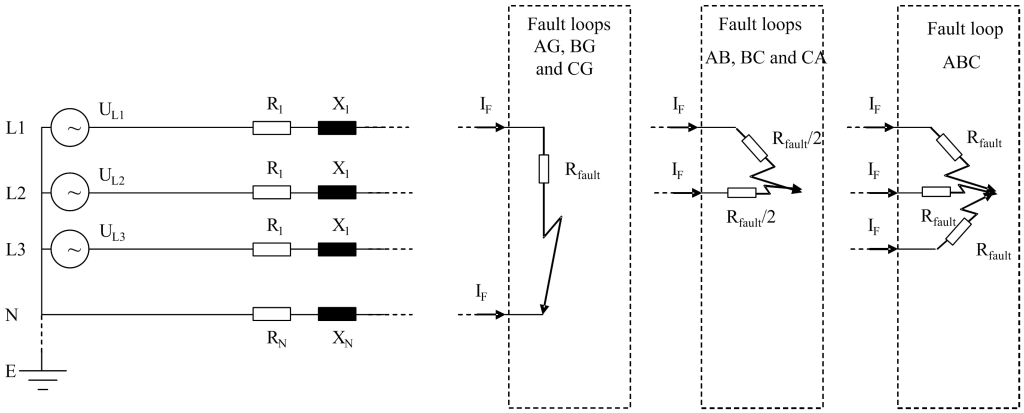

Figure 688: Definition of a physical fault point resistance in different fault loops

Steady-state asymmetry and load compensation

Power systems are never perfectly symmetrical. The asymmetry produces steady-state quantities in the form of zero-sequence and negative-sequence voltages and currents. If not compensated, these are error sources for fault distance calculation especially in case of earth faults. All earth-fault distance calculation algorithms of SCEFRFLO use the delta quantities which mitigate the effects of the steady-state asymmetry.

The load current is another error source for fault distance calculation. Its influence increases with higher fault resistance values. SCEFRFLO employs independent load compensation methods for each fault type to achieve optimal performance. The purpose of load compensation is to improve the accuracy of the fault distance calculation models by estimating the actual fault current in the fault location. Delta-quantities are used for this to mitigate the effect of load current on fault distance estimation.

For earth faults, the load compensation is done automatically inside the fault distance calculation algorithm. For short circuit faults, load compensation is enabled with setting *Load Com PP loops*. The default value is "Enabled". The parameter should be set to "Disabled" only if the ratio between the expected fault current and load current is high or when the fault distance estimate for the short circuit fault is required for each shot of an autoreclosing sequence.

The delta quantity describes the change in measured signal due to the fault.

$$\Delta x = x_{fault} + x_{pre\text{-}fault}$$

(Equation 305)

x_{fault}	Signal value during fault
$x_{pre\text{-}fault}$	Signal value during healthy state just before fault

Result quality indicator

The quality of the estimated fault distance is judged and reported in recorded data as the Flt Dist quality together with the fault distance estimate. The Flt Dist quality is a bit vector indicating detected sources of inaccuracy in the fault distance estimate. If Flt Dist quality equals 1, the result is not affected by error sources. This results in good quality for the fault distance estimate. If factors affecting negatively

the fault distance estimation are detected, the Flt Dist quality is according to *Table 93*. In this case, the estimated fault distance (Flt distance) value is given on the HMI in parentheses.

Table 1151: Fault distance quality indicator Flt Dist quality

Value	Corresponding inaccuracy description
2	Estimation stability criterion has not been reached
4	Fault point resistance exceeds 500 Ω
8	Fault point resistance exceeds 5 × X_{loop}
16	Fault point resistance exceeds 20 × X_{loop}[1]
32	Flt to Lod Cur ratio is below 1.00
64	Fault distance estimate outside tolerances (<-0.1 pu or >1.1 pu)
128	Distance estimate calculation is not done due to too low magnitudes of I or U
256	Distance estimate calculation cannot be performed (for example avoiding internal division by zero)

For example, if fault point resistance exceeds 500 Ω and Flt to Lod Cur ratio is below 1.0, Flt Dist quality is “36”. As another example, if no error sources are found, but stability criterion is not met, the value of Flt Dist quality is “2”.

Impedance settings

The fault distance calculation in SCEFRFLO is based on the fault loop impedance modeling. The fault loop is parametrized with the impedance settings and these can be set at maximum for three line sections (A, B and C). Each section is enabled by entering a section length, which ranges from zero to settings *Line Len section A*, *Line Len section B* or *Line Len section C* in the order section A-> section B-> section C.

The earth-fault loops require both positive-sequence and zero-sequence impedances, for example, *R1 line section A* and *X1 line section A*, *R0 line section A* and *X0 line section A*. For the short circuit loops, only positive-sequence impedances are needed, but they can be omitted if the setting *Enable simple model* equals "Enabled".

If the impedance settings are in use, it is important that the settings closely match the impedances of used conductor types. The impedance settings are given in primary ohms [ohm/pu] and the line section lengths in per unit [pu]. Thus, impedances can be either given in ohm/km and section length in km, or ohm/mile and section length in miles. The resulting Flt distance matches the units entered for the line section lengths.

Positive-sequence impedance values

Fault location requires accurate setting values for line impedances. Positive-sequence impedances are required both for location of short circuits and earth faults. As data sheet impedance per unit values are generally valid only for a certain tower configuration, the values should be adjusted according to the

[1] Xloop is the total loop reactance according to settings

actual installation configuration. This minimizes the fault location errors caused by inaccurate settings.

The positive-sequence reactance per unit and per phase can be calculated with a following approximation equation which applies to symmetrically transposed three-phase aluminium overhead lines without ground wires.

$$X_1 \approx \omega_n \cdot 10^{-4} \left(2 \cdot \ln \frac{a_{en}}{r} + 0.5 \right) [\Omega / km]$$

(Equation 306)

ω_n $2 \times \pi \times f_n$, where f_n = fundamental frequency [Hz]

Zero-sequence impedance values

Location of earth faults requires both positive-sequence and zero-sequence impedances. For short circuit faults, zero-sequence impedances are not required.

The positive-sequence impedance per unit values for the lines are typically known or can easily be obtained from data sheets. The zero-sequence values are generally not as easy to obtain as they depend on the actual installation conditions and configurations. Sufficient accuracy can, however, be obtained with rather simple calculations using the following equations, which apply per phase for symmetrically transposed three-phase aluminium overhead lines without ground wires.

$$R_0\,[50Hz] \approx R1 + 0.14804\,[\Omega / km]$$

(Equation 307)

$$R_0\,[60Hz] \approx R1 + 0.17765\,[\Omega / km]$$

(Equation 308)

$$X_0 \approx 2 \cdot \omega_n \cdot 10^{-4} \left(3 \cdot \ln \frac{w}{r_{en}} + 0.25 \right) [\Omega / km]$$

(Equation 309)

Ph leakage Ris and *Ph capacitive React* settings

The *Ph leakage Ris* and *Ph capacitive React* settings are used for improving fault distance estimation accuracy for earth faults. They are critical for an accurate fault location in unearthed networks. In other types of networks they are less critical. The *Ph leakage Ris* setting represents the leakage losses of the protected feeder in terms of resistance per phase. The *Ph capacitive React* setting represents the total phase-to-earth capacitive reactance of the protected feeder per phase. Based on experience, a proper estimate for *Ph leakage Ris* should be about 20...40 × *Ph capacitive React*.

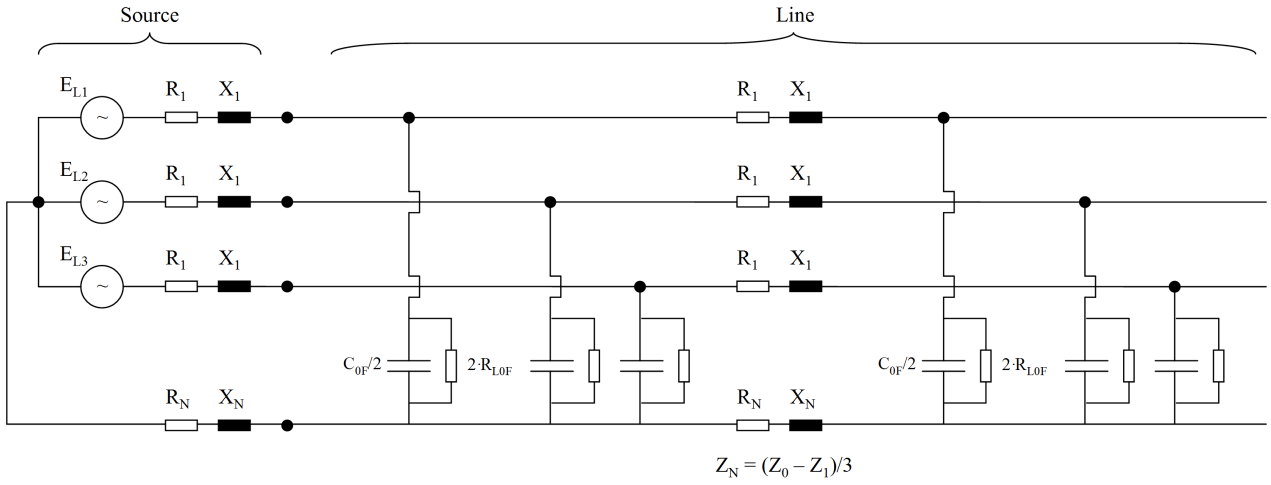

Figure 690: Equivalent diagram of the protected feeder. R L0F = Ph leakage Ris.

The determination of the *Ph capacitive React* setting can be based either on network data or measurement.

If the total phase-to-earth capacitance (including all branches) per phase C_{0F} of the protected feeder is known, the setting value can be calculated.

$$Ph\ capacitive\ React = \frac{1}{\left(\omega_n \cdot C_{0F}\right)}$$

(Equation 310)

In case of unearthed network, if the earth-fault current produced by the protected feeder I_{ef} is known, the setting value can be calculated.

$$Ph\ capacitive\ React = \frac{\sqrt{3} \cdot U_{xy}}{I_{ef}}$$

(Equation 311)

U_{xy} Phase-to-earth voltage

SCEFRFLO can also determine the value for the *Ph capacitive React* setting by measurements. The calculation of *Ph capacitive React* is triggered by the binary signal connected to the TRIGG_XC0F input when an earth-fault test is conducted outside the protected feeder during commissioning, for example, at the substation busbar. The *Calculation Trg mode* has to be “External”. After the activation of the TRIGG_XC0F triggering input, the calculated value for setting *Ph capacitive React* is obtained from recorded data as parameter *XC0F Calc*. This value has to be manually entered for the *Ph capacitive React* setting. The calculated value matches the current switching state of the feeder so if the switching state of the protected feeder changes, the value should be updated.

Figure 691 shows an example configuration, which enables the measurement of setting *Ph capacitive React*.

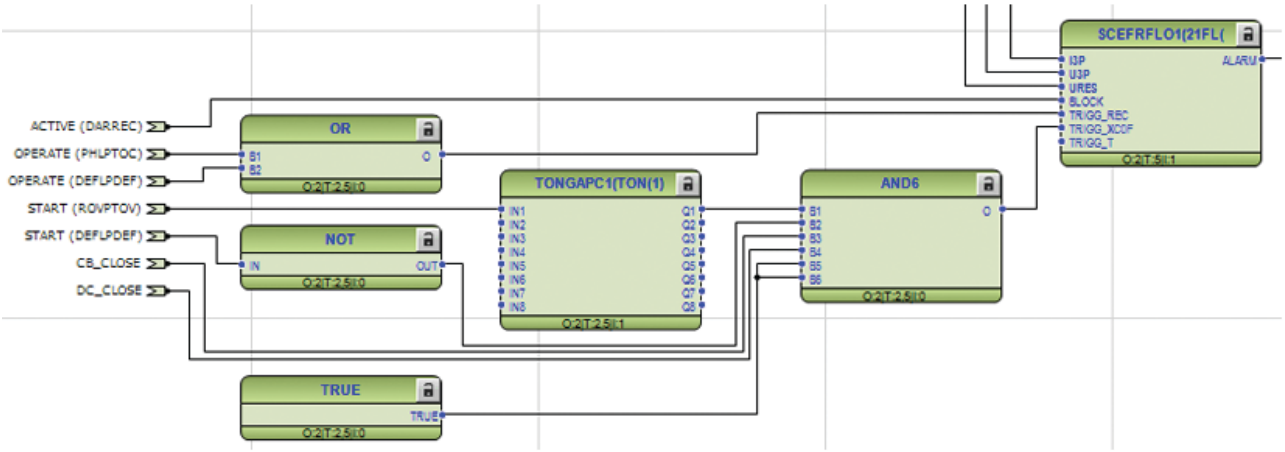

Figure 691: An example configuration, which enables the measurement of setting Ph capacitive React

If the earth fault is detected by the residual overvoltage function (START of ROVPTOV), but not seen by the forward-looking earth-fault protection function (START of DEFLPDEF), the fault is located outside the protected feeder. This is mandatory for valid measurement of setting *Ph capacitive React*. After a set delay (TONGAPC), the input TRIGG_XC0F is activated and the parameter *XC0F Calc* in the recorded data is updated. The delay (TONGAPC) must be set longer than the start delay of the directional earth-fault function DEFLPDEF, but shorter than the minimum operating time of the directional earth-fault functions in any of the feeders. For example, if the start delay is 100 ms and the shortest operating time 300 ms, a value of 300 ms can be used. Circuit breaker and disconnector status is used to verify that the entire feeder is measured.

Modeling a non-homogeneous line

A typical distribution feeder is built with several different types of overhead lines and cables. This means that the feeder is electrically non-homogeneous. SCEFRFLO allows the modeling of the line impedance variation in protection relay with three line sections with independent impedance settings. This improves the accuracy of

physical fault distance conversion done in the protection relay, especially in cases where the line impedance non-homogeneity is severe. Each section is enabled by entering a section length, which differs from zero, to settings *Line Len section A*, *Line Len section B* or *Line Len section C* in the order section A-> section B-> section C.

The impedance model with one line section is enabled by setting *Line Len section A* to differ from zero. In this case the impedance settings *R1 line section A*, *X1 line section A*, *R0 line section A* and *X0 line section A* are used for the fault distance calculation and for conversion from reactance to physical fault distance. This option should be used only in the case of a homogeneous line, that is, when the protected feeder consists of only one conductor type.

The impedance model with two line sections is enabled by setting both *Line Len section A* and *Line Len section B* to differ from zero. In this case the impedance settings *R1 line section A*, *X1 line section A*, *R0 line section A*, *X0 line section A*, *R1 line section B*, *X1 line section B*, *R0 line section B* and *X0 line section B* are used for the fault distance calculation and for conversion from reactance to physical fault distance. This option should be used in the case of a non-homogeneous line when the protected feeder consists of two types of conductors.

The impedance model with three line sections is enabled by setting *Line Len section A*, *Line Len section B* and *Line Len section C* to differ from zero. In this case, the impedance settings *R1 line section A*, *X1 line section A*, *R0 line section A*, *X0 line section A*, R1 line section B, *X1 line section B*, *R0 line section B*, *X0 line section B*, *R1 line section C*, *X1 line section C*, *R0 line section C* and *X0 line section C* are used for the fault distance calculation and for conversion from reactance to physical fault distance. This option should be used in the case of a non-homogeneous line when the protected feeder consists of more than two types of conductors.

The effect of line impedance non-homogeneity on the conversion of fault loop reactance into physical fault distance is demonstrated in the example shown in *Figure 692* with a 10-km-long feeder with three line types. The total line impedance for the 10 km line is R1 = 6.602 Ω (0.660 Ω/km) and X1 = 3.405 Ω (0.341 Ω/km), consisting of the following sections and impedance values.

- 4 km of PAS 150 (R1 = 0.236 Ω/km, X1 = 0.276 Ω/km)
- 3 km of Al/Fe 54/9 Raven (R1 = 0.536 Ω/km, X1 = 0.369 Ω/km)
- 3 km of Al/Fe 21/4 Swan (R1 = 1.350 Ω/km, X1 = 0.398 Ω/km)

The non-homogeneity of feeder impedance can be illustrated by drawing the protected feeder in RX-diagram (in the impedance plane), as shown in *Figure 692*.

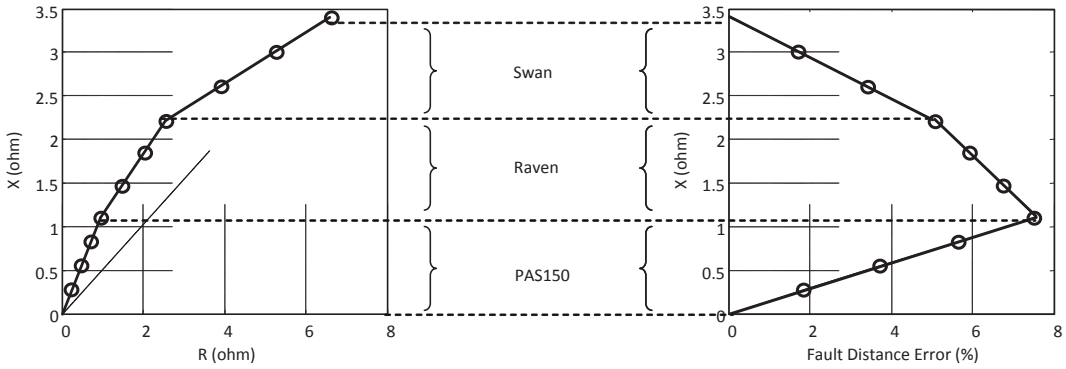

Figure 692: Example impedance diagram of an electrically non-homogeneous feeder (left), and the resulting error in fault distance if the measured fault loop reactance is converted into physical fault distance by using only one line section parameters (right).

In *Figure 692* the feeder is modelled either with one or three line sections with parameters given in *Table 1155*.

Table 1155: Impedance settings

Parameter	Impedance model with one section	Impedance model with three sections
R1 line section A	0.660 Ω/pu	0.236 Ω/pu
X1 line section A	0.341 Ω/pu	0.276 Ω/pu
Line Len section A	10.000 pu	4.000 pu
R1 line section B	N/A	0.536 Ω/pu
X1 line section B	N/A	0.369 Ω/pu
Line Len section B	0.000 pu	3.000 pu
R1 line section C	N/A	1.350 Ω/pu
X1 line section C	N/A	0.398 Ω/pu
Line Len section C	0.000 pu	3.000 pu

Figure 692 illustrates the error when converting the measured fault loop reactance into physical fault distance. The fault location is varied from 1 km to 10 km in 1 km steps (marked with circles). An error of nearly eight per cent at maximum is created by the conversion procedure when modeling a non-homogenous line with only one section. By using impedance model with three line sections, there is no error in the conversion.

The previous example assumed a short circuit fault and thus, only positive-sequence impedance settings were used. The results, however, also apply for earth faults.

Taps or spurs in the feeder

If the protected feeder consists of taps or spurs, the measured fault impedance corresponds to several physical fault locations (For example, A or B in *Figure 693*). The actual fault location must be identified using additional information, for example, short circuit current indicators placed on tapping points.

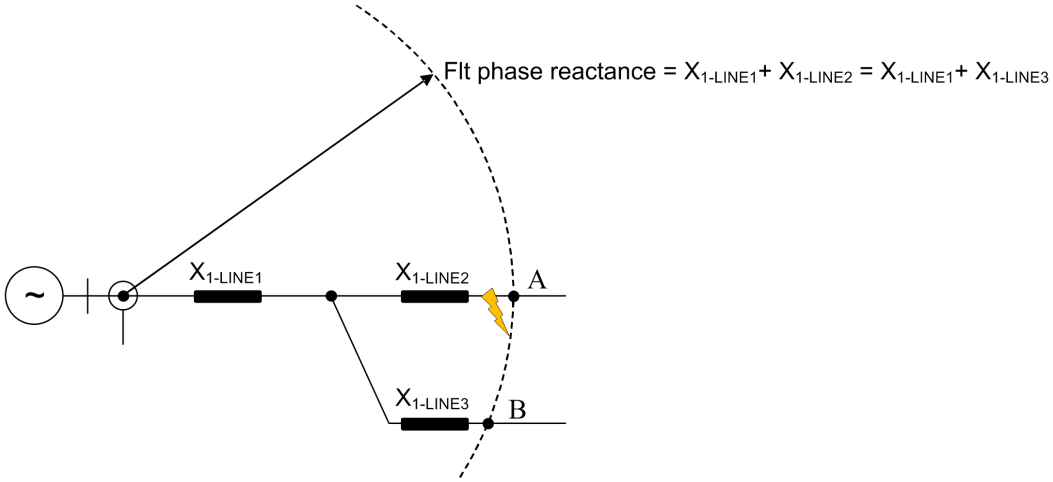

Figure 693: Fault on a distribution line with spurs

5.7.5.4 Trigger detection

The fault distance estimate is obtained when SCEFRFLO is triggered. The triggering method is defined with setting *Calculation Trg mode*. The options for selection are "External" or "Internal", where the default value is "External". The TRIGG_OUT event indicates the fault distance value recording moment. The fault distance estimate, Flt distance, together with the time stamp of actual triggering are saved in the recorded data of SCEFRFLO.

- In case of external triggering, an external trigger signal should be connected to the `TRIGG_REC` input. The triggering signal is typically a trip signal from a protective function. At triggering moment the fault distance is stored into recorded data. It is important that triggering be timed suitably to provide sufficient time for the distance estimation calculation before tripping of the feeder circuit breaker.
- In case of internal triggering, the `TRIGG_REC` input is not used for triggering. Instead, the trigger signal is created internally so that the estimation is started when Phase selection logic detects a fault and the estimate is triggered when its value has stabilized sufficiently. This is judged by maximum variation in fault distance estimate and defined with setting *Distance estimate Va* (in the same unit as the fault distance estimate). When successive estimates during one fundamental cycle are within “final value ± *Distance estimate Va*”, the fault distance estimate (mean of successive estimates) is recorded. If the stabilization criterion has not been fulfilled, the fault distance estimate is given right before the fault ends. Phase selection logic is a non-directional function so internal triggering should not be used when directionality is required.

Generally, SCEFRFLO requires a minimum of two fundamental cycles of measuring time after the fault occurrence. *Figure 694* illustrates typical behavior of fault distance estimate of SCEFRFLO as a function of time.

- Immediately after the fault occurrence, the estimate is affected by initial fault transients in voltages and currents.
- Approximately one fundamental cycle after the fault occurrence, the fault distance estimate starts to approach the final value.
- Approximately two fundamental cycles after the fault occurrence, the stability criterion for fault distance estimate is fulfilled and the TRIGG_OUT event is sent. The recorded data values are stored at this moment.

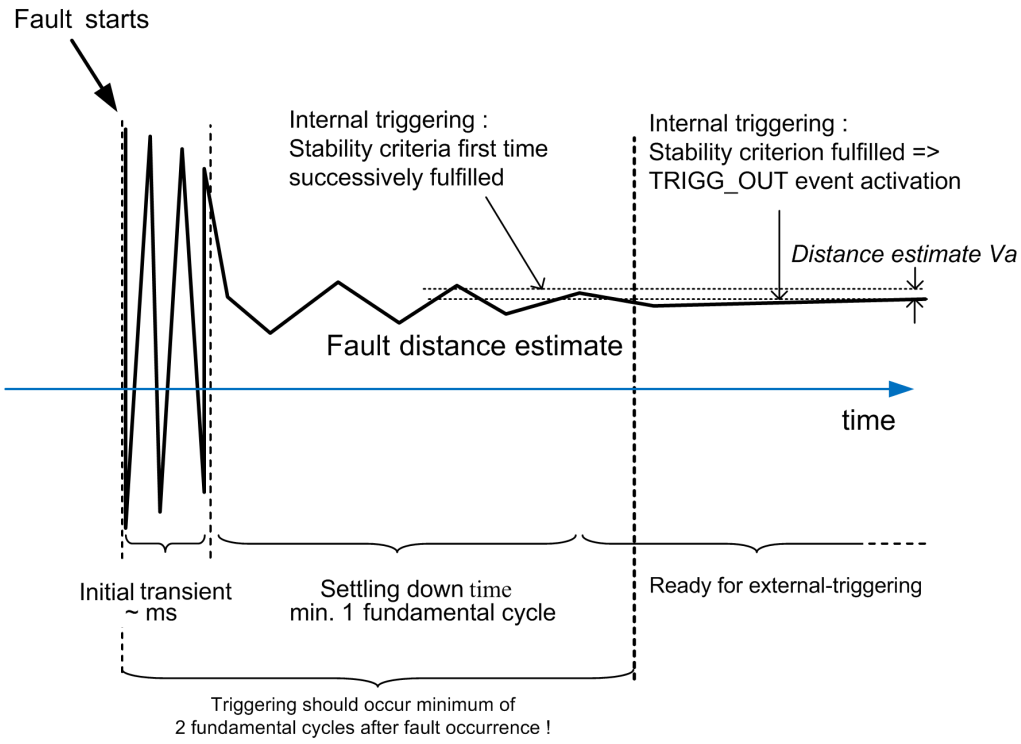

Figure 694: The behavior of fault distance estimate in time

5.7.5.5 Alarm indication

SCEFRFLO contains an alarm output for the calculated fault distance. If the calculated fault distance FLT_DISTANCE is between the settings *Low alarm Dis limit* and *High alarm Dis limit*, the ALARM output is activated. If setting *High alarm Dis limit* has been set below *Low alarm Dis limit*, the ALARM operation is inverted: the ALARM output is activated if *High alarm Dis limit* is undershot or *Low alarm Dis limit* is exceeded. The default value for both is zero so that no distance estimate activates ALARM.

The ALARM output can be utilized, for example, in regions with waterways or other places where knowledge of certain fault locations is of high importance.

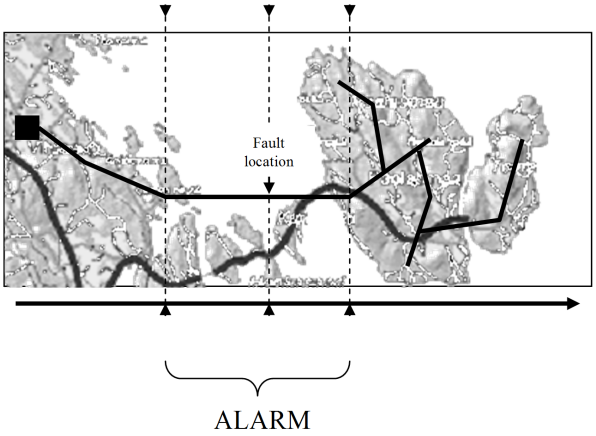

Figure 695: An example of the ALARM output use

5.7.5.6 Recorded data

All the information required for a later fault analysis is recorded to SCEFRFLO recorded data. In the protection relay, recorded data is found in **Monitoring** > **Recorded data** > **Other protection** > **SCEFRFLO**.

SCEFRFLO has also monitored data values which are used for the read-out of continuous calculation values. *Table 1156* shows which of the recorded data values are available as continuous monitoring values during a fault.

Table 1156: Cross reference table for recorded and monitored data values

Recorded data	Monitored data
Flt loop	FAULT_LOOP
Flt distance	FLT_DISTANCE
Flt Dist quality	FLT_DIST_Q
Flt loop resistance	RFLOOP
Flt loop reactance	XFLOOP
Flt phase reactance	XFPHASE
Flt point resistance	RF
Flt to Lod Cur ratio	IFLT_PER_ILD
Equivalent load Dis	S_CALC
XC0F Calc	XC0F_CALC

5.7.6 Measurement modes

The full operation of SCEFRFLO requires that all three phase-to-earth voltages are measured. The voltages can be measured with conventional voltage transformers or voltage dividers connected between the phase and earth (*VT connection* is set to “Wye”). Another alternative is to measure phase-to-phase voltages (*VT connection* is set to “Delta”) and residual voltage (Uo). Both alternatives are covered by setting the configuration parameter *Phase voltage Meas* to "Accurate".

The function can operate correctly with only two phase-to-earth voltages if the residual voltage is also measured and connected to the source UTVTR which provides the phase-to-earth voltages to the function. In this case, the missing phase-to-earth voltage is correctly calculated internally in the relay. If the measured residual voltage is connected to SCEFRFLO input URES, *Phase voltage Meas* can be set to "Accurate".

When the *Phase voltage Meas* setting is set to "Ph-to-ph without Uo" and only phase-to-phase voltages are available (but not Uo), only short-circuit measuring loops (fault loops “AB Fault”, “BC Fault”, “CA Fault” or “ABC Fault”) can be measured accurately. In this case, the earth-fault loops (fault loops “AG Fault”, “BG Fault” or “CG Fault”) cannot provide correct fault distance estimates and the triggering of the function in case of an earth fault is automatically disabled. The situation is similar if only two phase-to-earth voltages are measured and the measured residual voltage is not connected to SCEFRFLO.

5.7.7 Application

The main objective of the feeder terminals is a fast, selective and reliable operation in faults inside the protected feeder. In addition, information on the distance to the fault point is very important for those involved in operation and maintenance. Reliable information on the fault location greatly decreases the downtime of the protected feeders and increases the total availability of a power system.

SCEFRFLO provides impedance-based fault location. It is designed for radially operated distribution systems and is applicable for locating short circuits in all kinds of distribution networks. Earth faults can be located in effectively earthed and low-resistance/low-reactance earthed networks. With certain limitations, SCEFRFLO can also be used for locating an earth fault in unearthed distribution networks.

Configuration example

A typical configuration example for SCEFRFLO triggering is illustrated in *Figure 691* where external triggering is applied, that is, *Calculation Trg mode* is set to “External”. The OPERATE signal from non-directional overcurrent function PHLPTOC is used to provide an indication of a short circuit fault. The OPERATE signal from the directional earth-fault function DEFLPDEF is used to provide an indication of an earth fault at the protected feeder.

SCEFRFLO with the autoreclosing function

When SCEFRFLO is used with the autoreclosing sequence, the distance estimate from the first trip is typically the most accurate one. The fault distance estimates from successive trips are possible but accuracy can be decreased due to inaccurate load compensation. During the dead time of an autoreclosing sequence, the load condition of the feeder is uncertain.

The triggering of SCEFRFLO can also be inhibited during the autoreclosing sequence. This is achieved by connecting the signal ACTIVE from the autoreclosing function DARREC, which indicates that the autoreclosing sequence is in progress, to the BLOCK input of SCEFRFLO. Blocking of the SCEFRFLO triggering is indicated during the autoreclosing sequence when the load compensation or steady-state asymmetry elimination is based on the delta quantities. This applies to the short circuit faults when *Load Com PP loops* is set to "Enabled" or, to earth faults, when *EF algorithm Sel* is set to "Load compensation" or "Load modelling".

5.7.8 Signals

5.7.8.1 SCEFRFLO Input signals

Table 1157: SCEFRFLO Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
U3P	SIGNAL	-	Three-phase voltages
URES	SIGNAL	-	Residual voltage
BLOCK	BOOLEAN	0=False	Signal for blocking the triggering
TRIGG_REC	BOOLEAN	0=False	Distance calculation triggering signal
TRIGG_XC0F	BOOLEAN	0=False	XC0F calculation triggering signal
TRIGG_T	BOOLEAN	0=False	Start calculation sequence for compensation network

5.8 Switch-onto-fault protection CVPSOF (ANSI SOTF)

5.8.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Switch-onto-fault protection	CVPSOF	CVPSOF	SOTF

5.8.2 Function block

Figure 696: Function block

5.8.3 Functionality

The switch-onto-fault function CVPSOF is a complementary function, especially to the distance protection function (DSTPDIS), but it can also be used to complement the non-directional or directional overcurrent protection functions (PHxPTOC, DPHxPDOC).

CVPSOF accelerates the operation of the protection ensuring a fast trip when the breaker is closed onto faulted feeder or bus. Without CVPSOF the measured voltages may be too small for the impedance zones or the directional overcurrent stages to operate reliably. This condition exists when the voltage transformers are located in the feeder or the bus side to be energized and therefore the voltage memory required for a correct directional measurement is not available.

5.8.4 Analog channel configuration

CVPSOF has two analog group inputs which must be properly configured.

Table 1165: Analog inputs

Input	Description
I3P [1]	Three-phase currents, necessary when Operation mode is other than "Start"
U3P [2]	Three-phase voltages, necessary when Operation mode is other than "Start

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

[1] Can be connected to GRPOFF if *Operation mode* is set to "Start" and *Automatic SOTF Ini* is set to "DLD disabled" or "Voltage"

[2] Can be connected to GRPOFF if *Operation mode* is set to "Start" and *Automatic SOTF Ini* is set to "DLD disabled" or "Current"

Table 1166: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.8.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of CVPSOF can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

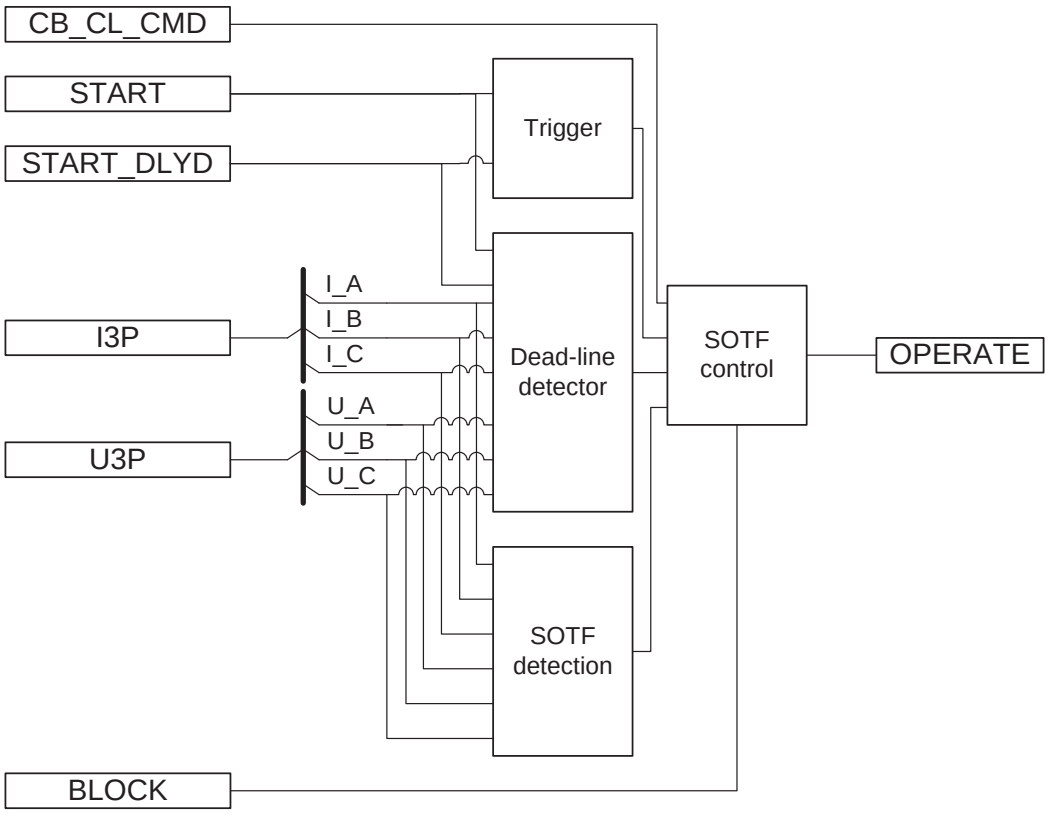

Figure 697: Functional module diagram

Trigger

This module is used for detecting a possible fault immediately after circuit breaker closing. The use of external protection function, typically the start signal from a

non-directional distance zone or overcurrent stage, is required for fault indication. The START and START_DLYD inputs are available for the purpose.

- The START input has no delay. Thus, a switch-onto-fault situation is immediately signalled to SOTF control.
- START_DLYD is used when an additional delay is required to start the signal. The switch-onto-fault situation is signalled to the SOTF control after the set *Operate delay time*.

Dead-line detector

The dead line detection should be used only when the voltage transformers are located on the line side of the circuit breaker.

The *Automatic SOTF Ini* setting is used to configure the internal dead line detection function.

Table 1167: Options for dead line detection

Automatic SOTF Ini	Description
DLD disabled	The dead line detection function is disabled. This operation mode must be applied when voltage transformers are located on the bus side of the circuit breaker.
Voltage	The dead line detection function is enabled and based solely on the undervoltage condition. A dead line condition is declared, if all the phase voltages are below the *Voltage dead Lin Val* setting. The dead line is detected if the dead line condition is declared and simultaneously no fault is detected by the START and START_DLYD inputs . The dead line condition is signalled to the SOTF control after the delay defined with the *Dead line time* setting.
Current	The dead line detection function is enabled and based solely on the undercurrent condition. A dead line condition is declared, if all the phase currents are below the *Current dead Lin Val* setting. The dead line is detected if the dead line condition is declared and simultaneously no fault is detected by the START and START_DLYD inputs. The dead line condition is signalled to the SOTF control after delay defined with the *Dead line time* setting.
Current & Voltage	The dead line detection function is enabled and based on undercurrent and undervoltage condition. A dead line condition is declared, if all the phase currents are below the *Current dead Lin Val* setting and simultaneously all phase voltages are below the *Voltage dead Lin Val* setting. The dead line is detected if the dead line condition is declared and simultaneously no fault is detected by the START and START_DLYD inputs. The dead line condition is signalled to the SOTF control after delay defined with the *Dead line time* setting.

SOTF detection

The purpose of this module is to detect the switch onto fault situation based on the current and voltage measurements. If the voltage, in any of the phases, is below the *Voltage dead Lin Val* setting and simultaneously the current in the same phase

exceeds the *Current dead Lin Val* setting, the SOTF situation is signalled to SOTF control module after the set *Cur voltage Det time*.

SOTF control

The SOTF control module needs to be activated before the operation is possible in the switch-onto-fault situation. There are two ways to activate the SOTF control module.

- By CB_CL_CMD (circuit breaker closing command).
- By the dead line condition received from the dead line detection module.

Dead line detection should be used only when the voltage transformers are located on the line side of the circuit breaker.

When the CB_CL_CMD input is activated or the dead line condition is detected, the SOTF control module becomes active. The reset timer is started when CB_CL_CMD is inactivated or the dead line condition disappears. Thus, the module becomes inactive after the set *SOTF reset time* is exceeded.

When the SOTF control module is active, the *Operation mode* setting defines the operation criteria for the detection of a switch-onto-fault condition. The detection can be based on the external start signals from the distance or overcurrent functions, on the measured internal voltage and current levels, or on both.

Table 1168: Options for SOTF detection

Operation mode	Description
Start	The OPERATE output is activated immediately after a signal from the trigger module. This indicates that the breaker is closed onto fault.
Current & Voltage	The OPERATE output is activated immediately after a signal from the SOTF detection module. This indicates that the breaker is closed onto fault. This operation mode can be used, for example, if the non-directional distance zone is not available.
Both	The OPERATE output is activated immediately after a signal from the trigger or SOTF detection modules. This indicates that the breaker is closed onto fault.

The OPERATE output can be blocked by activating the BLOCK input.

5.8.6 Application

The operation of CVPSOF is generally based on the non-directional distance zone or the non-directional overcurrent stage. When the feeder-side voltage transformers are used for providing the polarization quantity for the distance or directional overcurrent protection, the use of non-directional impedance or current based protection for starting CVPSOF secures a fast switch-onto-fault tripping in the close-in three-phase short circuits. The non-directional protection provides a fast fault clearance when the protection is used for energizing a bus from the feeder with a short circuit fault in it. Other protection functions, like time delayed zero-sequence overcurrent functions, can be connected to CVPSOF to increase the dependability of the scheme. The other main advantage of using CVPSOF is that it

typically accelerates the tripping in case of energizing a feeder onto a fault. Without CVPSOF, this tripping is normally performed by the normal time-graded protection or alternatively by the time-delayed local backup protection, for which operating times are considerably longer than with CVPSOF tripping.

An internal dead line detection check is provided to activate the function when the voltage transformers are located on the feeder side. An initiation by the dead line detection is highly recommended for the busbar configurations where more than one circuit breaker at one feeder end can energize the protected feeder or the feeder can also be energized from the other end.

Setting guidelines

Input `START`: If a distance zone is used for starting the switch-onto-fault function, the zone has to be set to cover the entire protected feeder with a safety margin of minimum 20 percent. If the non-directional zone is not available, the internal *Current & Voltage* criterion or the start signal from the GFC function can be used instead. If a non-directional overcurrent is used for starting, the current setting must not be higher than what is required for the non-delayed and dependable tripping for a close-in three-phase fault during minimum source conditions. If the short-circuit current along the feeder is considerably higher than the maximum load currents, it is possible that the whole feeder length is covered by CVPSOF tripping. If it is required to delay the tripping, for example, due to high inrush currents, the starting signal can be connected to the `START_DLYD` input instead.

The *Current dead Lin Val* setting parameter is set to 20 percent of the base current by default. The parameter must be set with a sufficient margin of 15...20 percent under the minimum expected load current. The setting must still exceed the maximum charging current of a feeder.

The *Voltage dead Lin Val* setting parameter is set to 70 percent of the base voltage by default. This is a suitable setting in most cases, but it is recommended to check the suitability in the actual application.

The *Cur voltage Det time* setting parameter is set to 0.02 seconds by default. This is suitable in most applications. This delay can be coordinated, for example, with the dead time settings of the AR shots to prevent the release of CVPSOF by the dead line detection function when the high-speed autoreclosing is in progress.

The *Dead line time* setting parameter is set to 0.2 seconds by default. This is suitable in most applications. The delay must not be set too short to avoid unwanted activations during the transients in the system.

The *SOTF reset time* setting parameter is set to 1 second by default. This is suitable for most applications.

5.9 Local acceleration logic DSTPLAL (ANSI 21LAL)

5.9.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Local acceleration logic	DSTPLAL	LAL	21LAL

5.9.2 Function block

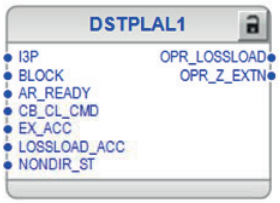

Figure 698: Function block

5.9.3 Functionality

The local acceleration logic function DSTPLAL is a complementary function to the distance protection function DSTPDIS. DSTPLAL is not intended for a stand-alone use.

The main purpose of DSTPLAL is to achieve a fast fault clearing which is independent of the fault location on the protected feeder when no communication channel is available between the local and remote terminals. DSTPLAL enables a fast fault clearing during certain conditions, but the function cannot completely replace the communication scheme logic.

DSTPLAL can be controlled either by the autorecloser (zone extension logic) or by monitoring the loss of load currents (the loss of load logic). Both operation modes are enabled independently.

5.9.4 Analog channel configuration

DSTPLAL has one analog group input which must be properly configured.

Table 1175: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.9.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of DSTPLAL can be described with a module diagram. All the modules in the diagram are explained in the next sections.

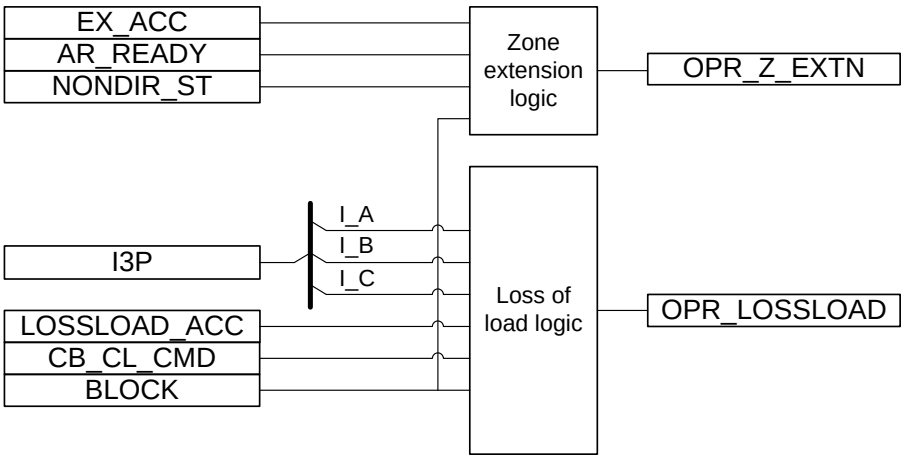

Figure 699: Functional module diagram

Zone extension logic

Zone extension logic is enabled with *Operation mode* = "Zone extension".

When the zone extension operation mode is enabled, the autoreclosing function DARREC enables a fast fault clearance that covers the entire length of the protected

feeder. This is achieved by allowing a time-delayed overreaching zone to trip instantaneously when a fault occurs. For this purpose, one of the DSTPDIS zones can be configured with an independently set reach.

After the overreaching zone instantaneously trips, the autoreclosing sequence starts. If the fault is transient, the system may get restored in the first shot of AR. However, in case of a persistent fault only the first trip of the AR sequence is accelerated by Zone extension logic. During the rest of the sequence, Zone extension logic is blocked and AR initiation is performed selectively by the time-graded distance zones.

If the fault is located on the adjacent feeder or bus within the reach of the overreaching zone, tripping and AR initiation take place in an external fault.

Zone extension logic can be described using a module diagram.

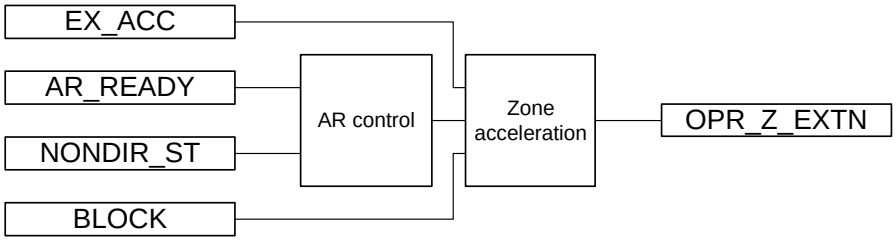

Figure 700: Functional module diagram of Zone extension logic

AR control

The AR control module supervises the zone acceleration by monitoring the status of the AR_READY and NONDIR_ST input signals. The READY output signal from the autorecloser (AR) function, which indicates the status of the autoreclosing, is connected to the AR_READY input. The start signal from the non-directional zone is connected to the NONDIR_ST input. If the non-directional zone is not available for this, then the start output from the overreaching zone with the biggest reach or GFC can be used instead.

The permission for zone acceleration is given if AR_READY = TRUE, that is, the AR function is ready to start a new AR sequence. If the set reclaim time of the AR function expires before the fault is cleared, the NONDIR_ST input signal is used to block the activation of the zone acceleration. This ensures that the accelerated trip followed by the AR initiation is not repeated for the same fault regardless of the reclaim time setting and the reach of the overreaching zone connected to the EX_ACC input. Otherwise, this could lead to pumping of the circuit breaker, that is, the repetition of the first shot without being able to complete the desired AR sequence.

The AR control module blocks the Zone acceleration module after the initiation of the first shot until the AR sequence has been completed, that is, until the AR_READY input signal changes its state back from FALSE to TRUE.

Zone acceleration

The start signal from the overreaching zone whose operation is to be accelerated is connected to the EX_ACC input. When the EX_ACC input is activated and, simultaneously, the AR control module gives permission for acceleration, the

operate signal from Zone extension logic is obtained from the OPR_Z_EXTN output, which is used to trip the circuit breaker and initiate the autoreclosing (the AR shot).

The activation of the BLOCK input blocks the OPR_Z_EXTN output.

Loss of load logic

Loss of load logic is enabled with *Operation mode* = "Loss of load".

When the loss of load operation mode is enabled, a time-delayed overreaching zone is allowed to trip instantaneously if the loss of load current condition is detected.

The loss of load function does not operate in case of a three-phase fault as all the phases are faulty. Therefore, none of the current values drops below the *Minimum current* setting, meaning that the loss of load current condition cannot be detected.

Loss of load logic can be described using a module diagram.

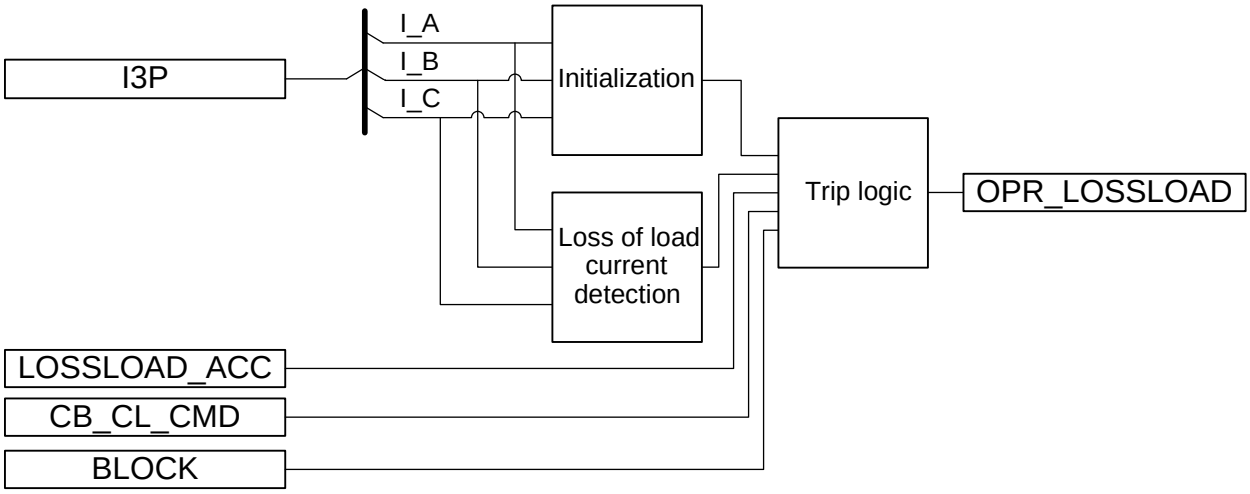

Figure 701: Functional module diagram of Loss of load logic

Initialization

The Initialization module gives an enabling signal to the Trip logic module when the values of all three phase currents are above the set value of *Load current value* for more than the time set with *Load release on time*. The enabling signal has a drop-off delay defined with the *Load release off Tm* setting.

Loss of load current detection

The Loss of load current detection module gives an enabling signal to the Trip logic module if any of the phase current values drops below the *Minimum current* setting due to a remote end breaker opening and, simultaneously, the value of at least one phase current exceeds the value of the *Load current value* setting due to a fault. Such a condition has to be valid for longer than the *Minimum current time* setting.

Trip logic

The operate signal is obtained from the OPR_LOSSLOAD output if the enable signal is received from both Initialization and Loss of load current detection modules and, simultaneously, a fault is seen by the overreaching zone connected to the LOSSLOAD_ACC input.

The activation of the BLOCK input blocks the OPR_LOSSLOAD output. Temporary blocking is achieved using the circuit breaker's close command pulse connected to the CB_CL_CMD input. It is used to prevent an unwanted operation due to initial transients after the breaker is closed, for example, in case of inrush currents.

5.9.6 Application

DSTPLAL is used in those applications where the conventional communication scheme logic cannot be applied (when no communication channel is available), but the user still requires a fast clearance for the faults on the entire feeder.

DSTPLAL enables a fast fault clearing during certain conditions, but it is unable to replace the communication scheme logic due to a possible lack of selectivity during the first trip and AR initiation and also as the loss of load logic cannot operate for three-phase faults. DSTPLAL is controlled either by the autoreclosing (Zone extension logic) or by monitoring the loss of load current (Loss of load logic).

Zone extension logic

The zone extension operation mode can be applied when the autoreclosing function DARREC is in operation. When the zone extension is enabled, DARREC is used to enable the fast fault clearance independent of the fault location on the protected feeder. This is achieved by allowing a time-delayed overreaching zone to trip instantly when a fault occurs. Also, if there are tapped loads on the protected feeder, it is required to set a dedicated zone to initiate one or two shots as fast as possible before the protection devices of these taps clear. If the fault is still present after these shots, further tripping is delayed in accordance with the other zones so that the operation becomes slower than the protection of the load taps, enabling it to clear. The final tripping that ends the sequence is always performed selectively according to the time grading of the zones.

If the fault is located on the adjacent feeder or bus within the reach of the overreaching zone, the tripping and the AR initiation take place during an external fault.

Setting guidelines

The *Load current value* setting must be set below the minimum three-phase load current during the healthy state. A security factor of 0.5 is used:

Load current value = $0.5 \cdot I_{minload}$

$I_{minload}$ minimum load current during normal operation conditions

The loss of load function is released after *Load release on time* is elapsed and the load current in all three phases is above the *Load current value* setting. If the current values drop below the *Load current value* setting, the release condition stays activated until the drop-out delay time has expired (the *Load release off Tm* setting). The value of *Load release off Tm* is by default set to "0.3 s". The *Load release on time* setting is used to increase the security of the loss of load function, for example, in the case of transient inrush currents during the energizing of a power transformer. When there is no need for delaying the release, the *Load release on time* is set to zero in applications.

The *Minimum current* setting is used to detect the loss of load condition in healthy phases during the fault. The *Minimum current* setting is set to a value higher than the maximum current flowing in the healthy phases during the fault when

the breaker at the remote end has been opened and the load flowing through has therefore been disconnected. This current can be, for example, due to the charging current of the phases or the load current of the tapped loads. The *Minimum current* setting value is set below the *Load current value* setting. By default, the *Minimum current* setting value is set to "0.05 pu".

The *Minimum current time* setting is used to provide the start delay for the loss of load current detection to avoid an unwanted release of the function. The value of *Minimum current time* is by default set to "0.2 s".

Scheme communication logic	DSOCPSCH	CL	85 21SCHLGC

5.10.2 Function block

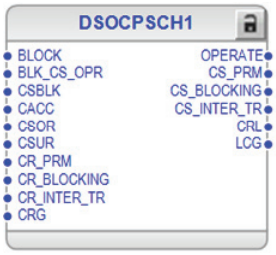

Figure 702: Function block

5.10.3 Functionality

The scheme communication logic function DSOCPSCH is used to achieve instantaneous fault clearing independent of the fault location on the protected feeder. Several communication scheme types are available.

- Direct underreaching transfer trip DUTT
- Permissive underreaching transfer trip PUTT
- Permissive overreaching transfer trip POTT
- Directional comparison blocking scheme DCB

The directional comparison unblocking scheme DCUB can also be implemented by complementing the permissive schemes with an additional logic called the unblocking function, which is also included in DSOCPSCH.

If the permissive overreach scheme is used, some of the power system conditions require additional special logic circuits, such as the current reversal and weak-end infeed logic function CRWPSCH.

5.10.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of DSOCPSCH can be described with a module diagram. All the modules in the diagram are explained in the next sections.

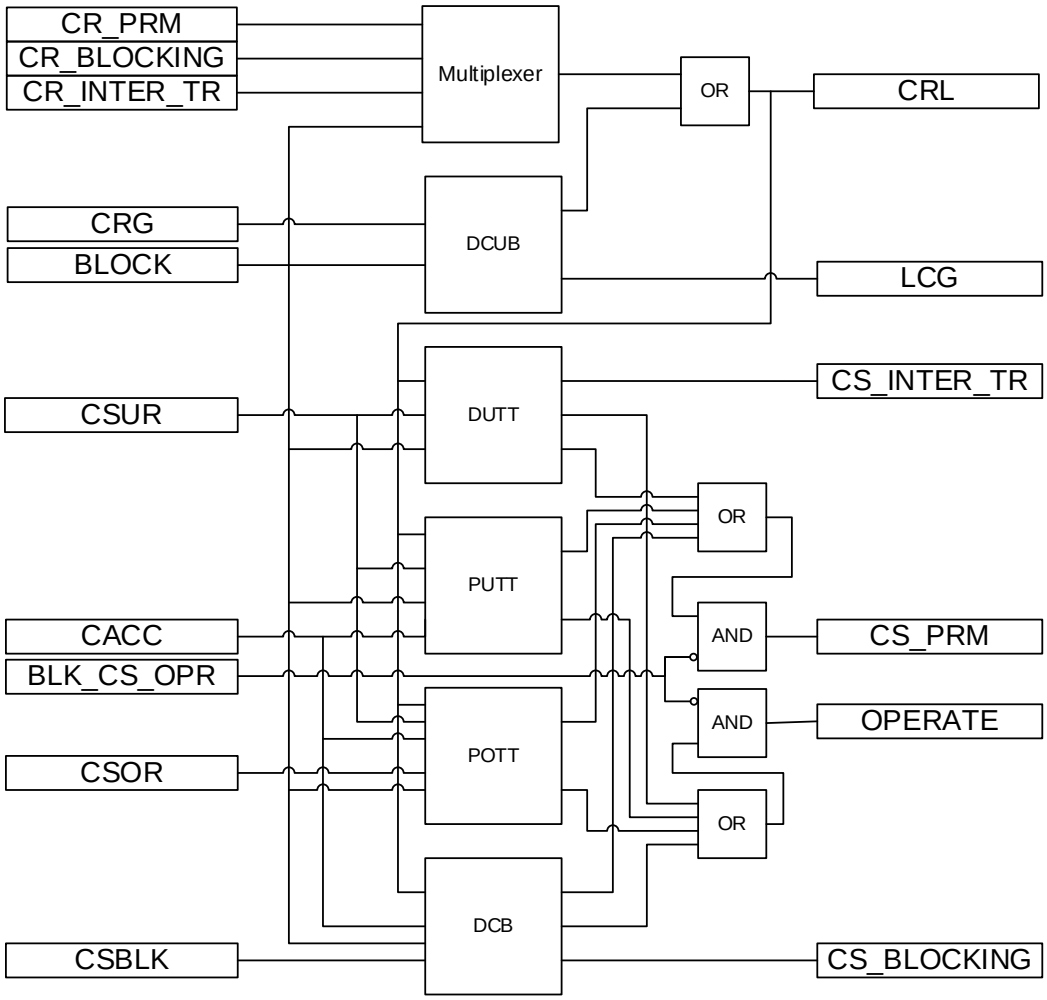

Figure 703: Functional module diagram

The applied communication scheme logic in DSOCPSCH is selected with the *Scheme type* setting.

Table 1181: Communication scheme based on the Scheme type value

***Scheme type* value**	**Communication scheme**
"Intertrip"	DUTT
"Permissive Underreach"	PUTT
"Permissive Overreach"	POTT
"Blocking"	DCB

The unblocking scheme (DCUB) is enabled with the *Unblock Mode* setting.

Multiplexer

The multiplexer connects an input signal to an output based on the value of the *Scheme type* setting.

Table 1182: Connected inputs based on the Scheme type value

Scheme type value	Inputs connected to an output
"Intertrip"	CR_INTER_TR
"Permissive Underreach" or "Permissive Overreach"	CR_PRM
"Blocking"	CR_BLOCKING

Direct underreaching transfer trip scheme DUTT

The direct intertrip scheme is enabled with *Scheme type* = "Intertrip".

In the direct intertrip scheme, the start signal from the underreaching zone Z1 is connected to the CSUR input to create a carrier send CS_INTER_TR signal. The duration of the CSUR input signal is prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration for the CS_INTER_TR signal.

The local circuit breaker is directly tripped (activation of the OPERATE output) with the carrier received CS_INTER_TR signal after a settable pick-up delay *Coordination Time* has elapsed without further local criteria.

The unblocking function (*Unblock Mode* = "Permanent" and *Unblock Mode* = "Time window") must not be enabled with the DUTT scheme, as the lost guard signal results in an immediate trip of the local circuit breaker.

The activation of the BLOCK input totally blocks the direct intertrip scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

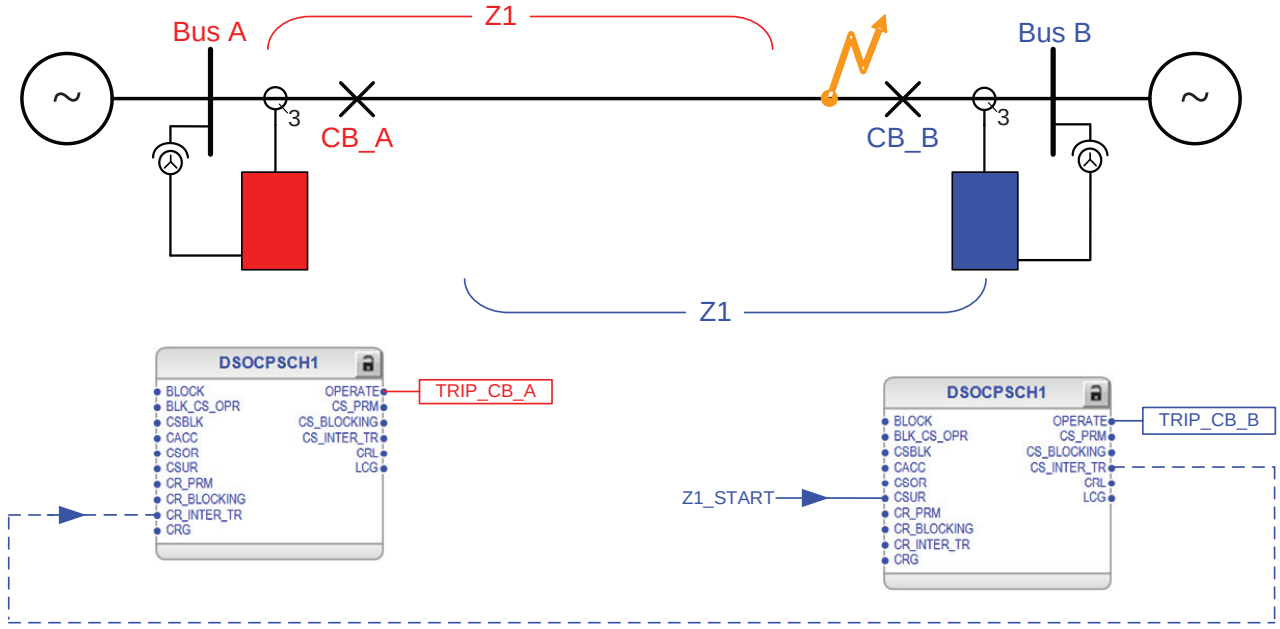

Figure 704: Simplified functional diagram of the direct intertrip scheme

Permissive underreaching transfer trip scheme PUTT

The permissive underreach scheme is enabled with *Scheme type* = "Permissive Underreach".

In the permissive underreach scheme, the start signal from the underreaching zone Z1 is connected to the CSUR input to create a CS_PRM signal. The duration of the CSUR input signal can be prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_PRM signal.

In the permissive underreach scheme, the CS_PRM signal, or the CRL signal if the unblocking function is enabled, is used to allow the overreaching zone Z2 to trip (activation of the OPERATE output) after the pick-up delay *Coordination Time*. The start signal from the overreaching zone Z2 is connected to the CACC input.

Activating the BLOCK input totally blocks the permissive underreach scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

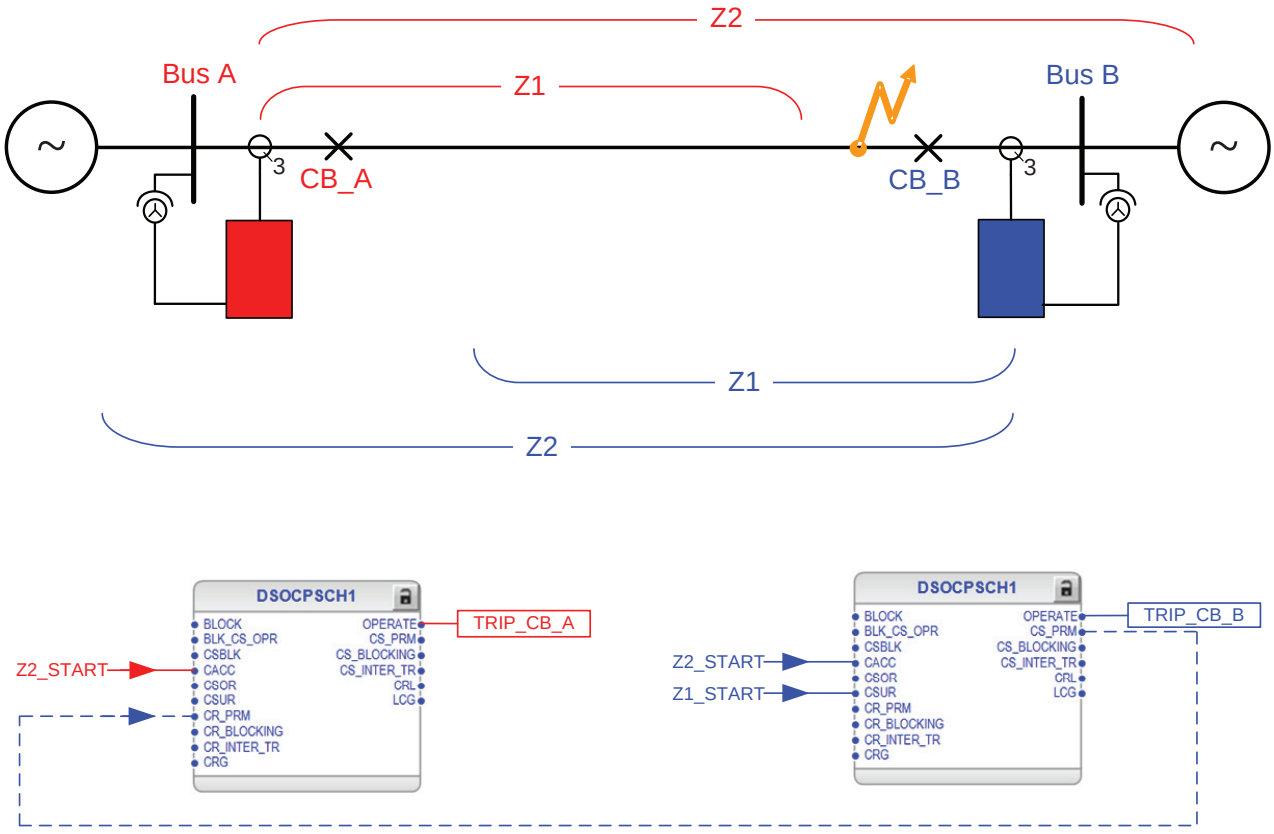

Figure 705: Simplified functional diagram of the permissive underreach scheme

Permissive overrreaching transfer trip scheme POTT

The permissive overreach scheme is enabled with *Scheme type* = "Permissive Overreach".

In this scheme, the start signal from the overreaching zone Z2 is connected to the CSOR input to create a CS_PRM signal. The CS_PRM signal can also be issued simultaneously from the underreaching zone Z1. In this case, the start signal from the underreaching zone Z1 is connected to the CSUR input. The duration of the CSUR input signal is prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_PRM signal.

In case of parallel feeders, and when the external current reversal logic (CRWPSCH) is enabled, the CS_PRM signal is not prolonged and the value of *Carrier Min Dur* is set to zero to secure correct operation.

In the permissive overreach scheme, the received signal CR_PRM, or CRL if the unblocking function is enabled, is used to allow the overreaching zone Z2 to trip (activation of the OPERATE output) after the settable pick-up delay *Coordination Time*. The start signal from the overreaching zone is connected to the CACC input.

Activating the BLOCK input totally blocks the permissive overreach scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

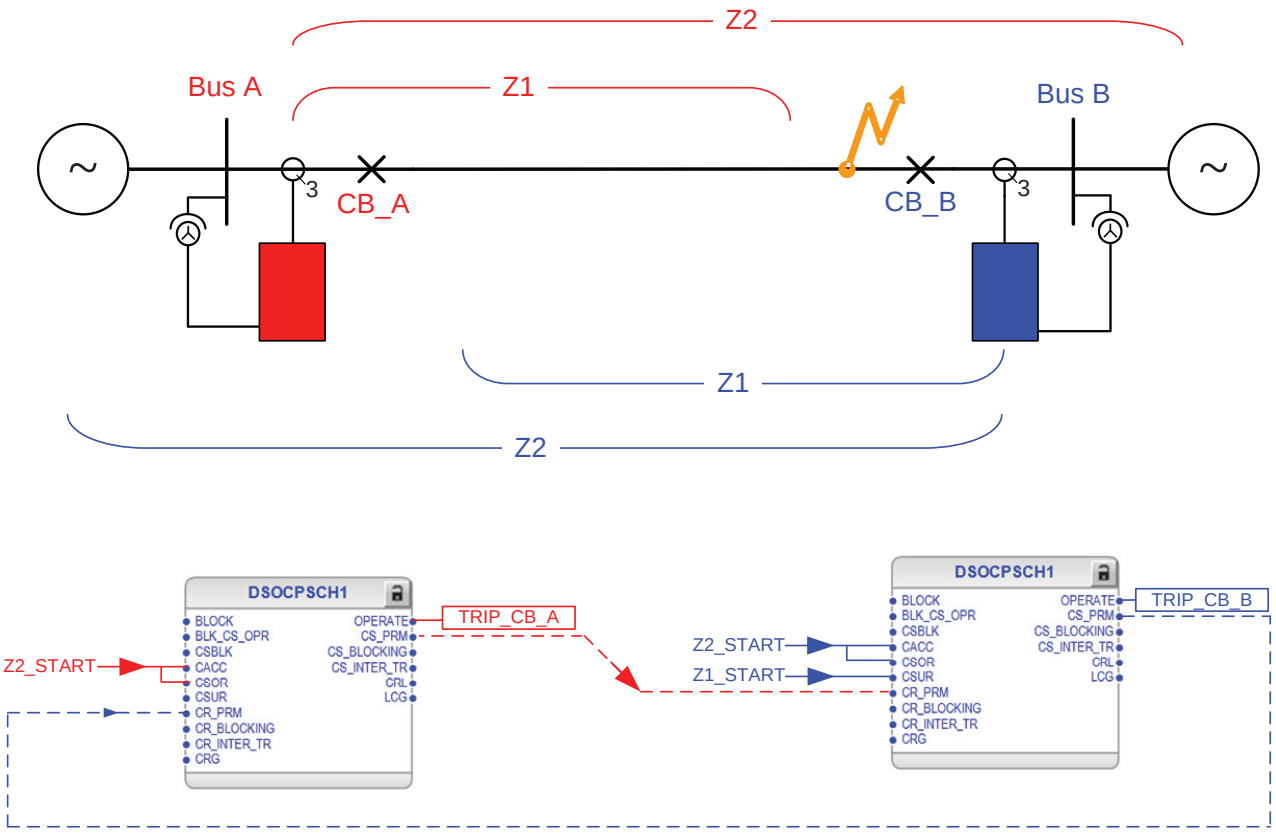

Figure 706: Simplified functional diagram of the permissive overreach scheme

Directional comparison blocking scheme DCB

The directional comparison blocking scheme is enabled with *Scheme type* = "Blocking".

In the blocking scheme, the start signal from the reverse-looking zone Z3 is connected to the CSBLK input to create a CS_BLOCKING signal. The starting of the reverselooking zone indicates that the fault is located outside the protected feeder. The duration of the CSBLK input signal can be prolonged with the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_BLOCKING signal.

The blocking scheme is mainly used to allow the overreaching zone Z2 to trip (activation of the OPERATE output) after the settable *Coordination Time* has elapsed, and if no blocking signal is received from the remote terminal. To prevent a false trip in case of an external fault, the block signal CR_BLOCKING must be received before the *Coordination Time* has elapsed. The start signal from the overreaching zone Z2 is connected to the CACC input.

The *Coordination Time* setting in the blocking scheme depends, for example, on the communication system delay and on the terminal's

response times in transmitting the CS_BLOCKING signal to the other feeder end. The *Coordination Time* setting must not be zero.

Activating the BLOCK input totally blocks the directional comparison blocking scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

In *Figure 707*, in case of internal faults, the CS_BLOCKING signal is not sent because the fault is not sent as it is not seen by the reverse-looking zones (Z3).

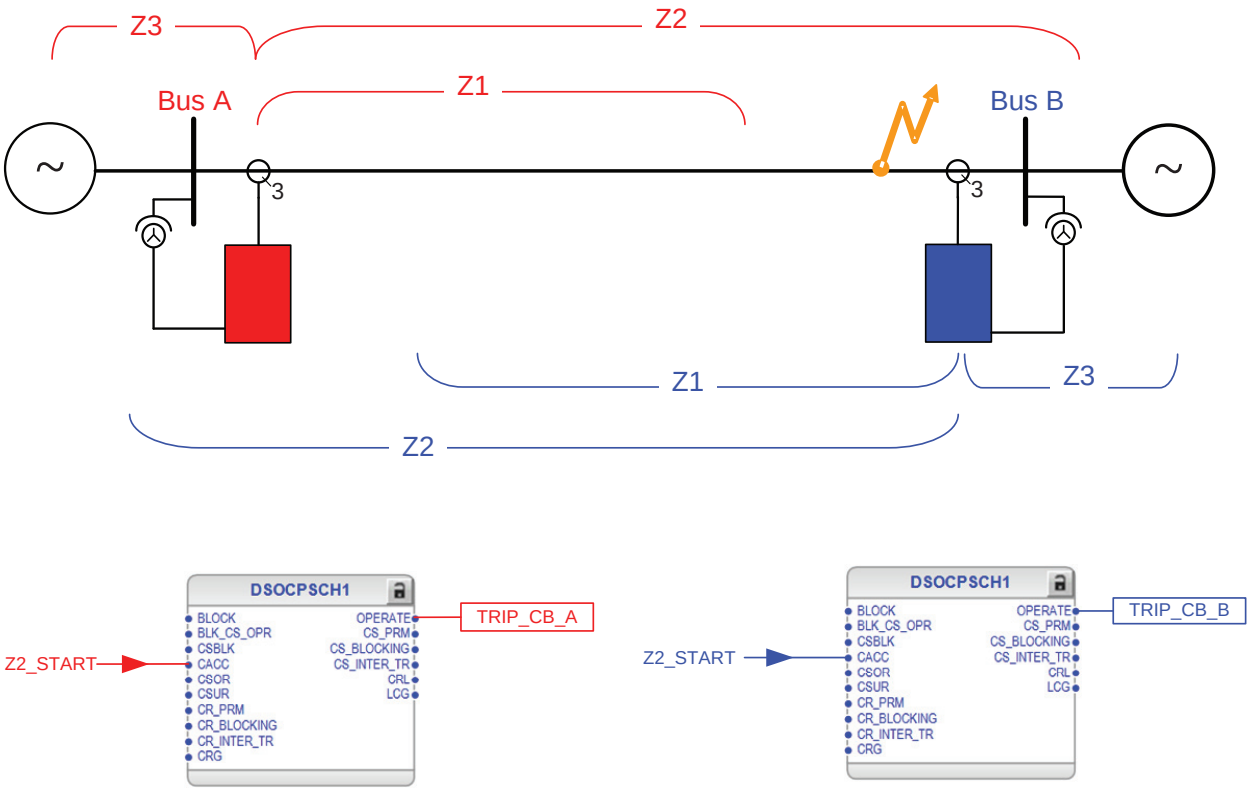

Figure 707: Simplified functional diagram of the blocking scheme, internal fault

In *Figure 708*, in case of external faults, the protection relay at bus B sees the fault in the reverse direction and sends a blocking signal CS_BLOCKING to the protection relay at bus A. There is no CB operation at either end.

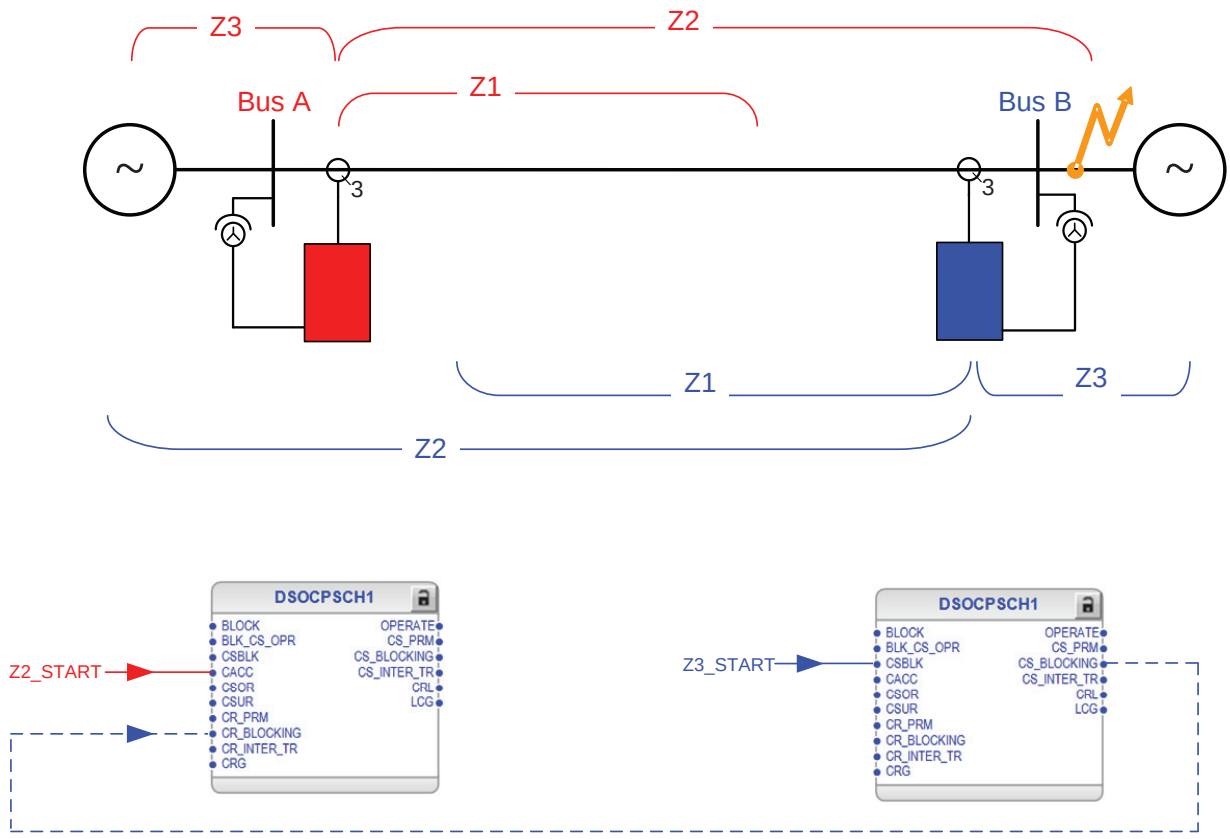

Figure 708: Simplified functional diagram of the blocking scheme, external fault

The unblocking function used with the blocking function provides a possibility to supervise the communication channel. In this case, the CRL output signal is used as a local blocking signal.

The operation mode *Unblock Mode* = "Time window" is not recommended as the blocking is activated only for 150 ms after the guard signal disappears. This results in an unwanted operation of the protection.

Directional comparison unblocking scheme DCUB

The unblocking function is a complementary logic which can be used together with the permissive communication schemes. In the unblocking scheme, the dependability of the permissive schemes is improved by using the loss of guard signal from the communication equipment to create a CRL output signal locally. This enables the permissive scheme to operate even if the communication channel is interrupted or lost.

The unblocking function uses a carrier guard signal which must always be present. The absence of the CRG signal for a time longer than the value of the *Loss of carrier time* setting generates a logical CRL signal. A communication failure shorter than the value of the *Loss of carrier time* setting is always ignored.

The unblocking function is configured with the *Unblock Mode* setting.

- *Unblock Mode* = "Off": The unblocking function is disabled.
- *Unblock Mode* = "Permanent": If the CRG signal disappears for a longer time than defined in the *Loss of carrier time* setting, the logical CRL signal is

generated. The CRL output signal remains active until the CRG signal reappears. The communication failure is not signaled by the LCG output.

- *Unblock Mode* = "Time window": If the CRG signal disappears for a longer time than defined in the *Loss of carrier time* setting, the CRL output signal is generated. The CRL output signal remains active for 150 ms, after which a communication failure is signaled by the LCG output. The LCG output is reset 200 ms after the CRG signal reappears. The purpose of this mode is to ensure tripping during a fixed delay of 150 ms after the loss of communication due to possible consequences of an internal fault. After this time, the accelerated tripping is allowed only if the CR_PRM signal is received again.

With operation modes *Unblock Mode* = "Permanent" and *Unblock Mode* = "Time window", the created CRL output signal is internally ORed with the CR_PRM input to allow the permissive scheme to operate even when the communication channel has been interrupted or lost. The CRL and LCG output signals are also available as outputs for monitoring purposes. Activating the BLOCK input blocks the CRL and LCG outputs.

5.10.5 Application

To achieve fast fault clearing on the part of the protected feeder not covered by the instantaneous zone Z1, the stepped distance protection function can be used with DSOCPSCH.

Applying DSOCPSCH requires a communication channel capable of transmitting an "On" or "Off" signal in each direction. To enable fast tripping, the most important requirement for the communication channel is the communication speed.

The performance of DSOCPSCH is directly related to the communication channel speed, and to the security against false or lost signals. Therefore, dedicated communication channels are recommended. With short distances of up to a few kilometers, a typical communication media is a simple pilot wire based on auxiliary power. With distances of up to 50 km with the integrated communication interface or up to 150 km with external equipment, fibre-optic cables using digital data transmission can be used. To avoid false signals causing unwanted operation, the security of the communication channel should be emphasized. Also, the dependability of the communication channel should be considered to ensure that the signals are reliably transmitted during the power system faults.

DSOCPSCH supports five communication schemes.

- Direct underreaching transfer trip DUTT
- Permissive underreaching transfer trip PUTT
- Permissive overreaching transfer trip POTT
- Directional comparison blocking scheme DCB
- Directional comparison unblocking scheme DCUB

Depending on whether the communication channel is used for sending a block or a trip signal, the communication schemes can be divided into blocking schemes and permissive schemes.

In permissive schemes, the trip signals of the distance zones are interchanged between the terminals to receive a permission to trip during an internal fault. The tripping of the local terminal depends on both the starting of its own forward-looking zone and on the received signal from the opposite terminal. In the underreaching scheme, no signals are sent during an external fault. During an external fault, a trip signal is also sent to the opposite terminal if the fault is seen

in the forward direction and the overreaching scheme is used. However, in case of external faults, tripping is always blocked because either no signal is received as the opposite terminal sees a reverse fault or because the signal is received but the fault is seen in the reverse direction. In either case, the blocking is not dependent on the received signal so a lost communication channel does not result in false operation.

In the blocking scheme, a blocking signal is sent to the opposite terminal if the fault is locally seen in the reverse direction, that is, during an external fault. Thus, the blocking is dependent on the received signal, and there is typically a need to delay the tripping of the terminal receiving the blocking signal. This delay depends, for example, on the response times of the communication channel and terminals. During an internal fault, there is no signal transmission between the terminals, so the tripping does not depend on the received signal from the opposite terminal.

In conclusion, compared to the blocking schemes, the permissive schemes are inherently faster and have better security [1] against false tripping, since tripping in an external fault is not possible in case of a channel interruption. In a blocking scheme, a lost communication channel and a simultaneous external fault may lead to a false operation of the protection if the communication channel is not supervised. On the other hand, as the fast trip of the permissive scheme depends on the received signal, its dependability [2] is lower than that of the blocking scheme.

The unblocking scheme enhances the dependability of the permissive scheme. If the communication channel is interrupted and, simultaneously, a fault occurs in the forward direction, tripping is still possible either during a fixed time interval, counting from the beginning of the interruption, or for as long as the communication channel is lost. This is achieved by connecting the supervision output of the implemented communication functionality to the dedicated carrier guard signal input of DSOCPSCH. In general, the unblocking scheme provides better security than the blocking scheme because tripping in external faults is only possible if the fault occurs within the fixed time interval after the beginning of the channel interruption.

The direct transfer trip scheme uses the underreaching zone to trip the local breaker and to transfer the trip signal to a remote terminal. The remote terminal operates immediately based on the received transfer trip signal, without any additional conditions. This scheme is very simple, but the security is low as a spurious signal results in false operation of the protection.

Direct underreaching transfer trip DUTT

In some applications, there is a need to trip the remote-end breaker immediately because of fault detection by the local measurements. This applies, for example, when the transformers or reactors are connected to the system without circuit breakers, or for remote tripping after the operation of the local breaker failure protection (CBFP).

In the direct intertrip scheme (DUTT), the carrier send signal `CS_INTER_TR` is initiated by an underreaching zone, or by the tripping signal from an external protection relay, such as transformer or reactor protection. At the remote end, the received signal initiates a breaker trip immediately without any further local protection criteria. To limit the risk of an unwanted trip due to spurious sending of signals, the trip can be delayed by the *Coordination Time* setting, which should be set to 10...30 ms, depending on the type of the communication channel. The

[1] The ability to block operation in case of an external fault.
[2] The ability to operate in case of an internal fault.

communication channel operating in direct intertripping applications should be secure and dependable.

Setting guidelines for the intertrip scheme DUTT

- *Scheme type* = "Intertrip"
- *Coordination Time* = "0.050" s (10 ms + maximal transmission time)
- *Carrier Min Dur* = "0.1" s

Permissive underreaching transfer trip PUTT

In the permissive underreach scheme, the permission to trip is obtained locally from the underreaching zone and sent to the remote end. The received signal is combined with the local fault indication from the overreaching zone resulting in a trip command after a settable pick-up delay *Coordination Time*.

The protection relay of either feeder end sends a permissive signal to trip the other end. The communication channel must be able to receive and transmit at the same time. In permissive schemes, the communication channel must be fast and secure, but also dependable. Inadequate security causes unwanted tripping for the external faults. Inadequate speed or dependability causes delayed tripping for internal faults.

The CS_PRM signal is issued based on the underreaching zone Z1.

The underreach scheme is not applicable on short feeder lengths because the impedance measurement cannot easily distinguish between the internal and external faults in such cases.

The underreaching zones Z1 at the local and remote ends must overlap to prevent a gap between the protection zones, where the faults are not detected. If the underreaching zone does not meet the required sensitivity, for example, the fault infeed from a remote end, the blocking or permissive overreach scheme is considered.

To achieve an instantaneous trip, the carrier received signal CR_PRM must be received when the overreaching zone Z2 is still starting. In some cases, due to a fault in current distribution, the overreaching zone can operate only after the fault has been cleared by the remote terminal. In this case, there is a risk that if the remote terminal is tripped directly by, for example, zone Z1, the CR_PRM signal issued by the zone resets before the overreaching zone of the local end terminal has operated. To assure a sufficient duration of the CR_PRM signal, the CR_PRM signal can be prolonged by the time *Carrier Min Dur*. The recommended value of the *Carrier Min Dur* setting is "0.1" s.

The received communication signal is combined with the output from the local overreaching zone. Therefore, there is less concern about a false signal causing an incorrect trip, and therefore the timer *Coordination Time* is set to "0". A communication channel failure does not affect the selectivity, but delays the tripping at the other end for certain fault locations.

Setting guidelines for the permissive underreach scheme PUTT

- *Scheme type* = "Permissive Underreach"
- *Coordination Time* = "0" s
- *Carrier Min Dur* = "0.1" s

Permissive overreaching transfer trip POTT

In the permissive overreach scheme, the permission to trip is obtained locally from an overreaching zone and sent to the remote end. The received signal is then combined with the local fault indication from the overreaching zone, resulting in a trip command after a settable pick-up delay *Coordination Time*.

The protection relay at either end of the feeder sends a permissive signal to trip the other end. Therefore the communication channel must be able to receive and transmit at the same time. The communication on permissive schemes should be fast and secure.

The CS_PRM signal is issued based on the overreaching zone Z2.

The permissive overreach scheme can be used for all feeder types and lengths.

In the permissive overreach scheme, the communication channel plays an essential role in obtaining a fast tripping at both ends. Typically, a lost communication channel does not cause false tripping. However, it delays the operation of the protection for the faults anywhere on the feeder.

The communication channel for a permissive overreach scheme must be fast and secure, but also dependable. Inadequate security can cause unwanted tripping for external faults. Inadequate speed or dependability can cause delayed tripping for internal faults.

In the permissive overreaching scheme, the CS_PRM signal can be issued in parallel both from the overreaching and underreaching zones. The CS_PRM signal from the overreaching zone must not be prolonged, while the CS_PRM signal from the underreaching zone must typically be prolonged. In parallel feeder applications, the scheme typically needs to be complemented by the current reversal logic. To ensure the correct operation in this case, the CS_PRM signal must not be prolonged (*Carrier Min Dur* = "0" s). There is no need to delay the tripping while receiving the carrier signal, so the timer *Coordination Time* is set to "0".

Setting guidelines for the permissive overreaching transfer trip scheme POTT

- *Scheme type* = "Permissive Overreach"
- *Coordination Time* = "0" s
- *Carrier Min Dur* = "0.1" s
- *Carrier Min Dur* = "0" s (in case of parallel lines and current reversal logic)

Directional comparison blocking scheme DCB

In the blocking scheme, the reverse-looking zone Z3 is used for sending a block signal to the remote end to block the overreaching zone.

The blocking scheme is very dependable because it operates on faults anywhere on the protected feeder, even if the communication channel is out of service. Conversely, it is less secure than a permissive scheme because it trips for the external faults within the reach of the overreaching local zone if the communication channel is out of service and no block signal is received.

Inadequate speed or low dependability of the communication channel can cause spurious tripping for external faults.

To secure that the blocking signal arrives before the local overreaching zone trips, the trip is delayed by the *Coordination Time* setting. This setting must be set longer than the sum of the maximal transmission time of the channel and the start and response times of the protection relays sending and receiving the CS_BLOCKING

signal. A security margin of at least 10 ms should be considered. The time delay *Carrier Min Dur* for prolonging the CS_BLOCKING signal is set to "0".

Setting guidelines for the blocking scheme DCB

- *Scheme type* = "Blocking"
- *Coordination Time* = "0.1" s (10 ms + maximal transmission time)
- *Carrier Min Dur* = "0" s

Directional comparison unblocking scheme DCUB

Metallic communication paths unfavorably affected by fault-generated noise or by other electrical phenomena, such as lightning, are not suitable for conventional permissive schemes that rely on the signal transmitted during a fault in the protected feeder. Principally, the communication media must be properly shielded or otherwise designed to provide an adequate performance during such conditions.

The unblocking scheme can be used to overcome the lower dependability of permissive schemes. The function is used in older, less reliable communication, where the signal has to be sent through the primary fault. The unblocking function uses a carrier guard signal CRG which must always be present, even when no CR_PRM signal is received. Due to the absence of the CRG signal during the security time, the *Loss of carrier time* setting is used as a CR_PRM signal. This also enables a permissive scheme to operate when the communication channel is temporarily lost during an internal fault.

Setting guidelines for the unblocking scheme DCUB

The unblocking function is configured with the *Unblock Mode* setting.

- *Unblock Mode* = "Off": The unblocking function is disabled.
- *Unblock Mode* = "Permanent": If the CRG signal disappears for a longer time than defined in the *Loss of carrier time* setting, a logical carrier received signal CRL is generated. The CRL signal remains active until the CRG signal is present. The communication failure is not signalled by the LCG output. The *Loss of carrier time* setting is set to "35" ms.
- *Unblock Mode* = "Time window": If the CRG signal disappears for a longer time period than the *Loss of carrier time* setting, a CRL signal is generated. The CRL signal remains active for 150 ms, after which a communication failure is signalled by the LCG output. The value of the LCG output is reset 200 ms after the CRG signal reappears. The *Loss of carrier time* setting is set to "35" ms.

5.11.2 Function block

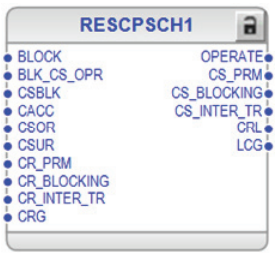

Figure 709: Function block

5.11.3 Functionality

The communication logic for residual overcurrent function RESCPSCH is used to achieve instantaneous fault clearing independent of the fault location on the protected feeder. There are four available communication scheme types.

- Direct underreaching transfer trip DUTT
- Permissive underreaching transfer trip PUTT
- Permissive overreaching transfer trip POTT
- Directional comparison blocking scheme DCB

The directional comparison unblocking scheme DCUB can also be provided by complementing the permissive schemes with an additional logic called the unblocking function, which is also included in RESCPSCH.

If the permissive overreaching scheme is used, some of the power system conditions require additional special logic circuits, such as the current reversal and weak-end infeed logic for residual overcurrent function RCRWPSCH.

5.11.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of RESCPSCH can be described with a module diagram. All the modules in the diagram are explained in the next sections.

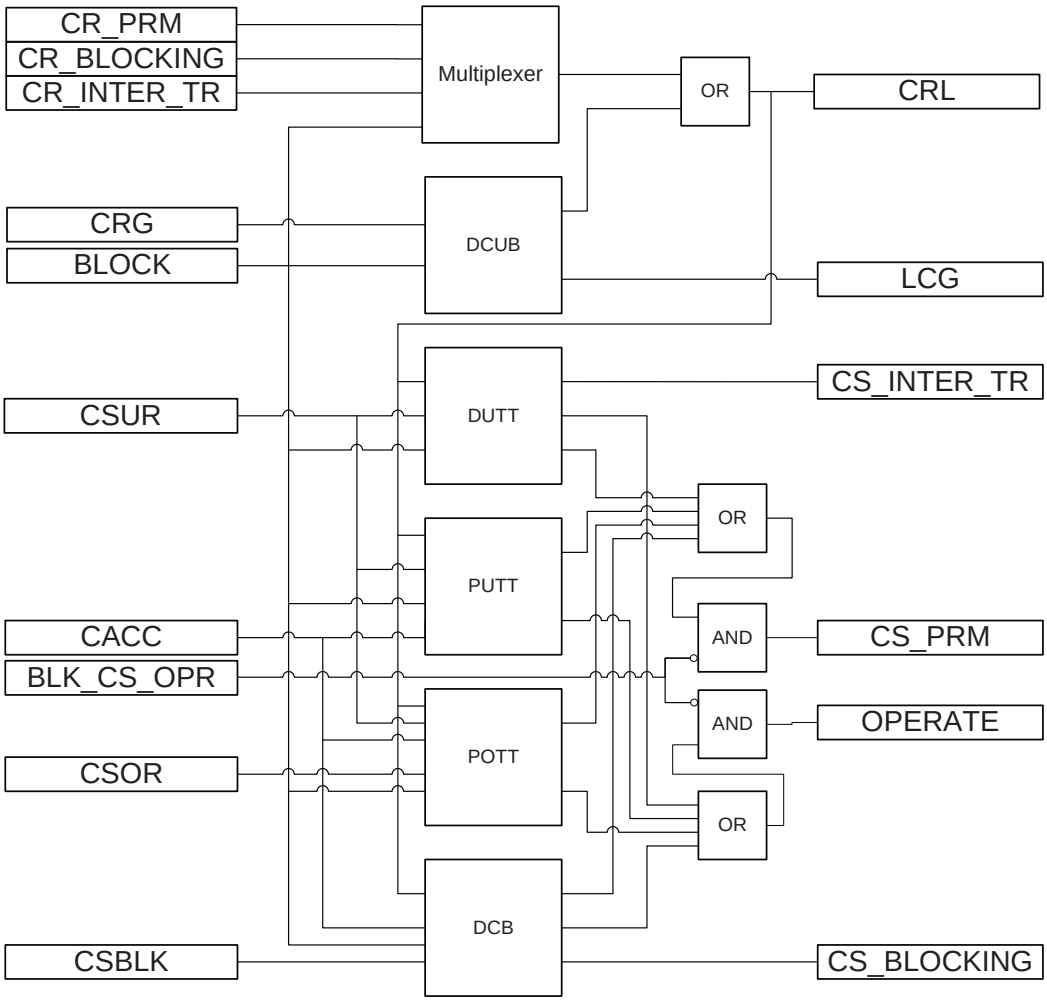

Figure 710: Functional module diagram

The applied communication scheme logic in RESCPSCH is selected with the *Scheme type* setting.

Table 1189: Communication scheme based on the Scheme type value

***Scheme type* value**	**Communication scheme**
"Intertrip"	DUTT
"Permissive Underreach"	PUTT
"Permissive Overreach"	POTT
"Blocking"	DCB

The unblocking scheme (DCUB) is enabled with the *Unblock mode* setting.

Multiplexer

The multiplexer connects an input signal to an output based on the value of the *Scheme type* setting.

Table 1190: Connected inputs based on the Scheme type value

Scheme type value	Inputs connected to an output
"Intertrip"	CR_INTER_TR
"Permissive Underreach" or "Permissive Overreach"	CR_PRM
"Blocking"	CR_BLOCKING

Direct underreaching transfer trip scheme DUTT

The direct intertrip scheme is enabled with *Scheme type* = "Intertrip".

In the direct intertrip scheme, the start signal from the underreaching (instantaneous) residual overcurrent function DEFHPDEF is connected to the CSUR input to create a carrier send CS_INTER_TR signal. The duration of the CSUR input signal can be prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration for the CS_INTER_TR signal.

The local circuit breaker is directly tripped (activation of the OPERATE output) with the carrier received CS_INTER_TR signal after a settable pick-up delay *Coordination time* has elapsed without further local criteria.

The unblocking function (*Unblock mode* = "Permanent" and *Unblock mode* = "Time window") must not be enabled with the DUTT scheme, as the lost guard signal results in an immediate trip of the local circuit breaker.

The activation of the BLOCK input totally blocks the direct intertrip scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

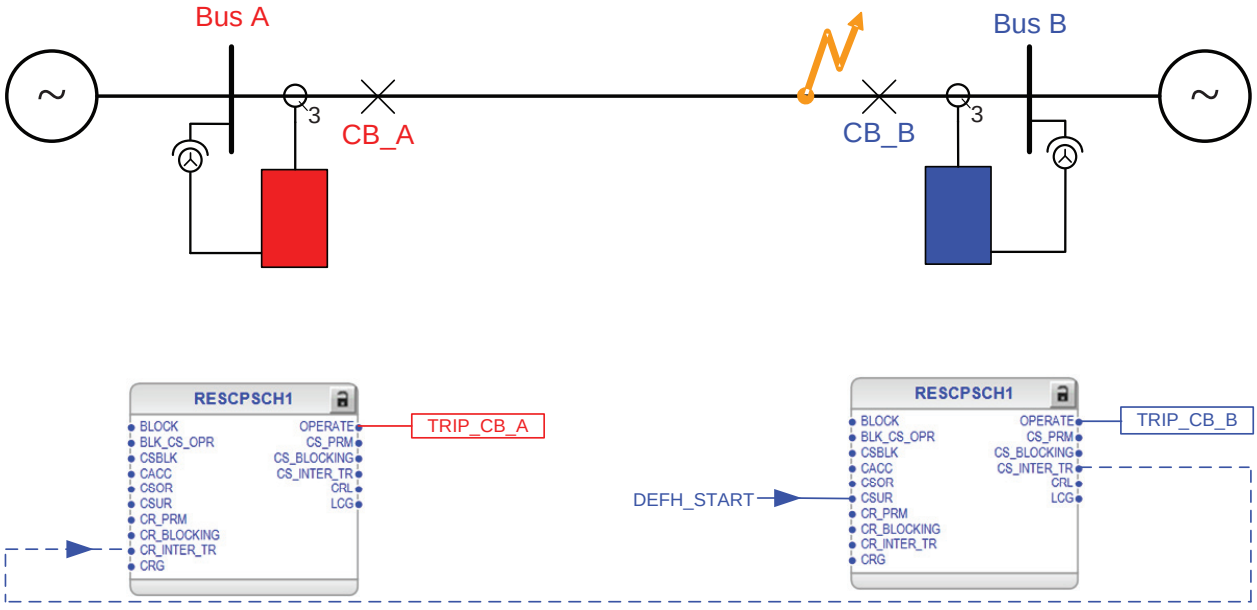

Figure 711: Simplified functional diagram of the direct intertrip scheme

Permissive underreaching transfer trip scheme PUTT

The permissive underreach scheme is enabled with *Scheme type* = "Permissive Underreach".

In the permissive underreach scheme, the start signal from the underreaching (instantaneous) residual overcurrent function DEFHPDEF is connected to the CSUR input to create a CS_PRM signal. The duration of the CSUR input signal can be prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_PRM signal.

In the permissive underreach scheme, the CR_PRM signal or CRL signal, if the unblocking function is enabled, is used to allow the overreaching residual overcurrent function DEFLPDEF to trip (activation of the OPERATE output) after the pick-up delay *Coordination time*. The start signal from the overreaching function is connected to the CACC input. A general start signal in the forward direction can also be connected to the CACC input.

The CS_PRM signal is also generated if the CR_PRM signal is received and the local carrier acceleration signal CACC is active.

Activating the BLOCK input totally blocks the permissive underreach scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

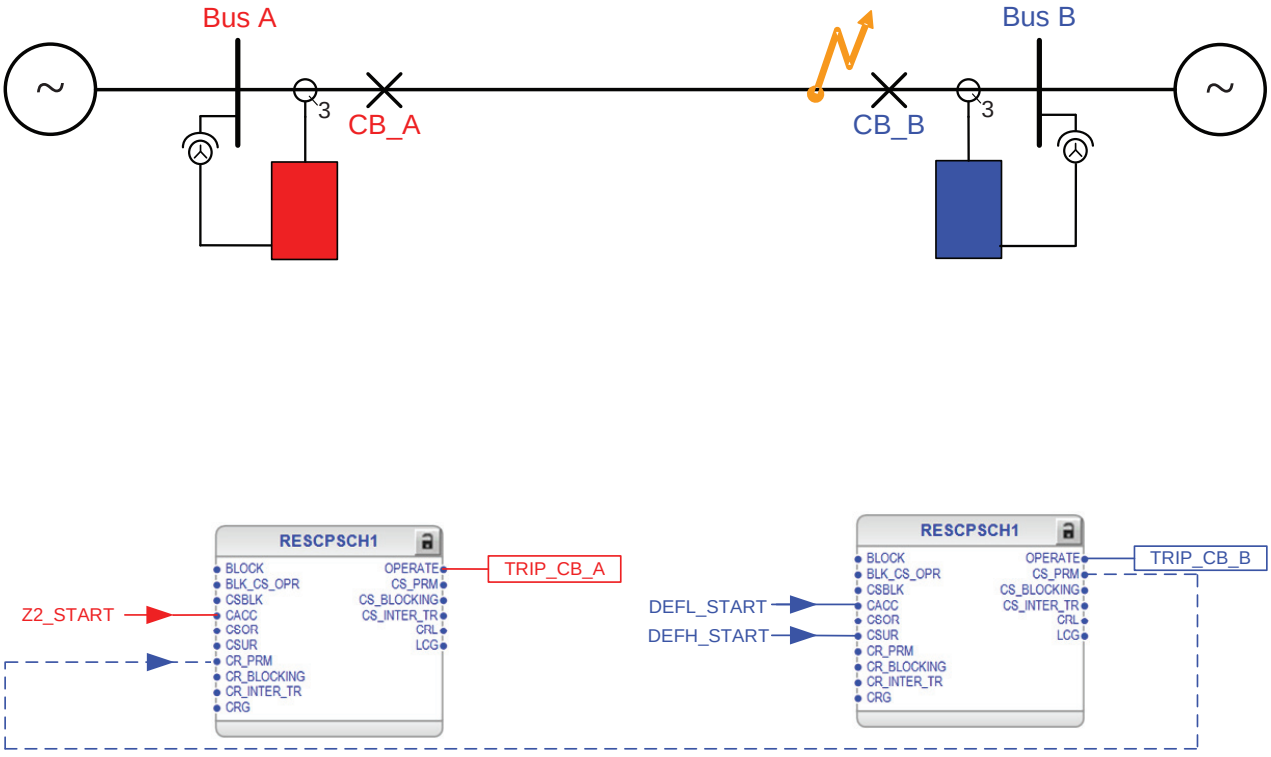

Figure 712: Simplified functional diagram of the permissive underreach scheme

Permissive overrreaching transfer trip scheme POTT

The permissive overreach scheme is enabled with *Scheme type* = "Permissive Overreach".

In this scheme, the START signal from the overreaching residual overcurrent function DEFLPDEF is connected to the CSOR input to create a CS_PRM signal. The CS_PRM signal can also be issued simultaneously from the underreaching residual overcurrent function DEFHPDEF. In this case, the start signal from the

underreaching function is connected to the CSUR input. The duration of the CSUR input signal can be prolonged by the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_PRM signal.

In case of parallel feeders, when the external current reversal logic (RCRWPSCH) is enabled, the CS_PRM signal is not prolonged and the value of *Carrier Min Dur* is set to zero to secure correct operation.

In the permissive overreach scheme, the received signal CR_PRM or CRL, if the unblocking function is enabled, is used to allow the overreaching residual overcurrent function DEFLPDEF to trip (activation of the OPERATE output) after the settable pick-up delay *Coordination time*. The start signal from the overreaching zone is connected to the CACC input.

The CS_PRM signal is also generated if the CR_PRM signal is received and the local carrier acceleration signal CACC is active.

Activating the BLOCK input totally blocks the permissive overreach scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

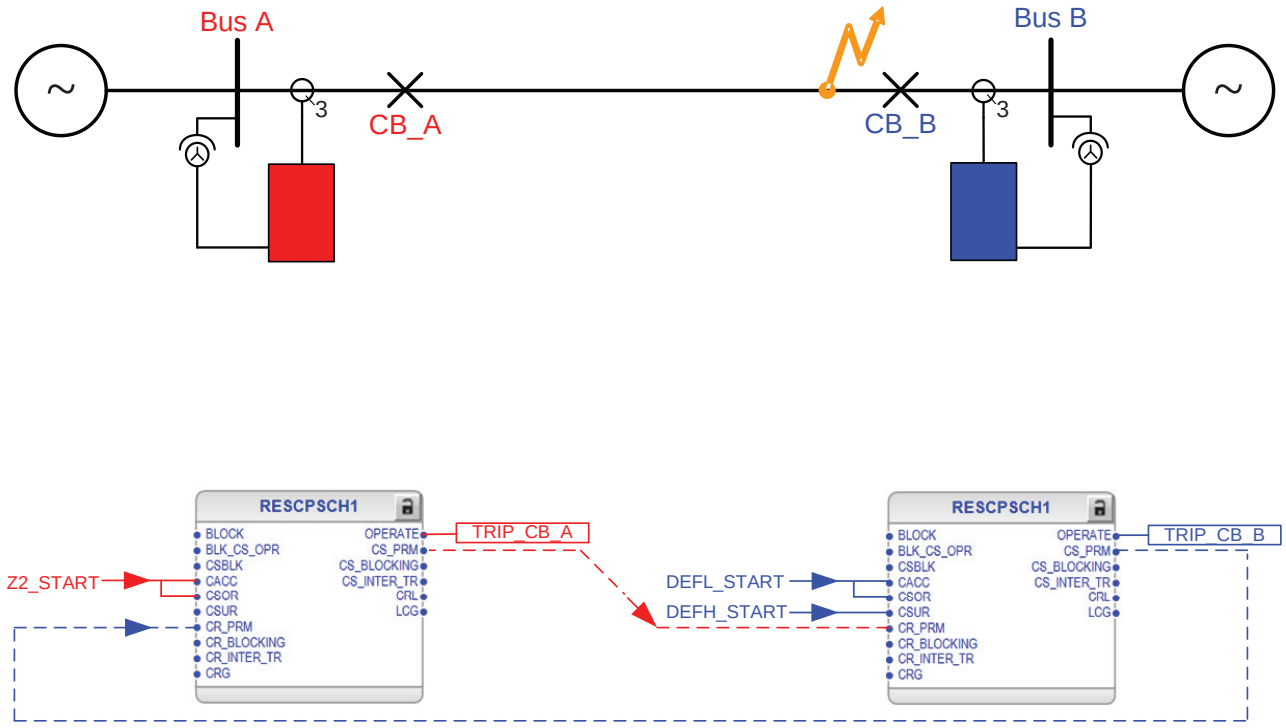

Figure 713: Simplified functional diagram of the permissive overreach scheme

Directional comparison blocking scheme DCB

The directional comparison blocking scheme is enabled with *Scheme type* = "Blocking".

In the blocking scheme, the START signal from the reverse-looking residual overcurrent function DEFLPDEF set to operate for the reverse direction earth fault, is connected to the CSBLK input to create a CS_BLOCKING signal. The starting of the reverse-looking function indicates that the fault is located outside the protected feeder. The duration of the CSBLK input signal can be prolonged with the *Carrier Min Dur* setting to ensure a sufficient duration of the CS_BLOCKING signal.

The blocking scheme is mainly used to allow the forward-looking overreaching residual overcurrent function to trip (activation of the OPERATE output) after the

settable *Coordination time*, and if no block signal is received from the remote terminal. To prevent a false trip in case of external faults, the CR_BLOCKING signal must be received before the *Coordination time* has elapsed. The start signal from the overreaching residual overcurrent function DEFLPDEF is connected to the CACC input.

The *Coordination time* setting in the blocking scheme depends, for example, on the communication system delay and on the terminal's response times in transmitting a CS_BLOCKING signal to the other feeder end. The *Coordination time* setting must not be zero.

Activating the BLOCK input totally blocks the directional comparison blocking scheme. The CS_PRM and OPERATE outputs can be blocked by the BLK_CS_OPR input.

In *Figure 714*, in case of internal faults, the CS_BLOCKING signal is not sent as the fault is not seen by the reverse-looking overreaching function.

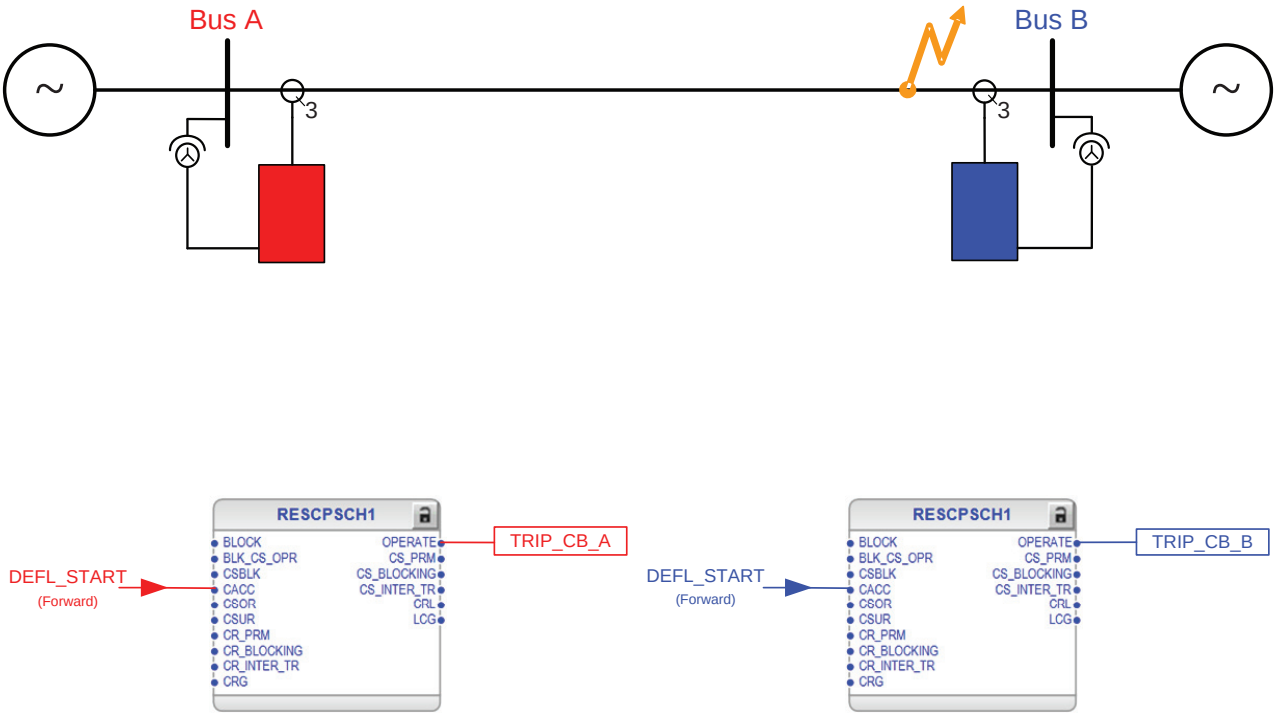

Figure 714: Simplified functional diagram of the blocking scheme, internal fault

In *Figure 715*, in case of external faults, the protection relay at bus B sees the fault in the reverse direction and sends a blocking signal CS_BLOCKING to the protection relay at bus A. There is no CB operation at either end.

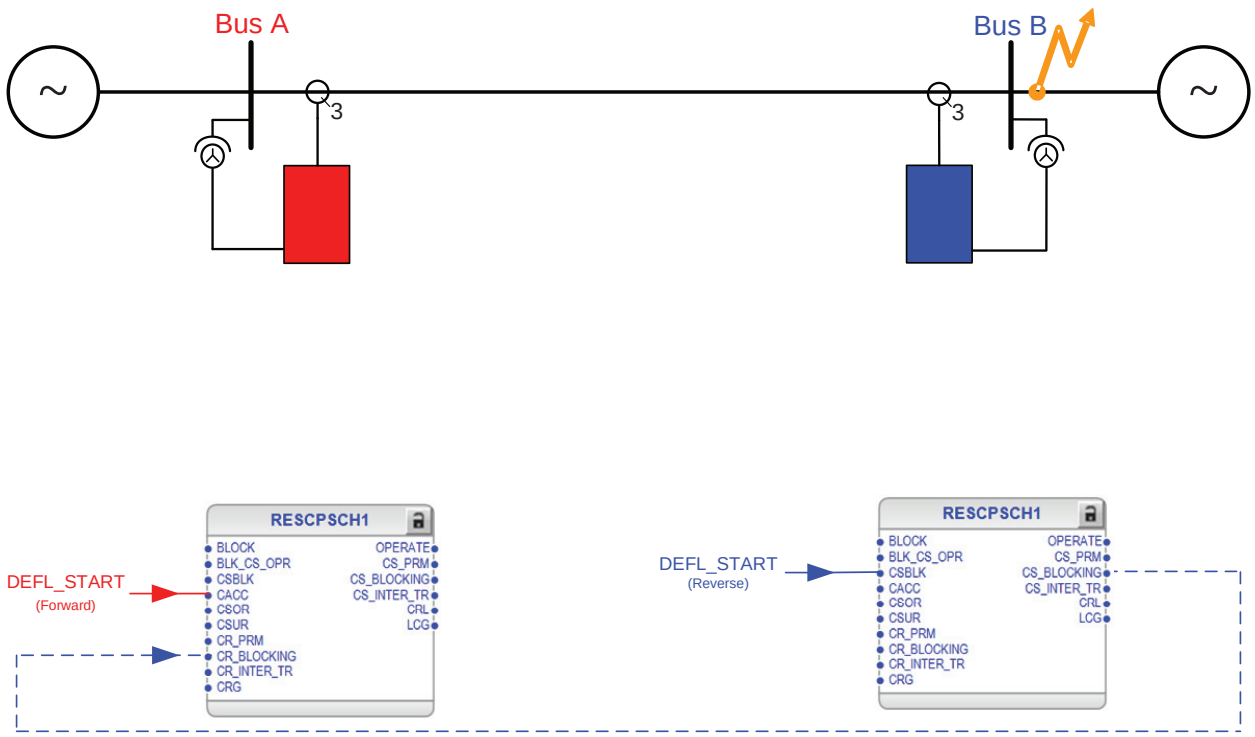

Figure 715: Simplified functional diagram of the blocking scheme, external fault

The unblocking function used with the blocking function provides a possibility to supervise the communication channel. In this case, the CRL output signal is used as a local blocking signal.

The operation mode *Unblock mode* = "Time window" is not recommended as the blocking is activated only for 150 ms after the guard signal disappears. This results in an unwanted operation of the protection.

Directional comparison unblocking scheme DCUB

The unblocking function is a complementary logic which can be used together with the permissive communication schemes. In the unblocking scheme, the dependability of the permissive schemes is improved by using the loss of guard signal from the communication equipment to create a CRL output signal locally. This enables the permissive scheme to operate even if the communication channel is interrupted or lost.

The unblocking function uses a carrier guard signal which must always be present. The absence of the CRG signal for a time longer than the value of the *Loss of carrier time* setting generates a logical CRL signal. A communication failure shorter than the value of the *Loss of carrier time* setting is always ignored.

The unblocking function is configured with the *Unblock mode* setting.

- *Unblock mode* = "Off": The unblocking function is disabled.
- *Unblock mode* = "Permanent": If the CRG signal disappears for a longer time than defined in the *Loss of carrier time* setting, the logical CRL signal is generated. The CRL output signal remains active until the CRG signal reappears. The communication failure is not signaled by the LCG output.

- *Unblock mode* = "Time window": If the CRG signal disappears for a longer time than defined in the *Loss of carrier time* setting, the CRL output signal is generated. The CRL output signal remains active for 150 ms, after which a communication failure is signaled by the LCG output. The LCG output is reset 200 ms after the CRG signal is present again. The purpose of this mode is to ensure tripping during a fixed delay of 150 ms after the loss of communication due to possible consequences of an internal fault. After this time, the accelerated tripping is allowed only if the CR_PRM signal is received again.

With operation modes *Unblock mode* = "Permanent" and *Unblock mode* = "Time window", the created CRL output signal is internally ORed with the CR_PRM input to allow the permissive scheme to operate even when the communication channel has been interrupted or lost. The values of CRL and LCG output signals are also available through the Monitored data view. Activating the BLOCK input blocks the CRL and LCG outputs.

5.11.5 Application

To achieve fast fault clearing on the part of the protected feeder not covered by the instantaneous step of the residual overcurrent protection, the directional residual overcurrent protection can be used with RESCPSCH.

Applying RESCPSCH requires a communication channel capable of transmitting an "On" or "Off" signal in each direction. To enable fast tripping, the most important requirement for communication is the communication speed.

The performance of RESCPSCH is directly related to the communication channel speed, and to the security against false or lost signals. Therefore, dedicated communication channels are recommended. With short distances of up to a few kilometers, a typical communication media is a simple pilot wire based on auxiliary power. With distances of up to 150 km, fibre-optic cables using digital data transmission can be used. To avoid false signals that could cause unwanted operation, the security of the communication channel should be emphasized. Also, the dependability of the communication channel should be considered to ensure that the signals are reliably transmitted during power system faults.

RESCPSCH supports five communication schemes.

- Direct underreaching transfer trip DUTT
- Permissive underreaching transfer trip PUTT
- Permissive overreaching transfer trip POTT
- Directional comparison blocking scheme DCB
- Directional comparison unblocking scheme DCUB

Depending on whether the communication channel is used for sending a block or a trip signal, the communication schemes can be divided into blocking schemes and permissive schemes.

In permissive schemes, the trip signals of the directional residual overcurrent protection are interchanged between the terminals to receive a permission to trip during an internal fault. The tripping of the local terminal depends on both the starting of its own forward-looking function and the received signal from the opposite terminal. In the underreaching scheme, no signals are sent during an external fault. A trip signal is sent to the opposite terminal during an external fault if the fault is seen in the forward direction and the overreaching scheme is used. However, in case of external faults, tripping is always blocked because either no signal is received as the opposite terminal sees a reverse fault or the signal

is received but locally the fault is seen in the reverse direction. In either case, the blocking is not dependent on the received signal so a lost communication channel does not result in false operation.

In the blocking scheme, a blocking signal is sent to the opposite terminal if the fault is locally seen in the reverse direction, that is, during an external fault. Thus, the blocking is dependent on the received signal, and there is typically a need to delay the tripping of the terminal receiving the blocking signal. This delay depends, for example, on the response times of the communication channel and terminals. During an internal fault, there is no signal transmission between the terminals, so the tripping does not depend on the received signal from the opposite terminal.

In conclusion, permissive schemes are inherently faster and have better security [1] against false tripping than a blocking scheme, since tripping in an external fault is not possible in case of a channel interruption. In a blocking scheme, a lost communication channel and a simultaneous external fault may lead to a false operation of the protection if the communication channel is not supervised. On the other hand, as the fast trip of the permissive scheme depends on a received signal, its dependability [2] is lower than that of the blocking scheme.

The unblocking scheme enhances the dependability of the permissive scheme. If the communication channel is interrupted and, simultaneously, a fault occurs in the forward direction, tripping is still possible either during a fixed time interval after the beginning of the interruption or as long as the communication channel is lost. This is achieved by connecting the supervision output of the implemented communication functionality to the dedicated carrier guard signal input of RESCPSCH. In general, the unblocking scheme provides better security than the blocking scheme because tripping in external faults is only possible if the fault occurs within the fixed time interval after the beginning of the channel interruption.

The direct transfer trip scheme uses the underreaching function to trip the local breaker and to transfer the trip signal to the remote terminal. The remote terminal operates immediately based on the received transfer trip signal, without any additional conditions. This scheme is very simple, but its security is low as a spurious signal results in false operation of the protection.

Direct underreaching transfer trip DUTT

In some applications, there is a need to trip the remote end breaker immediately because of fault detection by the local measurements. This applies, for example, when the transformers or reactors are connected to the system without circuit breakers, or for remote tripping following the operation of the local breaker failure protection (CBFP).

In the direct intertrip scheme (DUTT), the carrier send signal `CS_INTER_TR` is initiated by the underreaching or the tripping signal of an external protection relay, such as transformer or reactor protection. At the remote end, the received signal initiates the breaker trip immediately without any further local protection criteria. To limit the risk of an unwanted trip due to spurious sending of signals, the trip can be delayed by the *Coordination time* setting, which should be set to 10...30 ms, depending on the type of the communication channel. The communication channel operating in direct intertripping applications should be secure and dependable.

Setting guidelines for the intertrip scheme DUTT

- *Scheme type* = "Intertrip"

[1] The ability to block operation in case of an external fault.
[2] The ability to operate in case of an internal fault.

- *Coordination time* = "0.050" s (10 ms + maximal transmission time)
- *Carrier Min Dur* = "0.1" s

Permissive underreaching transfer trip PUTT

In the permissive underreach scheme, a permission to trip is obtained locally from the underreaching function and sent to the remote end. The received signal is then combined with the local fault indication from the overreaching function resulting in a trip command after a settable pick-up delay *Coordination time*.

The protection relay of either feeder end sends a permissive signal to trip the other end. The communication channel must be able to receive and transmit at the same time. In permissive schemes, the communication channel must be fast and secure, but also dependable. Inadequate security causes unwanted tripping for external faults. Inadequate speed or dependability causes delayed tripping for internal faults.

The CS_PRM signal is issued based on the underreaching residual overcurrent protection function.

The permissive scheme is not applicable on short feeder lengths because the residual overcurrent protection cannot easily distinguish between the internal and external faults in such cases.

The residual overcurrent function may start only at one end due to the system conditions such as weak zero-sequence source at one end, or high fault resistance. However, fast tripping from both ends can be achieved by connecting a general forward start signal to CACC. So, even if the local overreaching residual overcurrent function has not picked up, the local OPERATE output is activated. The function also generates a CS_PRM signal by combining the carrier received CR_PRM signal from a remote end and also the local activation of CACC, giving the permission to a remote function to trip instantaneously.

The CR_PRM signal must be received when the overreaching residual overcurrent protection is still active to achieve an instantaneous trip. In some cases, due to the fault current distribution, the overreaching protection can operate only after the fault has been cleared by the remote terminal. In this case, there is a risk that if the remote terminal is tripped directly by the instantaneous underreaching function, the CS_PRM signal that it issues resets before the overreaching function of the local end terminal is operated. To ensure a sufficient duration of the CR_PRM signal, the CS_PRM signal can be prolonged by time *Carrier Min Dur*. The recommended value of the *Carrier Min Dur* setting is "0.1" s.

The received communication signal is combined with the output from the local overreaching function. Therefore, there is less concern about a false signal causing an incorrect trip. Therefore, the timer *Coordination time* can be set to "0". A communication channel failure does not affect the selectivity, but delays the tripping at the other end for certain fault locations.

Setting guidelines for the permissive underreach scheme PUTT

- *Scheme type* = "Permissive Underreach"
- *Coordination time* = "0" s
- *Carrier Min Dur* = "0.1" s

Permissive overreaching transfer trip POTT

In the permissive overreach scheme, the permission to trip is obtained locally from an overreaching function and sent to the remote end. The received signal is then

combined with the local fault indication from the overreaching function, resulting in a trip command after a settable pick-up delay *Coordination time*.

The protection relay at either end of the feeder sends a permissive signal to trip the other end. Therefore the communication channel must be able to receive and transmit at the same time. A general requirement for the communication on permissive schemes is that it should be fast and secure.

In the permissive overreach scheme, the CS_PRM signal is issued based on the start of the overreaching residual overcurrent function.

The residual overcurrent function may start at one end due to the system conditions such as weak zero-sequence source at one end, or high fault resistance. However, fast tripping from both ends can be achieved by connecting a general forward start signal to CACC. So, even if the local overreaching residual overcurrent function has not picked up, the local OPERATE is activated. The function also generates a CS_PRM signal by combining the CR_PRM signal from a remote end and local activation of CACC, giving permission to the remote function to trip instantaneously.

The permissive overreach scheme can be used for all feeder types and lengths.

In the permissive overreach scheme, the communication channel is essential for obtaining fast tripping at both ends. Typically, a lost communication channel does not cause false tripping, but it delays the operation of the protection for the faults on the feeder.

The communication channel for a permissive overreach scheme must be fast and secure, but also dependable. Inadequate security can cause unwanted tripping for external faults. Inadequate speed or dependability can cause delayed tripping for internal faults.

In the permissive overreaching scheme, the CS_PRM signal can be issued in parallel both from the overreaching and underreaching functions. The CS_PRM signal from the overreaching function must not be prolonged, while the CS_PRM signal from the underreaching function must typically be prolonged. In parallel feeder applications, the scheme typically needs to be complemented by the current reversal logic. To ensure a correct operation in this case, the CS_PRM signal must not be prolonged (*Carrier Min Dur* = "0" s). There is no need to delay the tripping when receiving the carrier signal, so the time *Coordination time* is set to "0".

Setting guidelines for the permissive overreaching transfer trip scheme POTT

- *Scheme type* = "Permissive Overreach"
- *Coordination time* = "0" s
- *Carrier Min Dur* = "0.1" s
- *Carrier Min Dur* = "0" s (in case of parallel lines and current reversal logic)

Directional comparison blocking scheme DCB

In the blocking scheme, the reverse-looking residual overcurrent function is used for sending a block signal to the remote end to block the overreaching forward-looking residual overcurrent function.

The blocking scheme is very dependable because it operates for faults anywhere on the protected feeder, even if the communication channel is out of service. Conversely, it is less secure than a permissive scheme because it trips for the external faults within the reach of the overreaching local function if the communication channel is out of service and no block signal is received.

Inadequate speed or low dependability of the communication channel can cause spurious tripping for external faults.

To secure that the blocking signal arrives before the local overreaching function trips, the trip is delayed by the *Coordination time* setting. This setting must be set longer than the sum of the maximal transmission time of the channel and the start and response times of the protection relays sending and receiving the CS_PRM signal. A security margin of at least 10 ms should be considered. The time delay *Carrier Min Dur* for prolonging the CS_PRM signal is set to "0".

Setting guidelines for the blocking scheme

- *Scheme type* = "Blocking"
- *Coordination time* = "0.1" s (10 ms + maximal transmission time)
- *Carrier Min Dur* = "0" s

Directional comparison unblocking scheme DCUB

Metallic communication paths adversely affected by fault-generated noise or by other electrical phenomena, such as lightning, are not suitable for conventional permissive schemes that rely on signal transmission during a fault in the protected feeder. Principally, the communication media must be properly shielded or otherwise designed to provide an adequate performance during such conditions.

The unblocking scheme can be used to overcome the lower dependability of permissive schemes. The function is used in older, less reliable communication, where the signal has to be sent through the primary fault. The unblocking function uses a carrier guard signal CRG which must always be present, even when no CR_PRM signal is received. Due to the absence of the CRG signal during the security time, the *Loss of carrier time* setting is used as a CR_PRM signal. This also enables a permissive scheme to operate when the communication channel is temporarily lost during an internal fault.

Setting guidelines for the unblocking scheme

- *Unblock mode* = "Off": The unblocking function is disabled.
- *Unblock mode* = "Permanent": If the CRG signal disappears for a longer time period than defined in the Loss of carrier time setting, a logical carrier received signal CRL is generated. The CRL signal remains active until the CRG signal is present. The communication failure is not signalled by the LCG output. The *Loss of carrier time* setting is set to "35" ms.
- *Unblock mode* = "Time window": If the CRG signal disappears for a longer time period than the *Loss of carrier time* setting, a CRL signal is generated. The CRL signal remains active for 150 ms, after which a communication failure is signalled by the LCG output. The value of the LCG output is reset 200 ms after the CRG signal reappears. The *Loss of carrier time* setting is set to "35" ms.

5.12 Current reversal and weak-end infeed logic CRWPSCH (ANSI 85 21CREV,WEI)

5.12.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Current reversal and weak-end infeed logic	CRWPSCH	CLCRW	85 21CREV,WEI

5.12.2 Function block

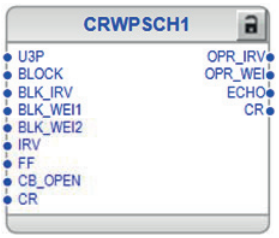

Figure 716: Function block

5.12.3 Functionality

The current reversal and weak-end infeed logic function CRWPSCH can be used when the scheme communication logic DSOCPSCH requires additional logics to operate correctly in all power system conditions.

In parallel feeder applications, the fault current direction on the healthy feeder can change when the circuit breaker on the faulty feeder opens to clear the fault. This can lead to an unwanted operation of the distance protection on the healthy parallel feeder when DSOCPSCH is used with the permissive overreach scheme. The main purpose of the current reversal logic is to prevent such unwanted operations.

The permissive communication schemes can operate only when the protection in the remote terminal can detect the fault. This detection requires sufficient minimum fault current. If such current is not available due to a too weak remote end source, the weak-end infeed logic can be used to overcome the situation and trip the remote end breaker.

5.12.4 Analog channel configuration

CRWPSCH has one analog group input which must be properly configured.

Table 1197: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1198: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phases connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.12.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of CRWPSCH can be described with a module diagram. All the modules in the diagram are explained in the next sections.

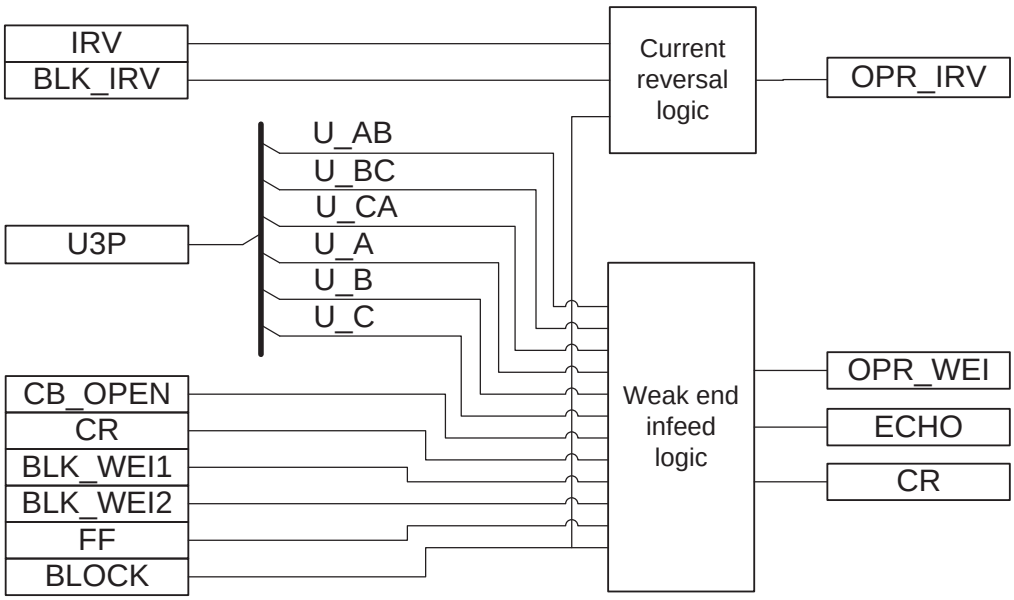

Figure 717: Functional module diagram

Current reversal logic

Current reversal logic is enabled by changing the value of the *Reversal mode* setting to "On".

This logic uses the start signal of the reverse-looking zone (Z3) connected to the IRV input, which is used to recognize the fault in the reverse direction, that is, in the parallel feeder. When the reverse zone is activated after a start delay (the *Reversal time* setting), the logic is ready to issue an OPR_IRV output signal. The OPR_IRV signal is connected to the BLK_CS_OPR input of DSOCPSCH in order to block the sending of the carrier send signal (CS) and the activation of the OPERATE output of the communication logic. The OPR_IRV signal has a drop-off delay defined with the *Reversal reset time* setting.

An internal 10 ms drop-off timer enables the current reversal logic to be activated for the short-duration input signals even if the *Reversal reset time* setting is set to zero.

The BLK_IRV input is used to block the activation of the OPR_IRV output. The BLK_IRV input is typically connected to the forward-looking zone start signals within the terminal. General blocking is achieved by activating the BLOCK input.

Weak-end infeed logic

Weak-end infeed logic is used to activate the distance protection function when the fault current infeed is too low due to, for example, high source impedance or fault current distribution between sources. When activated, the CR signal is logically combined with the local criteria to initiate the tripping of the weak-end breaker. The received signal is echoed back to accelerate the tripping in the opposite end with the stronger source.

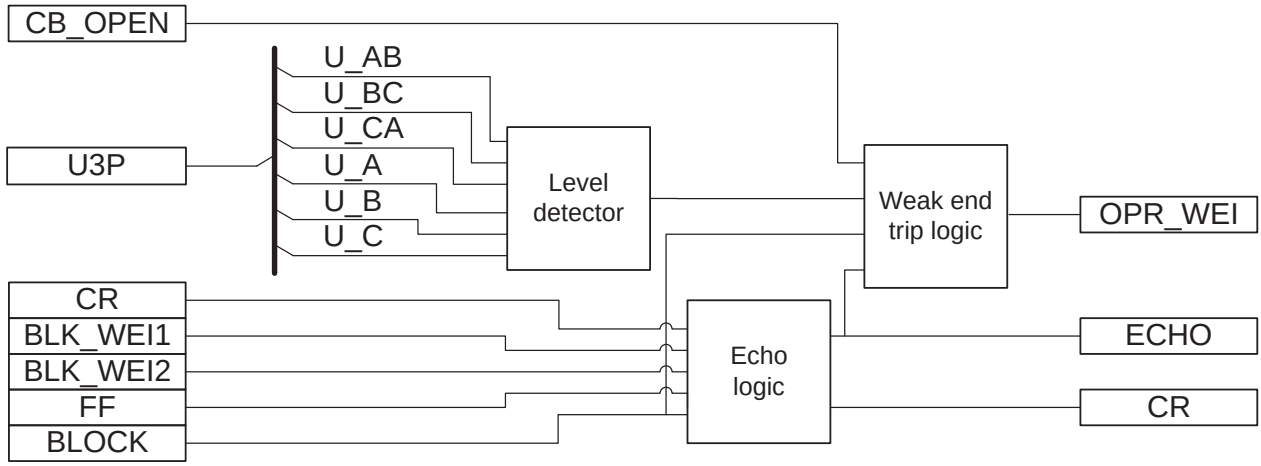

Figure 718: Functional module diagram of weak-end infeed logic

The WEI logic is enabled using the *Wei mode* setting.

- If *Wei mode*= "Off", the WEI logic is disabled.
- If *Wei mode*= "Echo", the WEI logic is enabled without Level detector.
- If *Wei mode*= "Echo and Operate", the WEI logic is enabled with Level detector.

Level detector

Both phase-to-earth and phase-to-phase voltages are monitored. The undervoltage criteria are applied to the phase-to-phase voltages with the *PPV level for Wei* setting and to the phase-to-earth voltages with the *PhV level for Wei*. Level detector sends an enable signal for a phase to Weak-end trip logic when one or more voltages are below the corresponding settings. Level detector blocks the enable signal if all three-phase voltages are above the set value more than 100 ms. This is to avoid sending an unnecessary operate signal if the breaker is already open.

Echo logic

Echo logic returns the received carrier signal with the ECHO output when it receives a CR signal if no fault has been detected by the forward- and reverse-looking zones and the duration of CR is longer than the coordination time delay (setting *Wei Crd time*). The received carrier receive signal is also given as the CR output.

When the WEI logic is enabled at both feeder ends, a spurious signal can be looped round by Echo logic. To avoid a continuous lockup of the system, the duration of the echoed signal is limited to 200 ms.

The ECHO and CR outputs can be blocked by activating the BLOCK input. The FF, BLK_WEI1 and BLK_WEI2 inputs can be used to block the ECHO output. The FF input is usually connected to the functional output of the fuse failure function, and the BLK_WEI1 input is typically connected to the start signals of the forward and reverse directional residual overcurrent functions within the terminal. The BLK_WEI2 signal has an in-built 200 ms drop-off delay. The BLK_WEI2 input is usually connected to all the fault detection functions within the terminal except the residual overvoltage function.

Weak-end trip logic

Weak-end trip logic is activated if it receives an enable signal from Level detector and ECHO output of Echo logic is activated. Then a general trip signal OPR_WEI is activated. The activation of the CB_OPEN input blocks the tripping.

The OPR_WEI output can be blocked by activating the BLOCK input.

5.12.6 Application

Current reversal logic

In parallel feeder applications, when the overreaching permissive communication schemes are used, unselective tripping may result due to the current reversal. Such a condition can occur in the healthy feeder when the fault is cleared in the faulty feeder. The tripping of the healthy parallel feeder may lead to losing the connection between the two buses. To avoid this situation, the current reversal logic (transient blocking logic) can be used.

Assume that Relay A1, Relay A2, Relay B1 and Relay B2 are equipped with DSOCPSCH and the permissive overreach scheme is enabled. A fault occurs at Feeder 1 close to bus B. Relay A2 at the healthy Feeder 2 recognizes the fault in the forward direction within the overreaching zone Z2 and sends a CS signal to Relay B2 according to the POTT scheme. Relay B2 does not recognize the fault in the forward direction and does not operate even though a permissive CR signal is received from Relay A2. Moreover, Relay B2 does not send a permissive signal to Relay A2.

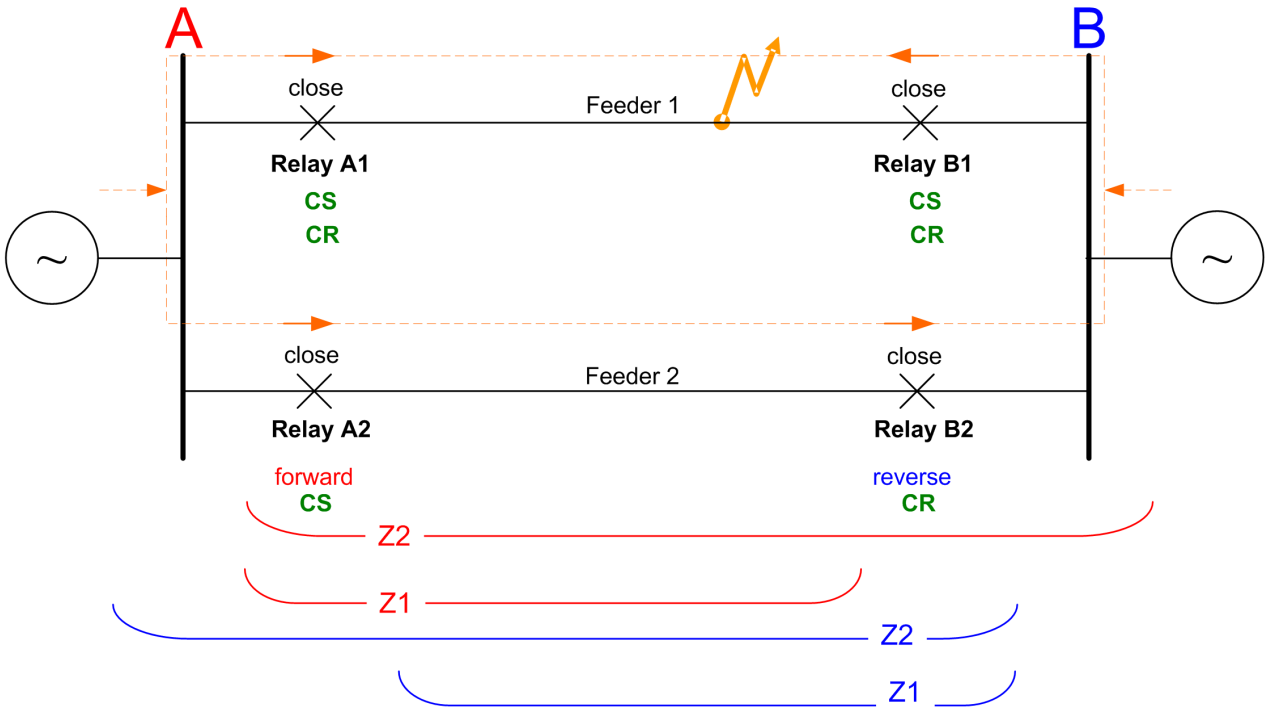

Figure 719: The fault occurs at one of the parallel lines.

The faulty feeder (Feeder 1) is not simultaneously tripped at both ends and it might occur that, for example, the circuit breaker closer to the fault at Relay B1 is tripped faster than the breaker at bus A due to the direct operation of the zone Z1 of Relay

B1. Thus, when the breaker at Relay B1 opens, the direction of the fault current at the healthy feeder (Feeder 2) is reversed.

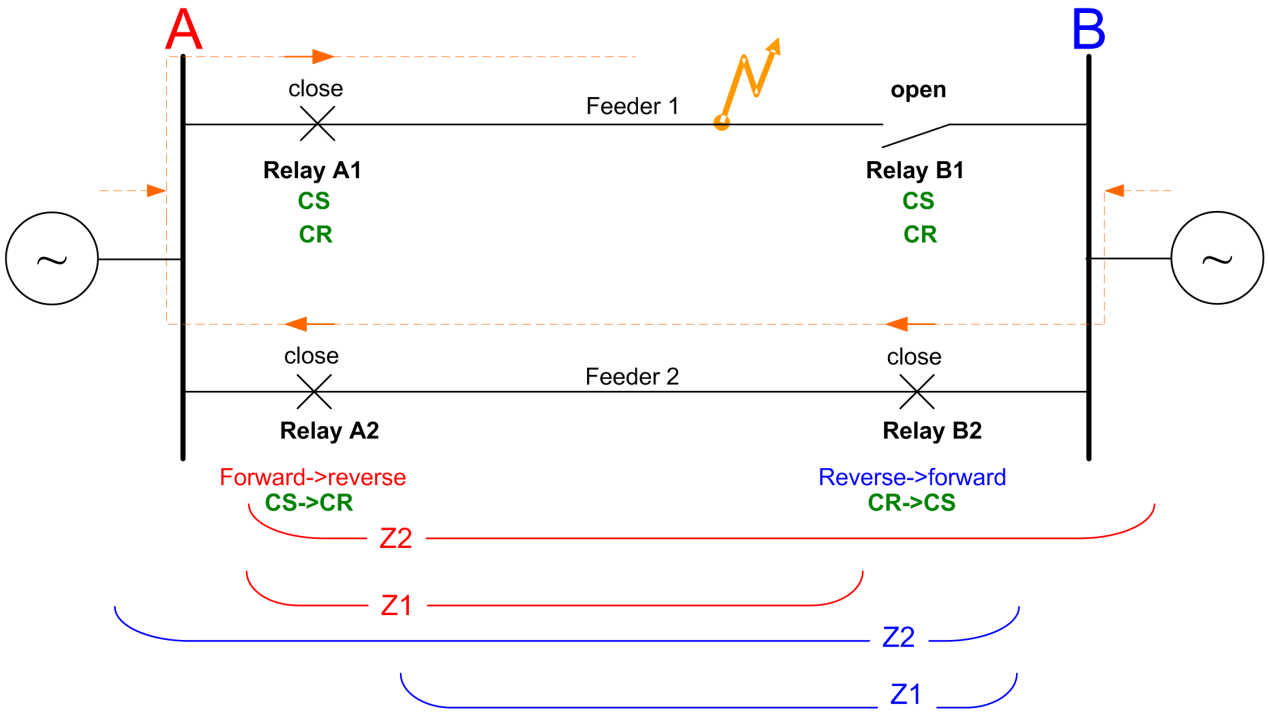

Figure 720: The circuit breaker at Relay B1 opens and creates a current reversal condition

Relay A2 is still sending the CS signal because of the reset time delay of the forward zone of Relay A2 when the overreaching zone of Relay B2 starts to recognize the fault in the forward direction. Relay B2 can malfunction and trip the breaker of the healthy feeder.

This problem can be solved by using the reverse-looking zone (Z3) to recognize the fault in reverse direction and temporarily block the operation of DSOCPSCH due to the current reversal condition. This is used in CRWPSCH.

Weak-end infeed logic

Avoid using the WEI function at both feeder ends. It can only be enabled at the weak end.

The weak-end infeed logic should be used only in permissive schemes.

Setting guidelines for current reversal logic

Setting *Reversal reset time*: Set the *Reversal reset time* setting to the maximum reset time of the communication channel. A minimum setting of 40 ms is recommended. A long *Reversal reset time* setting increases the security against unwanted tripping, but delays the fault clearing if the fault develops in one feeder and involves the other. However, the probability of this type of fault is small.

Setting *Reversal time*: Set the start delay *Reversal time* setting to less than 80 percent of the breaker operate time, but to a minimum of 20 ms.

Setting guidelines for weak-end infeed logic

The WEI function returns the received carrier signal with the ECHO output when it receives the carrier signal (CR) if no fault has been detected by forward- and reverselooking zones and the signal duration is longer than the *Wei Crd time* coordination time delay setting. Set the *Wei Crd time* = "0.010" s to avoid the spurious carrier received signals that activate the WEI logic and cause unwanted communication.

Set the voltage criteria *PPV level for Wei* and *PhV level for Wei* for the weak-end trip to 70 percent of the system's base voltage. The setting should be below the minimum operate voltage of the system but above the voltage that occurs for a fault on the protected feeder. The phase-to-phase elements must be verified not to operate for the phase-to-earth faults.

5.12.7 Signals

5.12.7.1 CRWPSCH Input signals

Table 1199: CRWPSCH Input signals

Name	Type	Default	Description

5.13 Current reversal and weak-end infeed logic for residual overcurrent RCRWPSCH (ANSI 85 67G/N CREV,WEI)

5.13.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Current reversal and weak-end infeed logic for residual overcurrent	RCRWPSCH	CLCRWN	85 67G/N CREV,WEI

5.13.2 Function block

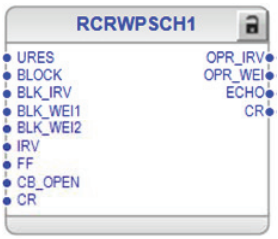

Figure 721: Function block

5.13.3 Functionality

The current reversal and weak-end infeed logic for residual overcurrent function RCRWPSCH can be used when the communication logic for residual overcurrent RESCPSCH requires additional logics to operate correctly in all power system conditions.

In parallel feeder applications, the direction of the fault current on the healthy feeder can change when the circuit breaker on the faulty feeder opens to clear the fault. This can lead to an unwanted operation of the residual overcurrent protection on the healthy parallel feeder when RESCPSCH with the permissive overreach scheme is used. The main purpose of the current reversal logic is to prevent such unwanted operations.

The permissive communication schemes can operate only when the protection in the remote terminal can detect the fault. This detection requires sufficient minimum fault current. If such current is not available due to too weak a remote end source, the WEI logic can be used to overcome the situation and trip the remote end breaker.

5.13.4 Analog channel configuration

RCRWPSCH has one analog group input which must be properly configured.

Table 1204: Analog inputs

Input	Description
URES [1]	Residual voltage (measured or calculated), necessary when *Wei mode* is set to "Echo and Operate"

See the preprocessing function blocks in this document for the possible signal sources. The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

Table 1205: Special conditions

Condition	Description
URES calculated	The function requires that all three voltage channels are connected to calculate the residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.13.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of RCRWPSCH can be described with a module diagram. All the modules in the diagram are explained in the next sections.

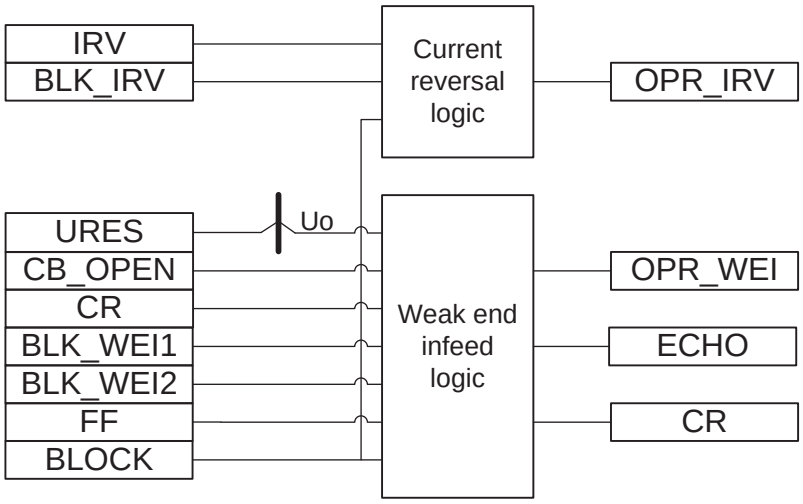

Figure 722: Functional module diagram

[1] Can be connected to GRPOFF if *Wei mode* is set to "Off" or "Echo".

Current reversal logic

Current reversal logic is enabled by changing the value of the *Reversal mode* setting to "On".

Current reversal logic uses the start signal of the reverse directional residual overcurrent function connected to the IRV input, which is used to recognize the fault in the reverse direction, that is, in the parallel feeder. When the reverse directional residual overcurrent function is activated, the logic is ready to issue an OPR_IRV output signal after a start delay (setting *Reversal time*). The OPR_IRV signal is connected to the BLK_CS_OPR input of the scheme communication logic function to block the sending of the carrier send signal (CS) and the activation of the OPERATE output of the communication logic. The OPR_IRV signal has a drop-off delay defined with the *Reversal reset time* setting.

An internal 10 ms drop-off timer is provided which ensures the current reversal logic is activated for short-duration input signals, even if the *Reversal reset time* setting is set to zero.

The BLK_IRV input is used to block the activation of the OPR_IRV output. The BLK_IRV input is typically connected to the start signals of the forward-looking residual overcurrent function in the terminal. General blocking is achieved by activating the BLOCK input.

Weak-end infeed (WEI) logic

The WEI logic is used to activate the residual overcurrent protection function when the fault current infeed is too low due to, for example, high source impedance or fault current distribution between sources. When activated, the carrier receive (CR) signal is logically combined with the local criteria to initiate the tripping of the weak-end breaker. The received signal is also echoed back to accelerate the tripping at the opposite end with the stronger source.

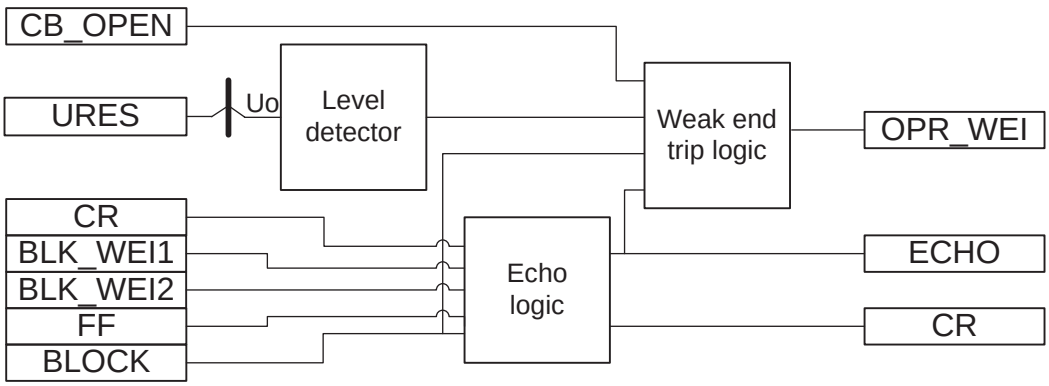

Figure 723: Functional module diagram of Weak-end infeed logic

The WEI logic is enabled using the *Wei mode* setting.

- If *Wei mode* = "Off", the WEI logic is disabled.
- If *Wei mode* = "Echo", the WEI logic is enabled without Level detector.
- If *Wei mode* = "Echo and Operate", the WEI logic is enabled with Level detector.

Level detector

Level detector sends an enabling signal to Weak-end trip logic when the residual voltage is above the *Residual voltage Val* setting.

Echo logic

Echo logic returns the received carrier signal with the ECHO output when it receives a carrier receive signal (CR) if no fault has been detected by the forward and reverse directional residual overcurrent functions and the duration of CR is longer than the coordination time delay (the setting *Wei Crd time*). The received carrier receive signal is also given as the CR output.

When the WEI logic is enabled at both feeder ends, a spurious signal can be looped round by Echo logic. To avoid a continuous lockup of the system, the duration of the echoed signal is limited to 200 ms.

The ECHO and CR outputs can be blocked by activating the BLOCK input. The FF, BLK_WEI1 and BLK_WEI2 inputs can be used to block the ECHO output. The FF input is usually connected to the functional output of the fuse failure function, and the BLK_WEI1 input is typically connected to the start signals of the forward and reverse directional residual overcurrent functions in the terminal. The BLK_WEI2 signal has an in-built 200 ms drop-off delay and is usually connected to all the fault detection functions in the terminal except the residual overvoltage function.

Weak-end trip logic

Weak-end trip logic is activated if it receives an enable signal from Level detector and ECHO output of Echo logic is activated. Then a general trip signal OPR_WEI is activated. The activation of the CB_OPEN input blocks the tripping.

The OPR_WEI output can be blocked by activating the BLOCK input.

5.13.6 Application

Current reversal logic

When the overreaching permissive communication schemes are used in parallel feeder applications, the current reversal can result in unselective tripping. Such a condition can occur in the healthy feeder when the fault is cleared in the faulty feeder. The tripping of the healthy parallel feeder can lead to losing the connection between the two buses. To avoid this situation, the current reversal logic (transient blocking logic) can be used.

In the current reversal condition, the relays Relay A1, Relay A2, Relay B1 and Relay B2 can be equipped with the scheme communication logic RESCPSCH and the permissive overreach scheme can be enabled.

A fault occurs at Feeder 1 close to bus B. Relay A2 at the healthy feeder 2 recognizes the fault in the forward direction and sends a CS signal to Relay B2 according to the PUTT scheme. Relay B2 does not recognize the fault in the forward direction and hence does not send a permissive signal to Relay A2.

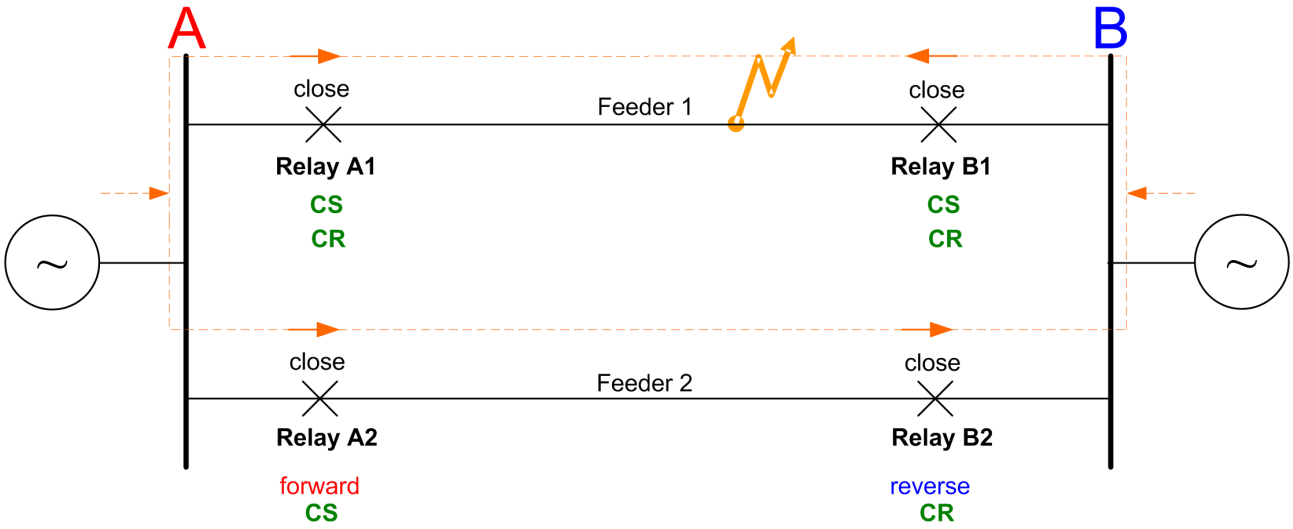

Figure 724: Fault occurs at one of the parallel lines. CS=carrier signal sending, CR=carrier signal receiving

The faulty feeder (Feeder 1) is not simultaneously tripped at both ends and, for example, the circuit breaker closer to the fault at Relay B1 may be tripped faster than the breaker at bus A. As a result, when the breaker at Relay B1 opens, the direction of the fault current at the healthy feeder (Feeder 2) is reversed.

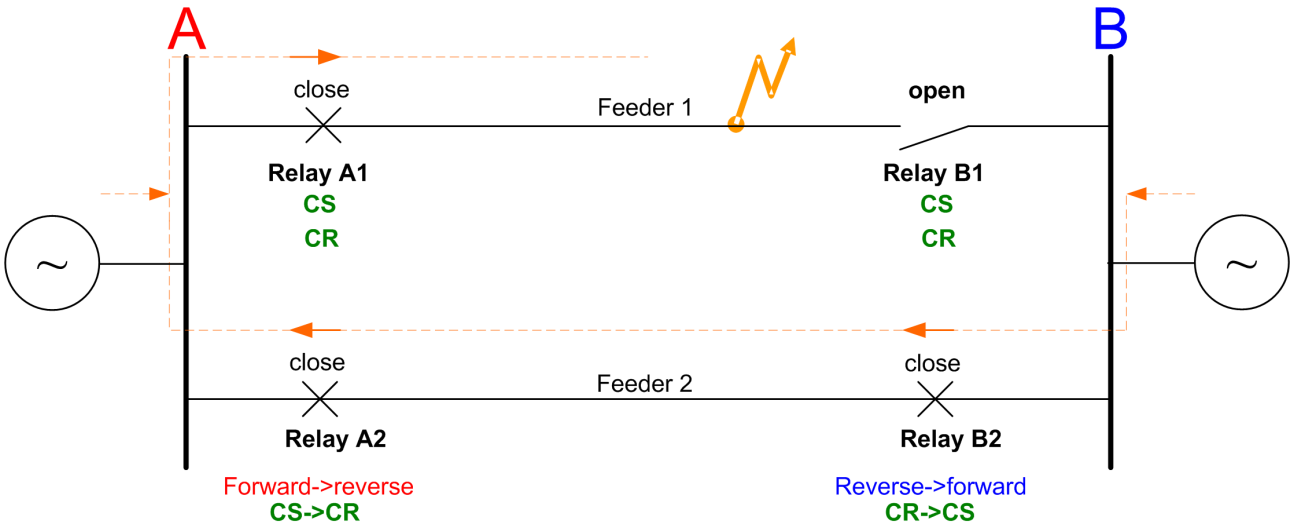

Figure 725: Circuit breaker at Relay B1 opens and creates a current reversal condition. CS=carrier signal sending, CR=carrier signal receiving

Relay A2 still sends the CS signal because of the reset time delay of the forward direction residual overcurrent function of Relay A2. When Relay B2 starts to recognize the fault in the forward direction, Relay B2 can malfunction and trip the breaker of the healthy feeder.

This problem can be solved using the reverse directional residual overcurrent function to recognize the fault in reverse direction and temporarily block the operation of the scheme communication logic due to the current reversal condition. This is used in RCRWPSCH.

Weak-end infeed (WEI) logic

Do not use the WEI function at both feeder ends. It can only be enabled at the weak end.

The WEI logic is recommended to be used only in the permissive schemes.

Setting guidelines for current reversal logic

Reversal reset time: This setting can be set to the maximum reset time of the communication channel. A minimum setting of 40 ms is recommended. A long *Reversal reset time* setting increases the security against unwanted tripping, but delays the fault clearing if the fault develops from one feeder to involve the other. However, the probability of this type of fault is small.

Reversal time: Set the start delay reversal time below 80 percent of the breaker operate time, but to a minimum of 20 ms.

Setting guidelines for Weak-end infeed (WEI) logic

The WEI logic returns the received carrier signal with the `ECHO` output when it receives the carrier signal (CR) if no fault has been detected by the forward and reverse directional measuring elements and the duration is longer than the *Wei Crd time* coordination time delay setting. To prevent the spurious carrier receive signals from activating the WEI logic and causing unwanted communication, the *Wei Crd time* setting can be set to "0.010 s".

5.14 Three-phase power directional element DPSRDIR (ANSI 67P-TC)

5.14.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase power directional element	DPSRDIR	I1->	67P-TC

5.14.2 Function block

Figure 726: Function block

5.14.3 Functionality

The three-phase power directional element function DPSRDIR is used to detect positive-sequence power direction. The output of the function is used for blocking or releasing other functions in protection scheme.

The directional positive-sequence power protection contains a blocking functionality which blocks function output and resets Timer.

DPSRDIR executes on the direction of positive-sequence power and not the value. If overpower or underpower is needed, refer to DOPPDPR and DUPPDPR. DPSRDIR is generally used for directional controls.

5.14.4 Analog channel configuration

DPSRDIR has two analog group inputs which must be properly configured.

Table 1211: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1212: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.14.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of DPSRDIR can be described with a module diagram. All the modules in the diagram are explained in the next sections.

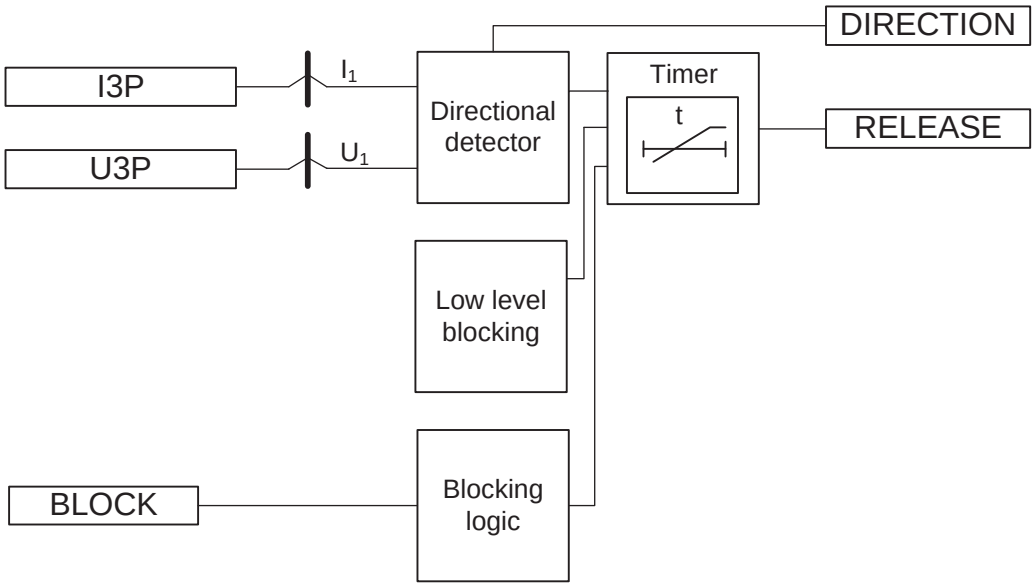

Figure 727: Functional module diagram

Directional detector

The Directional detector module compares the angle of the positive-sequence current I1 to the angle of the positive-sequence voltage V1. Using the positive-sequence voltage angle as reference, the positive-sequence current angle is compared to the *Characteristic angle* setting. If the angular difference is within the operating sector selected with the *Directional mode* setting, the On signal is sent to Timer.

The operating sector is defined by the setting *Min forward angle*, *Max forward angle*, *Min reverse angle* and *Max reverse angle*. The options that can be selected for the *Directional mode* setting are “Forward” and “Reverse”.

The sector limits are always given as positive degree values.

The *Characteristic angle* setting is also known as Relay Characteristic Angle (RCA), Relay Base Angle or Maximum Torque Line.

Low-level blocking

For a reliable operation, signal levels should be greater than the minimum level. If they are not greater than the minimum level, Timer is blocked. If the amplitude of the positive-sequence current is greater than the *Min trip current* value and the positive-sequence voltage amplitude is greater than the *Min trip voltage* value, the On signal is sent to Timer.

Timer

Once activated, the internal operating timer is started. The Timer characteristic is according to definite time DT. When Timer has reached the value of *Release delay time*, the RELEASE output is activated. If a drop-off situation happens, that is, if the operating current moves outside the operating sector or signal amplitudes drop

below the minimum level before *Release delay time* is exceeded, the Timer reset state is activated. If the drop-off continues for more than *Reset delay time*, Timer is deactivated.

Blocking logic

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates the RELEASE output and resets Timer.

5.14.6 Application

The three-phase power directional element function DPSRDIR improves the possibility to obtain a selective function of the overcurrent protection in meshed networks. DPSRDIR is used to block or release other overcurrent protection functions.

Neutral power directional element	DNZSRDIR	I2->, Io->	67N-TC

5.15.2 Function block

Figure 728: Function block

5.15.3 Functionality

Neutral power directional element function DNZSRDIR is used to detect negative or residual power direction. The output of the function is used for blocking or releasing other functions in protection scheme.

In negative-sequence voltage selection, if the angle difference between negativesequence voltage and negative-sequence current is in a predefined direction (either in forward or reverse direction), DNZSRDIR gives a release signal after a definite time delay.

In residual voltage selection, if the angle difference between residual voltage and residual current is in a predefined direction (either in forward or reverse direction), DNZSRDIR gives release signal after a definite time delay.

This function contains a blocking functionality which blocks the function output and resets Timer.

DNZSRDIR executes on the direction of either negative-sequence or zero-sequence power and not the value. The function is generally used for directional controls.

5.15.4 Analog channel configuration

DNZSRDIR has four analog group inputs which must be properly configured.

Table 1219: Analog inputs

Input	Description
I3P [1]	Three-phase currents, necessary when Pol quantity is "Neg. seq. volt."
IRES [2]	Residual current (measured or calculated), necessary when Pol quantity is "Zero seq. volt."
U3P [1]	Three-phase voltages, necessary when Pol quantity is "Neg. seq. volt."
URES [2]	Residual voltage (measured or calculated), necessary when Pol quantity is "Zero seq. volt."

See the preprocessing function blocks in this document for the possible signal sources.The GRPOFF signal is available in the function block called Protection.

There are a few special conditions which must be noted with the configuration.

Table 1220: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two phase voltage channels connected but it is recommended to connect all three voltage channels.
URES calculated	The function requires that all three voltage channels are connected to calculate residual voltage. Setting *VT connection* must be "Wye" in that particular UTVTR.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.15.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of DNZSRDIR can be described with a module diagram. All the modules in the diagram are explained in the next sections.

[1] Can be connected to GRPOFF if *Pol quantity* is set to "Zero seq. volt.".
[2] Can be connected to GRPOFF if *Pol quantity* is set to "Neg. seq. volt.".

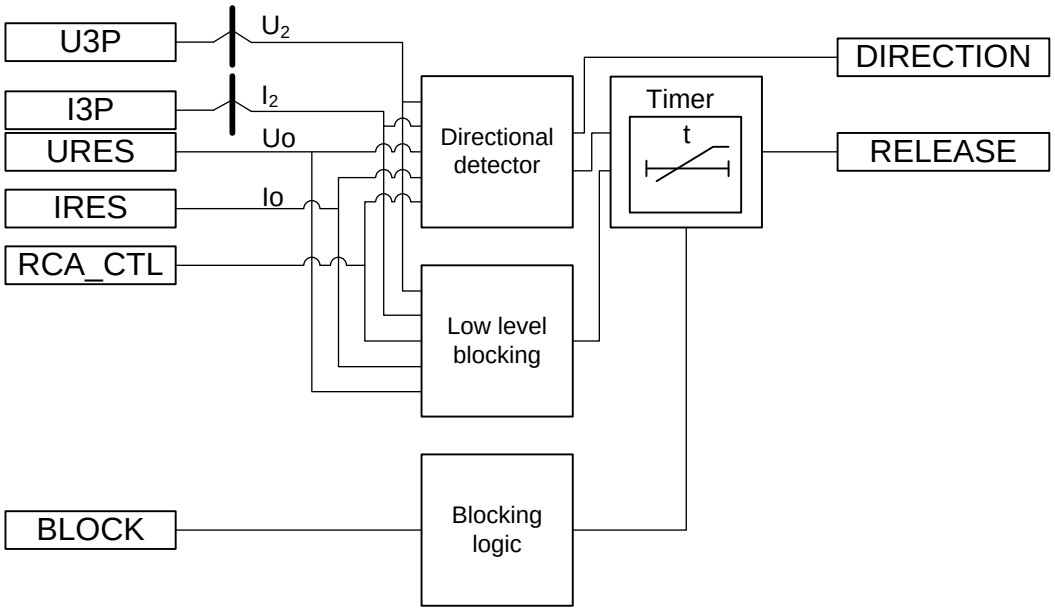

Figure 729: Functional module diagram

Directional detector

When "Neg. seq. volt." selection is made using the *Pol quantity* setting, the Directional detector module compares the angle of the negative-sequence current (I_2) to the negative-sequence voltage ($–U_2$). Using the negative-sequence voltage angle as the reference, the negative-sequence current angle is compared to the *Characteristic angle* setting. If the angle difference is within the operating sector selected by *Direction mode* setting, the Enable signal is sent to Timer.

The value of *Characteristic angle* should be chosen in such way that all the faults in the operating direction are seen in the operating zone and all the faults in the opposite direction are seen in the backward zone.

The operating sector is defined by the settings *Max forward angle*, *Max reverse angle*, *Min forward angle* and *Min reverse angle*. The options that can be selected for *Directional mode* settings are “Forward” and “Reverse”.

Characteristic angle is also known as Relay Characteristic Angle RCA, Relay Base Angle or Maximum Torque Line.

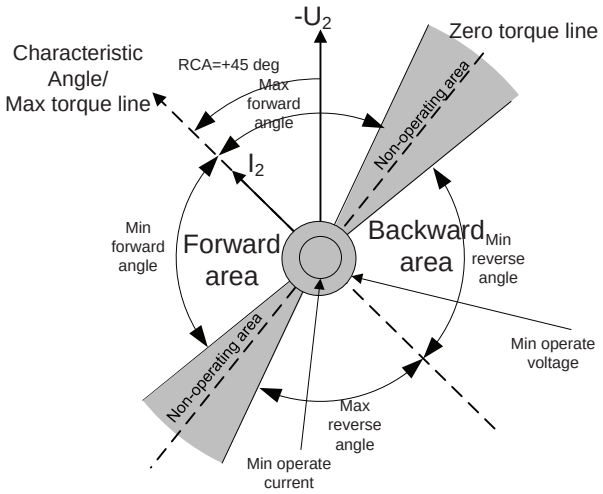

Figure 730: Configurable directional setting when "Neg. seq. volt." selection is made using the Pol quantity setting

When *Zero seq. volt.* voltage selection is made using *Pol quantity* setting, the directional detector module compares the angle of the residual current to the residual voltage. Using the residual voltage as reference, the residual current angle is compared to the *Characteristic angle* setting. If the angle difference is within the operating sector selected by the *Directional mode* setting, the Enable signal is sent to Timer.

The polarizing quantity (residual voltage) is inverted because of switched voltage measurement cables, the correction can be done by setting the *Pol reversal* setting to "True", which rotates the polarizing quantity by 180 degrees.

The directional characteristic for the measured or calculated residual power is same.

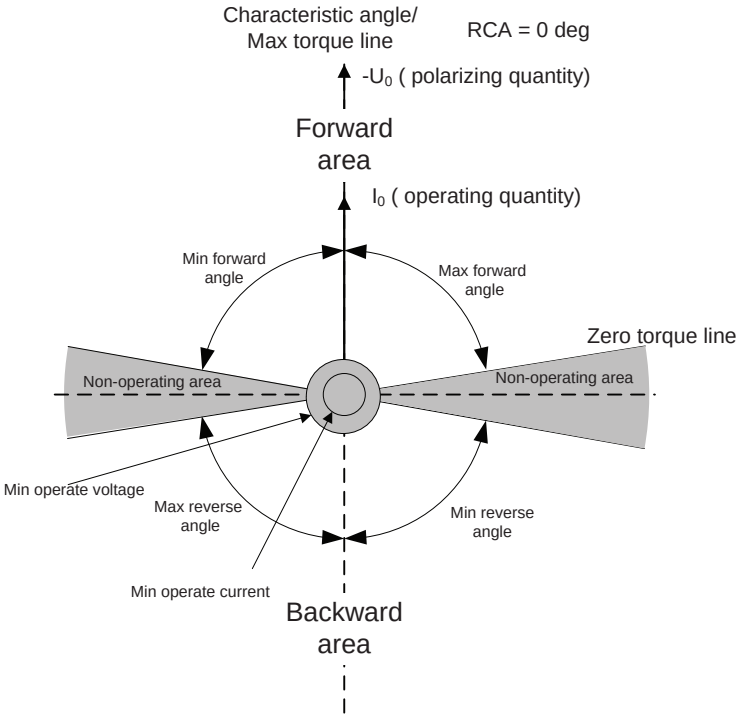

Figure 731: Configurable directional setting for Zero seq. volt. (residual voltage) using the Pol quantity setting

The *Characteristic angle* setting is done based on method of grounding employed in the network. For example, in case of an isolated network, *Characteristic angle* is set to –90°, and in case of a compensated network, *Characteristic angle* is set to 0° and 60° for solidly grounded systems. In general *Characteristic angle* is selected so that it matches close to the expected fault angle value, which results in maximum sensitivity. *Characteristic angle* can be set anywhere between –179° to +180°. The figures show examples of the operating area with RCA set to +60° and –90°, respectively.

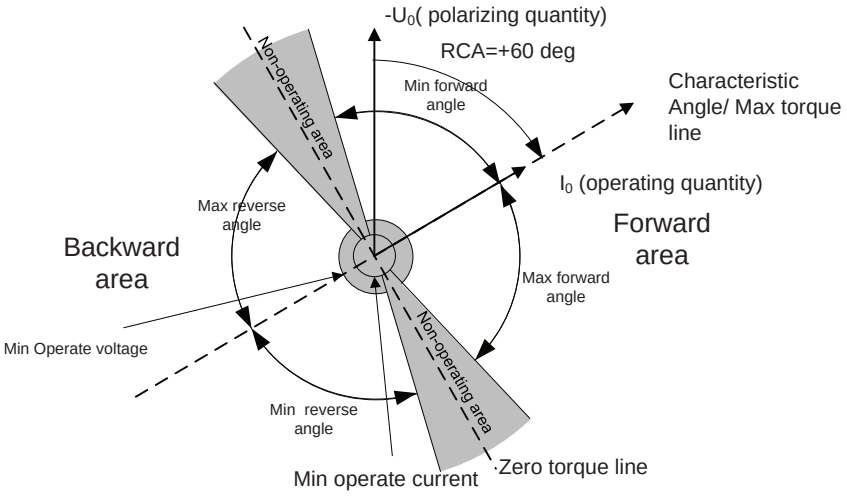

Figure 732: Configurable directional characteristics (RCA =+60 ˚) for a solidly earthed network

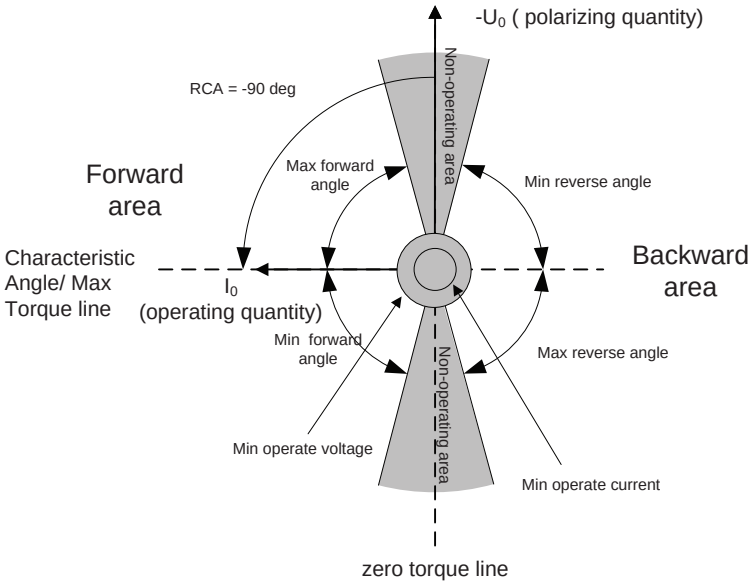

Figure 733: Configurable directional characteristics (RCA = -90 ˚) for an isolated network

Characteristic angle should be set to a positive value if the operating signal lags the polarizing quantity -VG or -VN, respectively, and a negative value if operating signal leads the polarizing quantity, respectively.

Table 1221: Recommended Characteristic angle setting for different network

Type of network	Characteristic angle recommended
Compensated network	0°
Solidly grounded network	+60°
Isolated network	–90°

The *Characteristic angle* setting is adjusted to the operation according to the method of neutral-point grounding, so that in an isolated network *Characteristic angle* is –90° and in a compensated network 0°. In addition, *Characteristic angle* can be changed via the control signal RCA_CTL, in which case the alternatives are –90° and 0°. The operation of the `RCA_CTL` input depends on the *Characteristic angle* setting.

The Peterson coil or the grounding resistor may be temporarily out of operation. To keep the protection scheme selective, it is necessary to update the *Characteristic angle* settings accordingly. This is done with an auxiliary input in the relay which receives a signal from an auxiliary switch of the disconnector of the Peterson coil in compensated networks or of the grounding resistor in grounded network as a result the *Characteristic angle* is set automatically to suit the earthing method.

Table 1222: Characteristic angle control for the RCA_CTL condition

Characteristic angle Setting	RCA_CTL=FALSE	RCA_CTL=TRUE
–90°	*Characteristic angle* = –90°	*Characteristic angle* = 0°
0°	*Characteristic angle* = 0°	*Characteristic angle* = –90°

When the phase angle criterion is used, the DIRECTION output indicates on which operating sector the negative or residual power is measured.

Low-level blocking

For a reliable operation, signal levels should be greater than the minimum level. If they are not greater than the minimum level, Timer is blocked.

In the "Neg. seq. volt." polarization selection using the *Pol quantity* setting, if the amplitude of the negative-sequence current is greater than the *Min operate current* value and the negative-sequence voltage amplitude is greater than the *Min operate voltage* value, the Enable signal is sent to Timer.

In the "Zero seq. volt." polarization selection using *Pol quantity*, if the amplitude of the residual current is greater than the *Min operate current* value and residual voltage amplitude is greater than the *Min operate voltage* value, the Enable signal is sent to Timer.

Timer

Once activated, the internal operating timer is started. The Timer characteristic is according to DT. When Timer has reached the value of *Release delay time*, the RELEASE output is activated. If a drop-off situation happens, that is, if the operating current moves out of the operating sector or signal amplitudes drop below the minimum levels, before *Release delay time* is exceeded, the Timer reset state is activated. If the drop-off continues for more than *Reset delay time*, Timer is deactivated.

Blocking logic

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates RELEASE output and resets Timer.

5.15.6 Application

The neutral power directional element function DNZSRDIR improves the possibility to obtain selective function of the overcurrent protection in meshed networks. DNZSRDIR is used to block or release other overcurrent protection functions.

5.16 Load blinder LBRDOB (ANSI 21LB)

5.16.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE identification
Load blinder	LBRDOB	LB	21LB

5.16.2 Function block

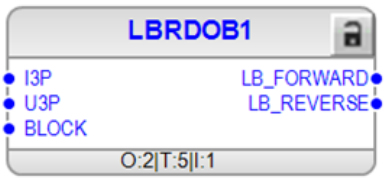

Figure 734: Function block

5.16.3 Functionality

Load blinder, or Load encroachment, function LBRDOB is used to block the directional overcurrent protection aiming at avoiding incorrect trip in case of heavy loading condition in network whose power factor close to 1.00.

Operation principle is based on calculated positive sequence impedance. Function provides blocking signal if positive sequence impedance is in load blinder forward or reverse area.

5.16.4 Analog channel configuration

LBRDOB has two analog group inputs which must be properly configured.

Table 1229: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1230: Special conditions

Condition	Description
U3P connected real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

5.16.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of Load blinder LBRDOB can be described by using a module diagram (see *Figure 735*). All the modules in the diagram are explained in the next sections.

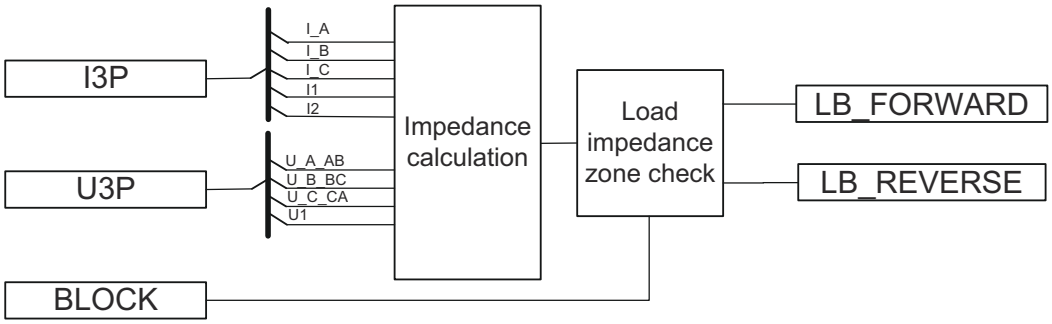

Figure 735: Functional module diagram

Impedance calculation

The impedance calculation is enabled if the negative sequence current stays below the *Max Ng Seq current* setting and the positive sequence voltage stays above the *Min Ps Seq voltage* setting.

The positive sequence impedance phasor $\bar{Z}_1$ is calculated according to:

$$\bar{Z}_1 = \frac{\bar{U}_1}{\bar{I}_1}$$

(Equation 312)

where $\bar{U}_1$ is positive sequence voltage phasor and $\bar{I}_1$ is positive sequence current phasor.

The calculated positive sequence impedance amplitude *Z1_AMPL* (primary ohms) and angle *Z1_ANGLE* (degrees) are available in monitored data view.

The calculated impedance is converted to primary ohms as the operating characteristics are defined with settings in primary ohms.

Load impedance zone check

The forward and reverse load blinder sectors are defined separately. The load blinder forward area, or load-out region, or load exporting is limited with the *Max impedance angle* and *Min impedance angle*. Similarly, these two setting parameters are also as limitations for the load blinder reverse area, or load-in region, or load importing. the *Resistive reach Fw* is maximum resistive load on forward load blinder area. *Resistive reach Rv* is maximum resistive load on reverse load blinder area. Characteristics are shown *Figure 736*.

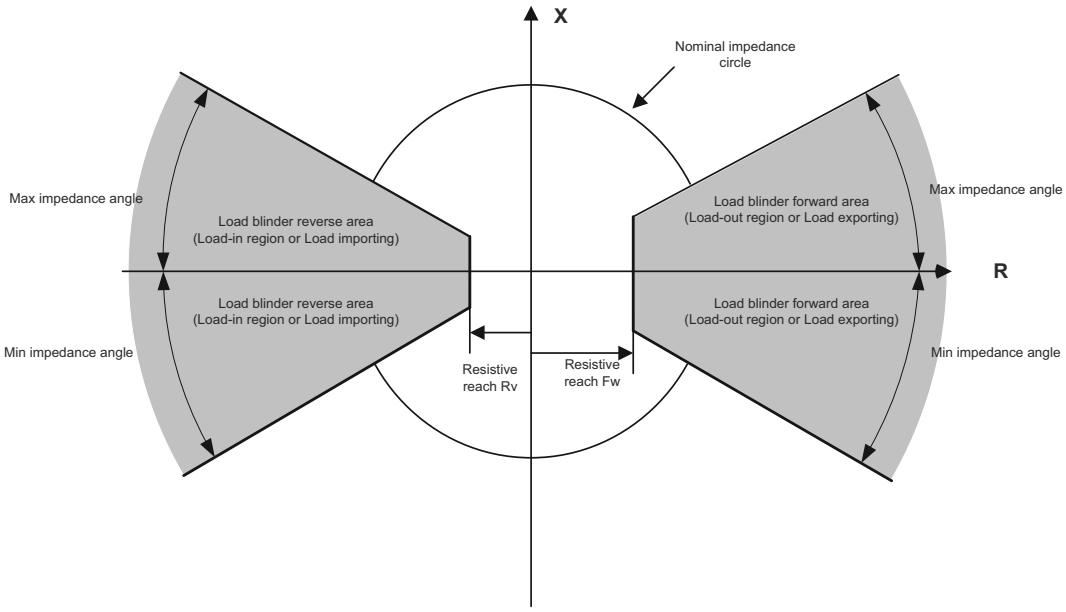

Figure 736: Operating sectors for load blinder

The blinder directional operation can be selected with the *Directional mode* setting. The alternatives are "Non-directional", "Forward" and "Reverse" operation.

Forward operation is allowed if *Directional mode* is set to “Forward”. If the resistive part value of positive sequence impedance is higher than *Resistive reach Fw* and the angle of positive sequence impedance stays in the range limited with the *Max impedance angle* and *Min impedance angle* on forward area, the function output `LB_FORWARD` is activated.

Reverse operation is allowed if *Directional mode* is set to “Reverse”. If the resistive part value of positive sequence impedance exceeds the limitation of *Resistive reach Rv* and the angle of positive sequence impedance stays in the range limited with the *Max impedance angle* and *Min impedance angle* on reverse area, the function output `LB_REVERSE` is activated.

In case *Directional mode* is set to “Non-directional”, operation is allowed both directions according to conditions described above.

Activation of the `BLOCK` input deactivates the function outputs.

5.16.6 Application

Load blinder or load encroachment, function LBRDOB is used to block the directional overcurrent protection aiming at avoiding incorrect trip in case of heavy loading condition in network. In general, the active power increases to the level leading to a high power factor, the network turns into heavy load status, and there exists risk of incorrect trip for the directional overcurrent protection because of high level of load current.

The suitability of *Resistive reach Fw* and *Resistive reach Rv* settings will influence the activation of load blinder function. If *Resistive reach Fw* and *Resistive reach Rv* are set beyond the network minimal resistive load, the function will not be activated in the case that the load impedance approaches the network minimal impedance load. Hence, the absolute values of *Resistive reach Fw* and *Resistive reach Rv* should be set less than that of the minimal resistive load.

The blinder in forward direction, *Resistive reach Fw*, can be calculated according to

$$Resistive\ reach\ Fw = K \cdot \frac{U_{expmin}^2}{P_{expmax}}$$

(Equation 313)

where:

P_{expmax}	is the maximum exporting active power
U_{expmin}	is minimum phase-to-phase voltage when the exporting active power occurs
K	is a security factor to ensure that the setting of *Resistive reach Fw* less than minimal resistive load, with a recommended value 0.8.

The resistive boundary *Resistive reach Rv* can be obtained in the same way as *Resistive reach Fw*, but replace the maximum exporting active power P_{expmax} and the corresponding voltage U_{expmin} with the maximum importing active power P_{impmax} and the corresponding voltage U_{impmin}.

The *Max impedance angle* and *Min impedance angle* are symmetric in forward and reverse direction, these values are recommended to set the maximum possible load angle when load active power arrives at top. A value bigger than 20° must be used.

6 Supervision functions

6.1 Trip circuit supervision TCSSCBR (ANSI TCM)

6.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Trip circuit supervision	TCSSCBR	TCS	TCM

6.1.2 Function block

Figure 737: Function block

6.1.3 Functionality

The trip circuit supervision function TCSSCBR is designed to supervise the control circuit of the circuit breaker. The invalidity of a control circuit is detected by using a dedicated output contact that contains the supervision functionality. The failure of a circuit is reported to the corresponding function block in the relay configuration.

The function starts and operates when TCSSCBR detects a trip circuit failure. The operating time characteristic for the function is DT. The function operates after a predefined operating time and resets when the fault disappears.

The function contains a blocking functionality. Blocking deactivates the `ALARM` output and resets the timer.

6.1.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of TCSSCBR can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

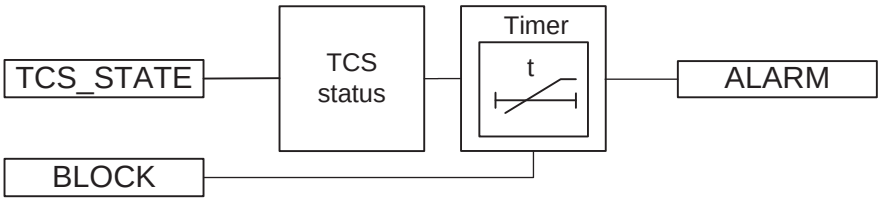

Figure 738: Functional module diagram

TCS status

This module receives the trip circuit status from the hardware. A detected failure in the trip circuit activates the timer.

Timer

Once activated, the timer runs until the set value of *Operate delay time* has elapsed. The time characteristic is according to DT. When the operation timer has reached the maximum time value, the `ALARM` output is activated. If a drop-off situation occurs during the operate time up counting, the fixed 0.5 s reset timer is activated. After that time, the operation timer is reset.

The `BLOCK` input can be controlled with a binary input, a horizontal communication input or an internal signal of the relay program. The activation of the `BLOCK` input prevents the `ALARM` output to be activated.

6.1.5 Application

TCSSCBR detects faults in the electrical control circuit of the circuit breaker. The function can supervise both open and closed coil circuits. This supervision is necessary to find out the vitality of the control circuits continuously.

Figure 739 shows an application of the trip circuit supervision function use. Example of both mechanical (on the left) and static (on the right) outputs TCS connections are shown.

The mechanical outputs (PODPx) are used in both AC or DC circuits, and polarity is insignificant. The static outputs (SPOx) can be used in DC only and polarity must be correct.

The best solution is to connect an external R_{ext} shunt resistor in parallel with the circuit breaker internal contact as shown with the dashed line. This way, although the circuit breaker auxiliary contact is open, TCS can see the trip circuit through R_{ext}. The R_{ext} resistor should have such a resistance that the current through the circuit breaker coil remains small, that is, it does not harm or overload the circuit breaker's trip coil if the trip is latched/locked-out.

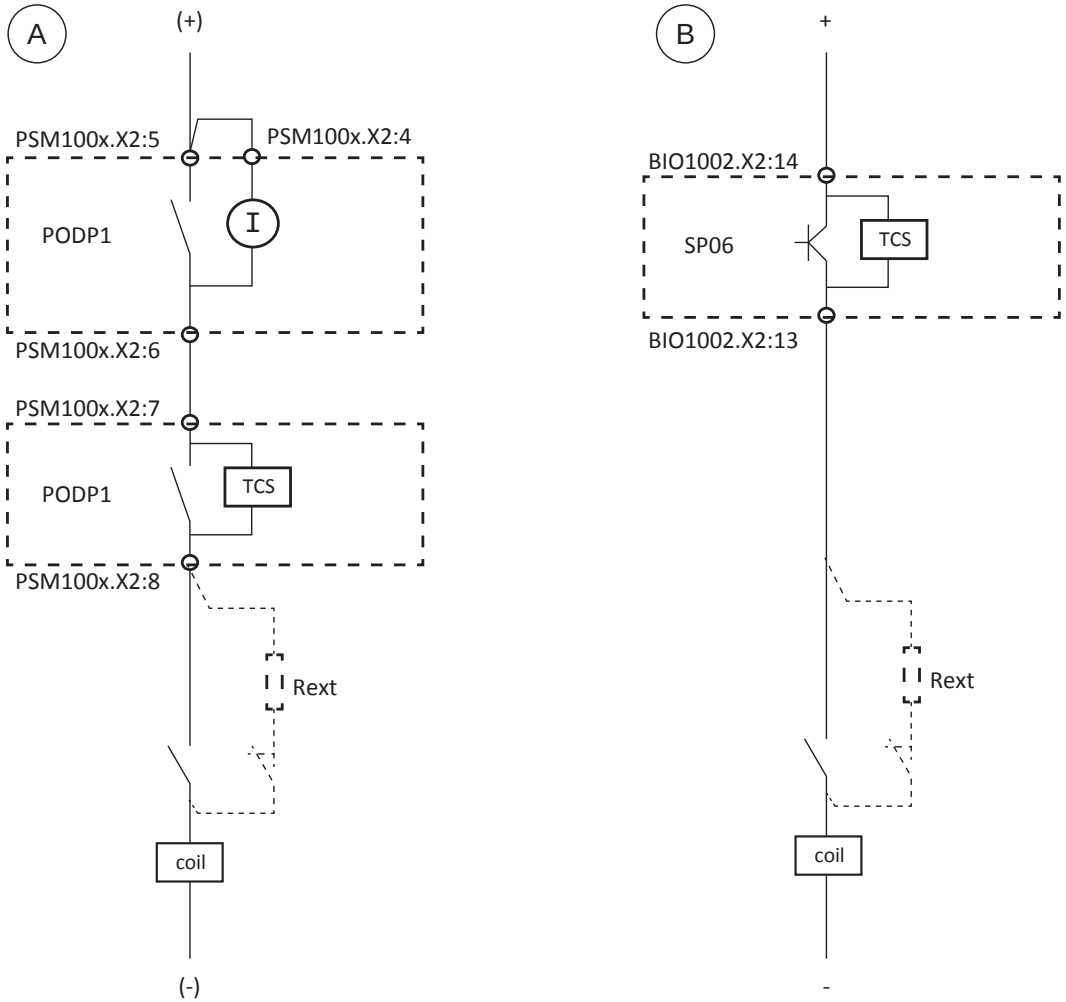

Figure 739: Operating principle of the trip-circuit supervision, single-pole connection

If TCS is required only in a closed position, the external shunt resistance can be omitted. When the circuit breaker is in the open position, TCS sees the situation as a faulty circuit. One way to avoid TCS operation in this situation is to block the supervision function whenever the circuit breaker is open.

It is also recommended to block the supervision function when the trip output is active. Otherwise, TCS issues an alarm if the trip remains active over the set TCS *Operate delay time*.

Figure 740 shows a double-pole connection of the trip circuit supervision. For the static output, this requires using SPO5 or SPO6 output in series of the circuit.

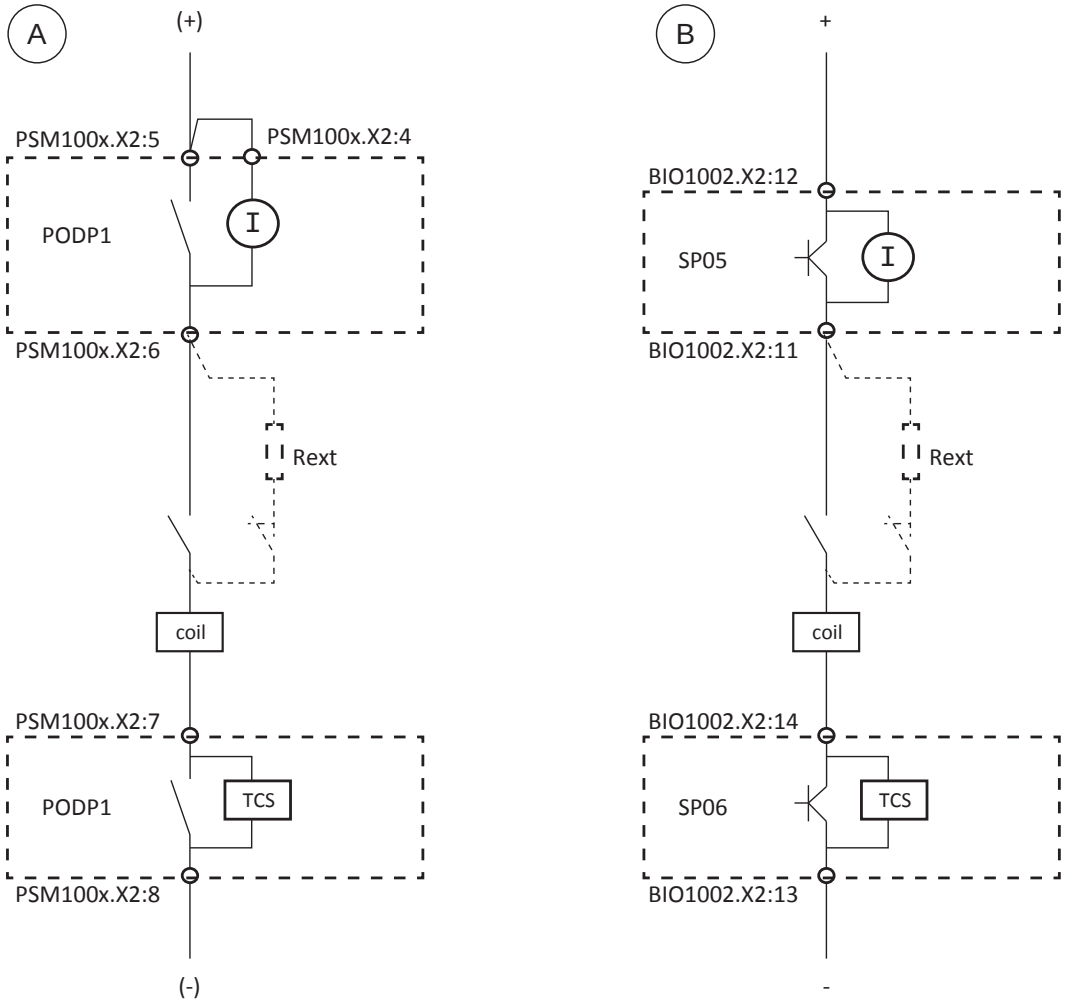

Figure 740: Operating principle of the trip-circuit supervision, double-pole connection

Trip circuit supervision and other trip contacts

It is typical that the trip circuit contains more than one trip contact in parallel, for example in transformer feeders where the trip of a Buchholz relay is connected in parallel with the feeder terminal and other relays involved. The supervising current cannot detect if one or all the other contacts connected in parallel are not connected properly.

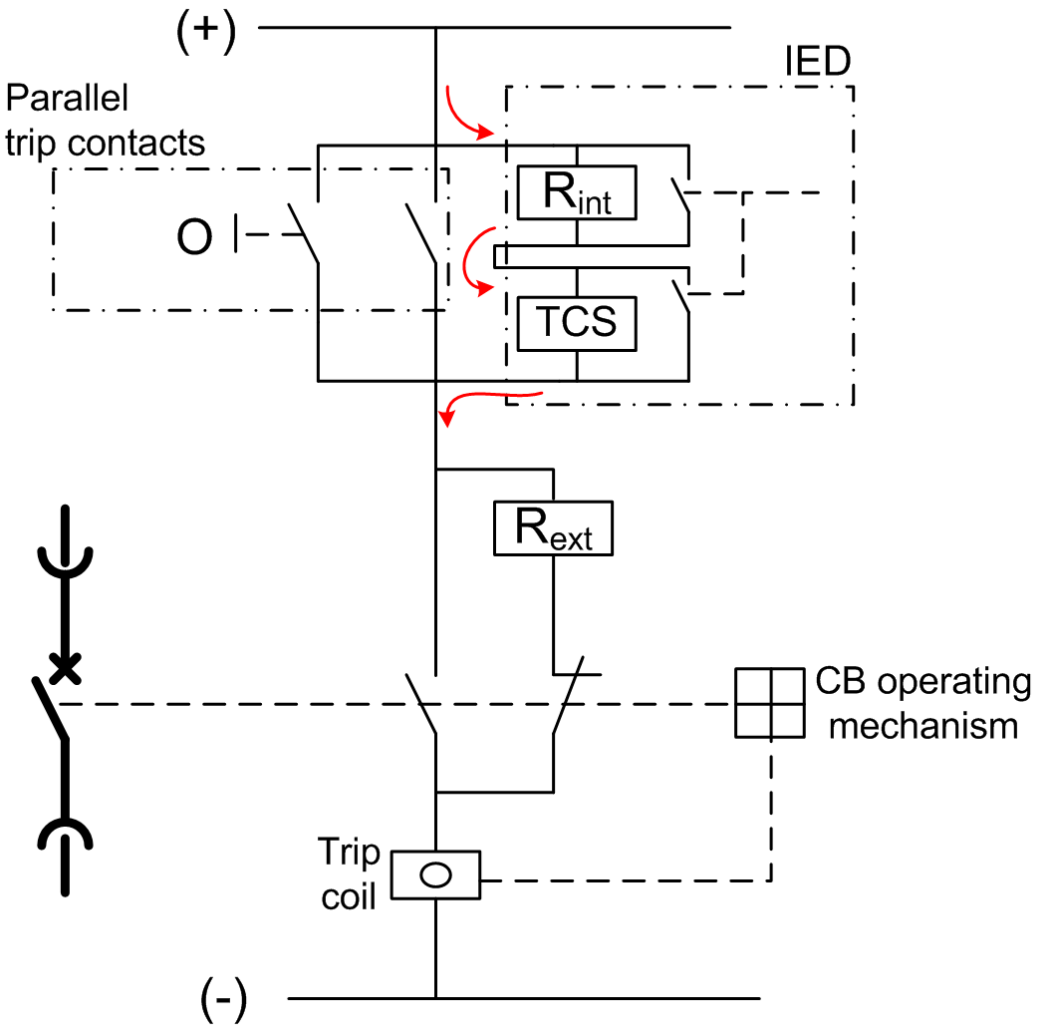

Figure 741: Constant test current flow in parallel trip contacts and trip circuit supervision

In case of parallel trip contacts, the recommended way to do the wiring is that the TCS test current flows through all wires and joints.

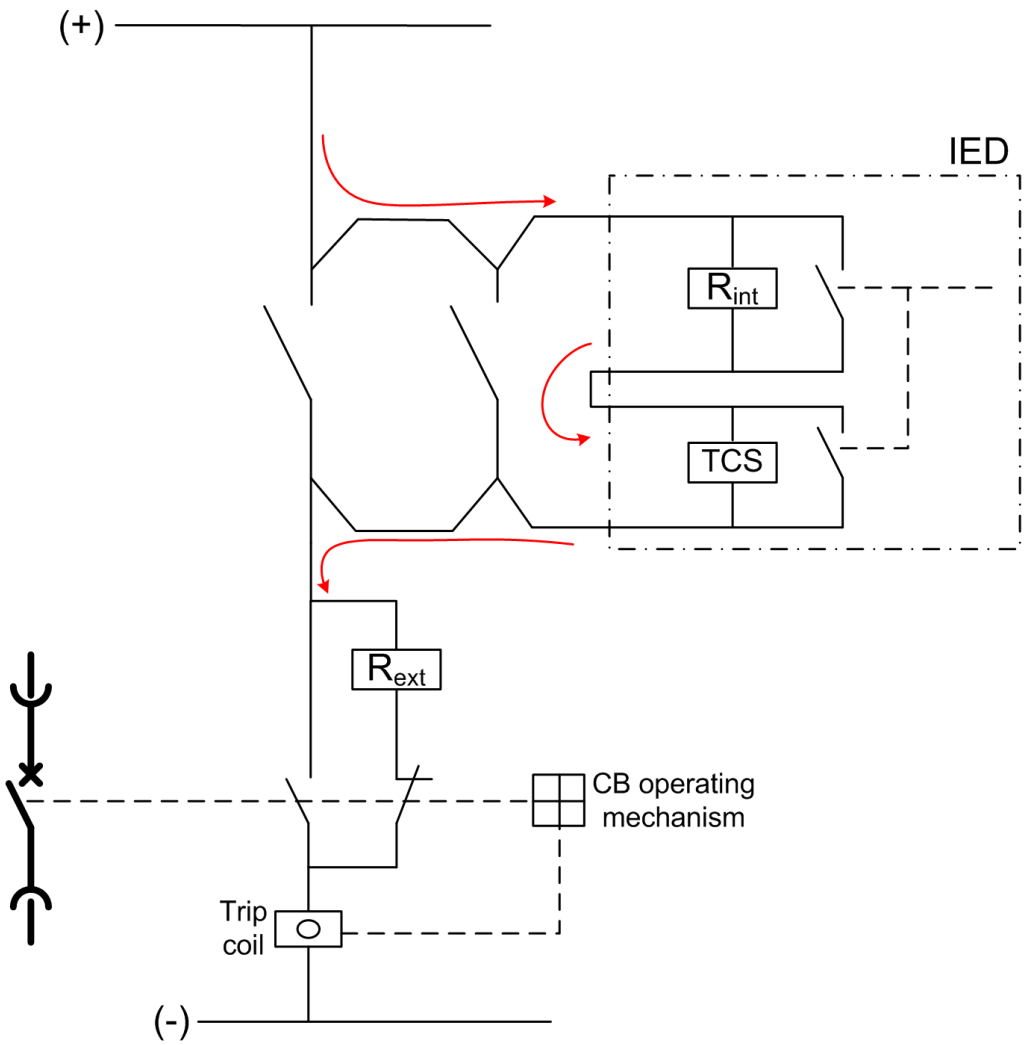

Figure 742: Improved connection for parallel trip contacts where the test current flows through all wires and joints

Several trip circuit supervision functions parallel in circuit

Not only the trip circuit often have parallel trip contacts, it is also possible that the circuit has multiple TCS circuits in parallel. Each TCS circuit causes its own supervising current to flow through the monitored coil and the actual coil current is a sum of all TCS currents. This must be taken into consideration when determining the resistance of R_{ext}.

Setting the TCS function in a protection relay not-in-use does not typically affect the supervising current injection.

Trip circuit supervision with auxiliary relays

Many retrofit projects are carried out partially, that is, the old electromechanical relays are replaced with new ones but the circuit breaker is not replaced. This creates a problem that the coil current of an old type circuit breaker can be too high for the protection relay trip contact to break.

The circuit breaker coil current is normally cut by an internal contact of the circuit breaker. In case of a circuit breaker failure, there is a risk that the protection relay trip contact is destroyed since the contact is obliged to disconnect high level of electromagnetic energy accumulated in the trip coil.

An auxiliary relay can be used between the protection relay trip contact and the circuit breaker coil. This way the breaking capacity question is solved, but the TCS circuit in the protection relay monitors the healthy auxiliary relay coil, not the circuit breaker coil. The separate trip circuit supervision relay is applicable for this to supervise the trip coil of the circuit breaker.

Dimensioning of the external resistor

Under normal operating conditions, the applied external voltage is divided between the relay's internal circuit and the external trip circuit so that at the minimum 20 V (15...20 V) remains over the relay's internal circuit. Should the external circuit's resistance be too high or the internal circuit's too low, for example due to welded relay contacts, a fault is detected.

Mathematically, the operation condition can be expressed as:

$$U_C - U_D - I_C \cdot (R_s + R_{ext}) \geq 20V \quad AC / DC$$

(Equation 314)

U_c	Operating voltage over the supervised trip circuit
U_D	Voltage drop over internal 3 mA current drain, about 6.5 V
I_c	Measuring current through the trip circuit, appr. 1.5 mA (0.99...1.72 mA)
R_{ext}	External shunt resistance
R_s	Trip coil resistance

If the external shunt resistance is used, it has to be calculated not to interfere with the functionality of the supervision or the trip coil. Too high a resistance causes too high a voltage drop, jeopardizing the requirement of at least 20 V over the internal circuit, while a resistance too low can enable false operations of the trip coil.

Table 1238: Values recommended for the external resistor R ext

Operating voltage U_c	Shunt resistor R_{ext}
48 V AC/DC	1.2 kΩ, 5 W
60 V AC/DC	5.6 kΩ, 5 W
110...130 V AC/DC	22 kΩ, 5 W
220...250 V AC/DC	33 kΩ, 5 W

Due to the requirement that the voltage over the TCS contact must be 20 V or higher, the correct operation is not guaranteed with auxiliary operating voltages lower than 48 V DC because of the voltage drop in U_D and R_{ext} and the operating coil or even voltage drop of the feeding auxiliary voltage system which can cause too low voltage values over the TCS contact. In this case, erroneous alarming can occur.

At lower (<48 V DC) auxiliary circuit operating voltages, it is recommend either touse the static output and single-pole connection (as then there is no internal currentdrain and U_D = 0 V), or not to use R_{ext} and block TCS when the circuit breaker isopen.

Using power output contacts without trip circuit supervision

In case of mechanical outputs, if TCS is not used, the internal current drain (PSM100x.X2:4, PSM100x.X2:9 and PSM100x.X2:14 in PODP1, PODP2 and PODP2 outputs, respectively) can be left unconnected. The output can then be used as a normal power output.

Incorrect connections and use of trip circuit supervision

Although the TCS circuit in the PODP1, PODP2 and PODP2 outputs consists of two separate contacts, it must be noted that those are designed to be used as series connected to guarantee the breaking capacity given in the technical manual of the protection relay. *Figure 743* shows incorrect usage of a TCS circuit when only one of the contacts is used.

6.2 Current circuit supervision CCSPVC (ANSI CCM)

6.2.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Current circuit supervision	CCSPVC	MCS 3I	CCM

6.2.2 Function block

Figure 744: Function block

6.2.3 Functionality

The current circuit supervision function CCSPVC is used for monitoring current transformer secondary circuits.

CCSPVC calculates internally the sum of phase currents (I_A, I_B and I_C) and compares the sum against the measured single reference current (I_REF). The reference current must originate from other three-phase CT cores than the phase currents (I_A, I_B and I_C) and it is to be externally summated, that is, outside the protection relay.

CCSPVC detects a fault in the measurement circuit and issues an alarm or blocks the protection functions to avoid unwanted tripping.

It must be remembered that the blocking of protection functions at an occurring open CT circuit means that the situation remains unchanged and extremely high voltages stress the secondary circuit.

6.2.4 Analog channel configuration

CCSPVC has two analog group inputs which must be properly configured.

Table 1244: Analog inputs

Input	Description
I3P	Three-phase currents
IRES	Residual current (measured)

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1245: Special conditions

Condition	Description
IRES measured	In case IRES needs to be derived, the function requires that all CT cores, except for the one used for phase current measurement, must be used and summed externally.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

6.2.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of CCSPVC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

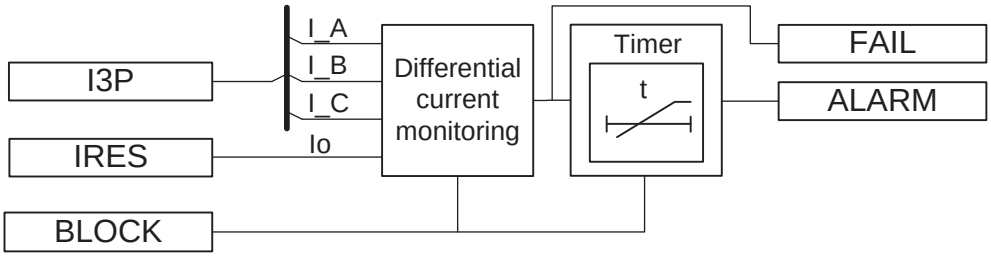

Figure 745: Functional module diagram

Differential current monitoring

Differential current monitoring supervises the difference between the summed phase currents I_A, I_B and I_C and the reference current I_REF.

The current operating characteristics can be selected with the *Start value* setting. When the highest phase current is less than 1.0 × In, the differential current limit is defined with *Start value*. When the highest phase current is more than 1.0 × In, the differential current limit is calculated with the equation.

$$MAX(I_A, I_B, I_C) \times Start\ value$$

(Equation 315)

The differential current is limited to 1.0 × In.

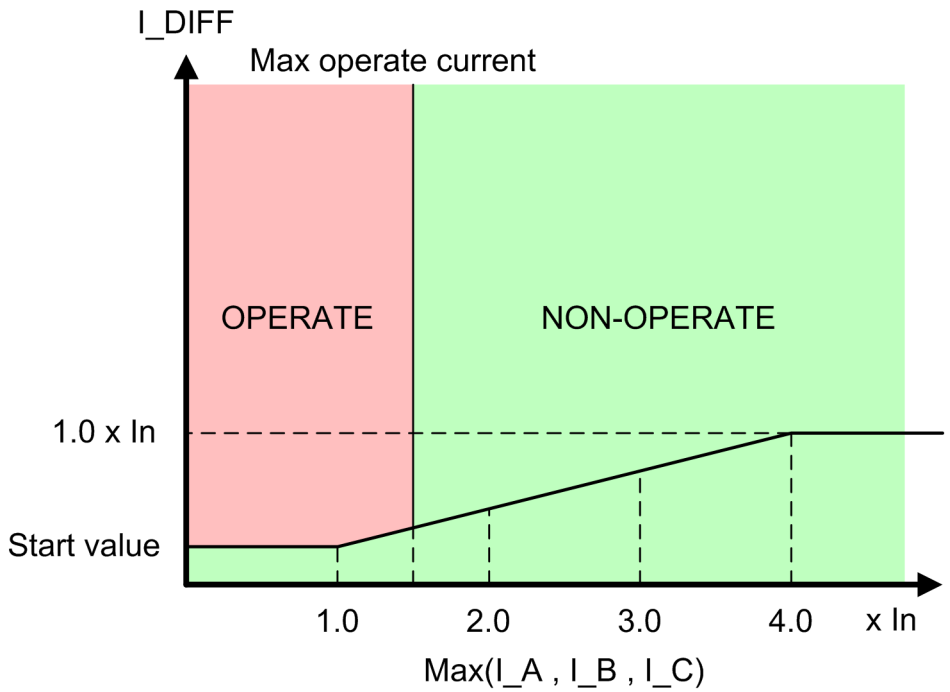

Figure 746: CCSPVC operating characteristics

When the differential current I_DIFF is in the operating region, the `FAIL` output is activated.

The function is internally blocked if any phase current is higher than the set *Max operate current*. When the internal blocking activates, the FAIL output is deactivated immediately. The internal blocking is used for avoiding false operation during a fault situation when the current transformers are saturated due to high fault currents.

The value of the differential current is available in the monitored data view on the LHMI or through other communication tools. The value is calculated with the equation.

$$I_DIFF = \left| \overline{I_A} + \overline{I_B} + \overline{I_C} \right| - \left| \overline{I_REF} \right|$$

(Equation 316)

The *Start value* setting is given in units of ×In of the phase current transformer. The possible difference in the phase and reference current transformer ratios is internally compensated by scaling I_REF with the value derived from the *Primary current* setting values. These setting parameters can be found in the Basic functions section.

The activation of the BLOCK input deactivates the FAIL output immediately.

Timer

The timer is activated with the FAIL signal. The ALARM output is activated after a fixed 200 ms delay. FAIL needs to be active during the delay.

When the internal blocking is activated, the FAIL output deactivates immediately. However, the ALARM output deactivates after a fixed delay of three seconds.

The function resets when the differential current is below the start value and the highest phase current is more than 5 percent of the nominal current (0.05 × In).

If the current falls to zero when the FAIL or ALARM outputs are active, the deactivation of these outputs is prevented.

The activation of the BLOCK input deactivates the ALARM output.

6.2.6 Application

Open or short-circuited current transformer cores can cause unwanted operation in many protection functions such as differential, earth-fault current and negative-sequence current functions. When currents from two independent three-phase sets of CTs or CT cores measuring the same primary currents are available, reliable current circuit supervision can be arranged by comparing the currents from the two sets. When an error in any CT circuit is detected, the protection functions concerned can be blocked and an alarm given.

In case of high currents, the unequal transient saturation of CT cores with a different remanence or saturation factor can result in differences in the secondary currents from the two CT cores. An unwanted blocking of protection functions during the transient stage must then be avoided.

The supervision function must be sensitive and have a short operation time to prevent unwanted tripping from fast-acting, sensitive numerical protections in case of faulty CT secondary circuits.

Open CT circuits create extremely high voltages in the circuits, which may damage the insulation and cause further problems. This must be taken into consideration especially when the protection functions are blocked.

When the reference current is not connected to the protection relay, the function should be turned off. Otherwise, the FAIL output is activated when unbalance occurs in the phase currents even if there was nothing wrong with the measurement circuit.

Reference current measured with core-balanced current transformer

CCSPVC compares the sum of phase currents to the current measured with the core-balanced CT.

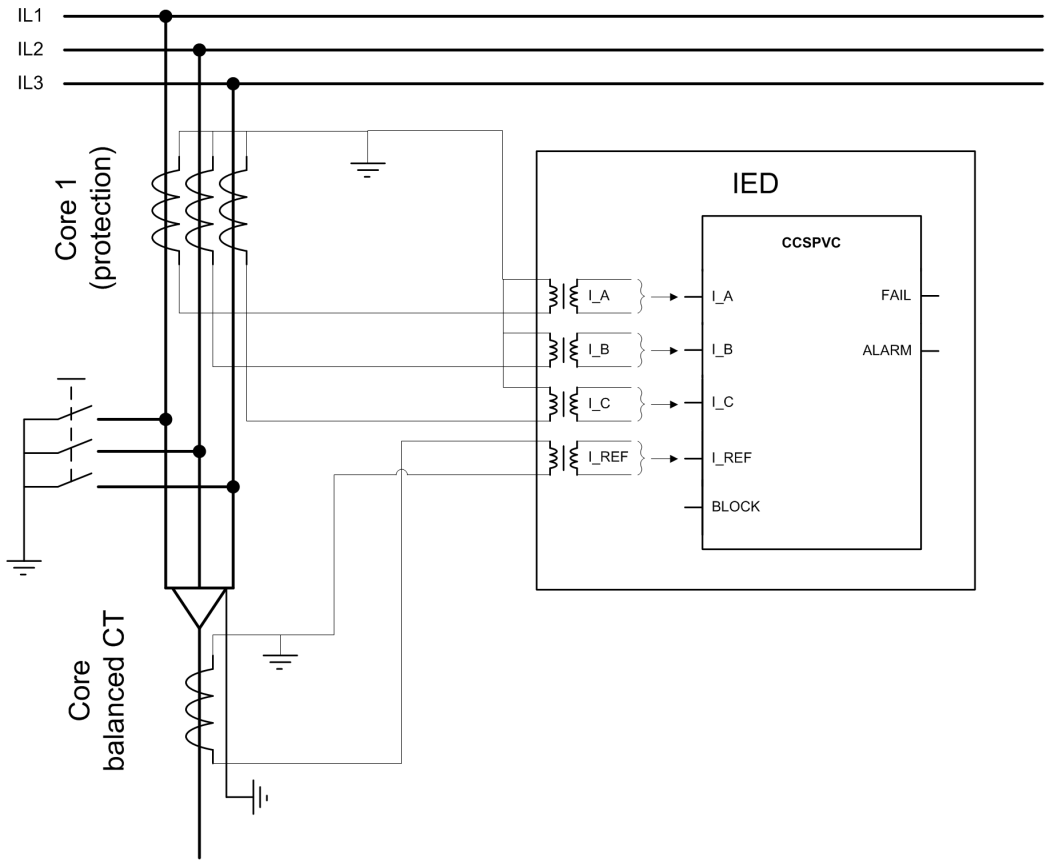

Figure 747: Connection diagram for reference current measurement with core-balanced current transformer

Current measurement with two independent three-phase sets of CT cores

Figure 748 and *Figure 749* show diagrams of connections where the reference current is measured with two independent three-phase sets of CT cores.

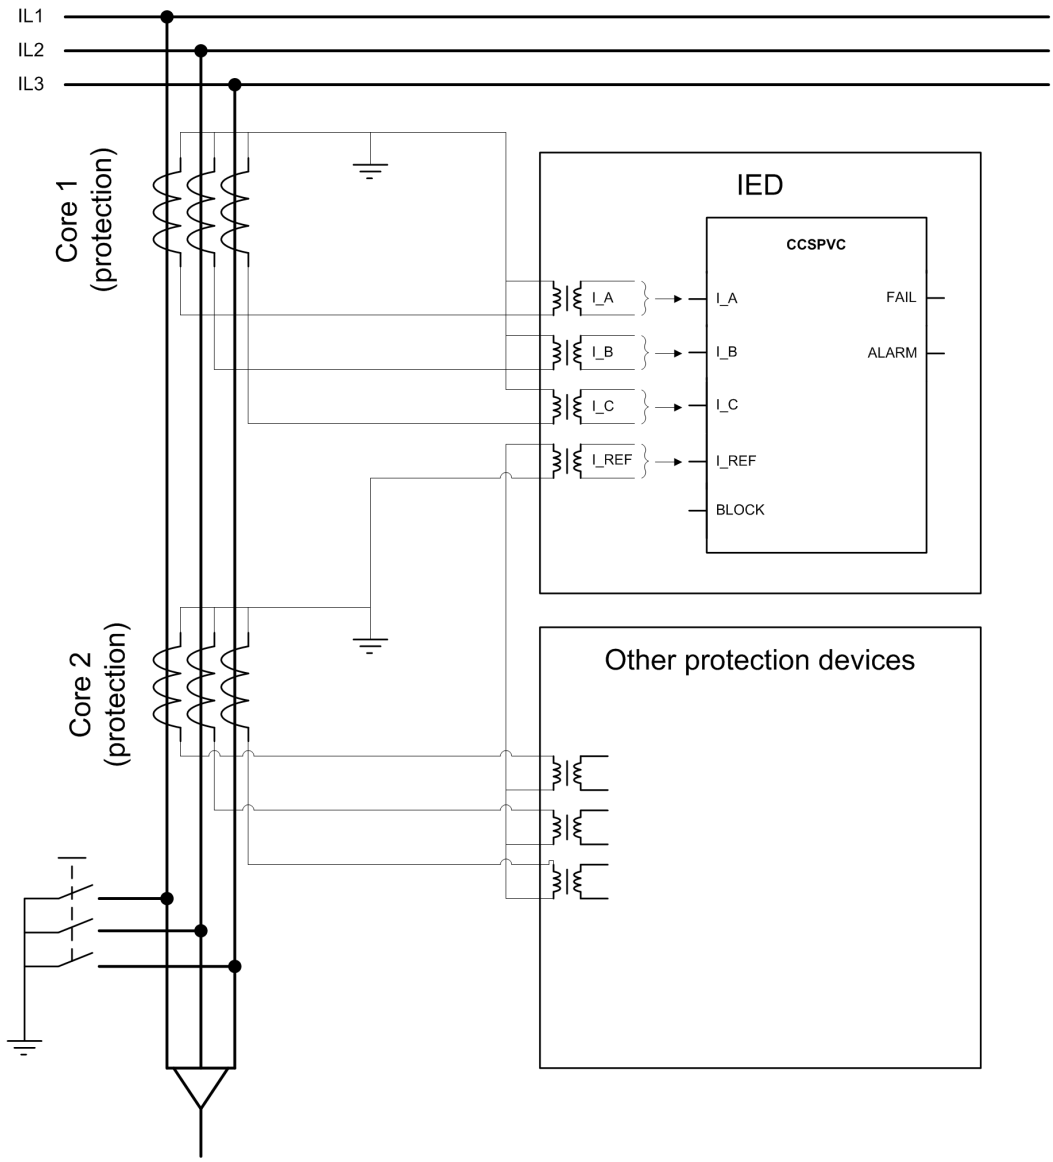

Figure 748: Connection diagram for current circuit supervision with two sets of three-phase current transformer protection cores

When using the measurement core for reference current measurement, it should be noted that the saturation level of the measurement core is much lower than with the protection core. This should be taken into account when setting the current circuit supervision function.

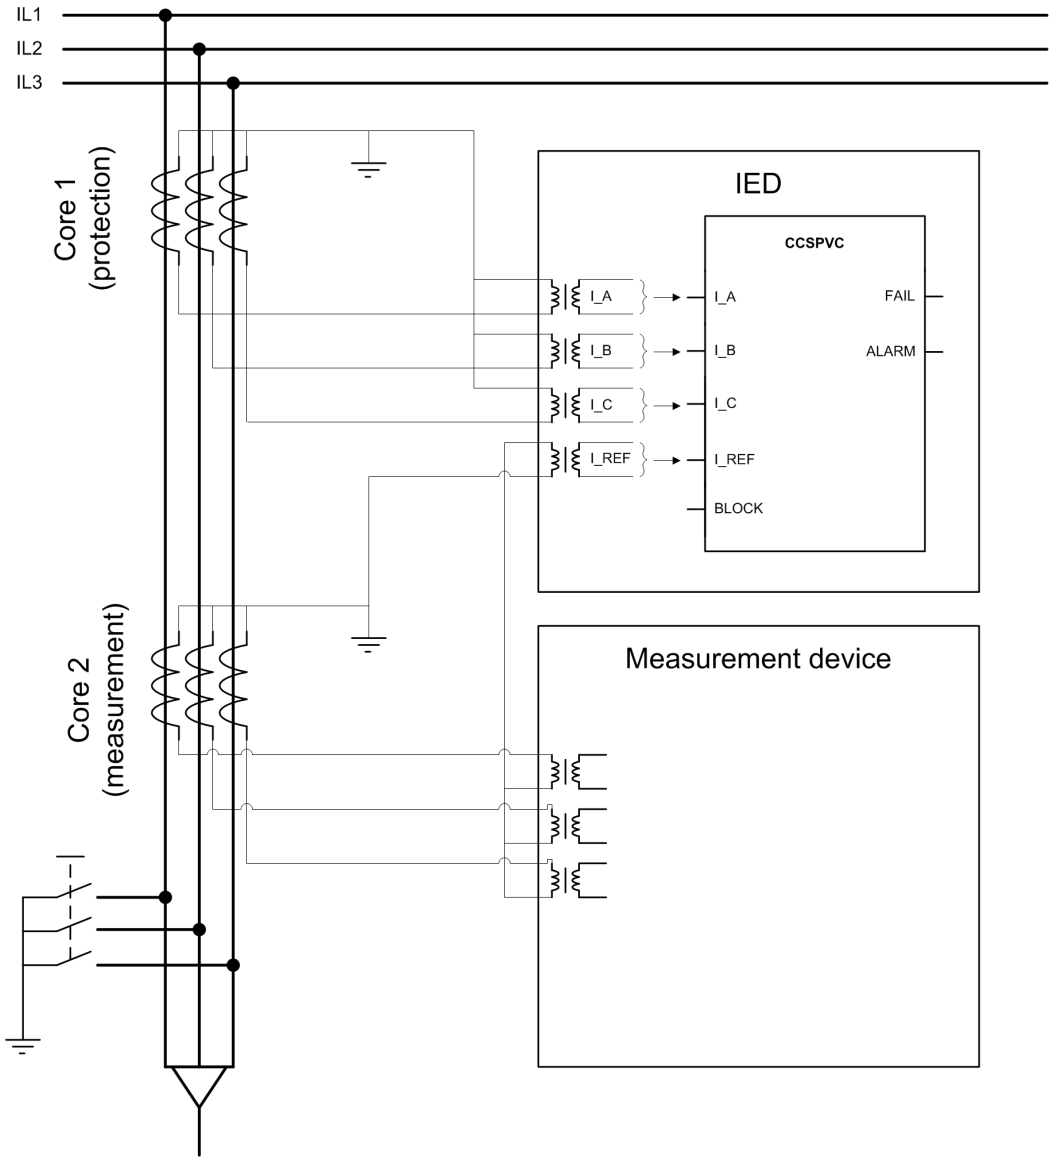

Figure 749: Connection diagram for current circuit supervision with two sets of three-phase current transformer cores (protection and measurement)

Example of incorrect connection

The currents must be measured with two independent cores, that is, the phase currents must be measured with a different core than the reference current. A connection diagram shows an example of a case where the phase currents and the reference currents are measured from the same core.

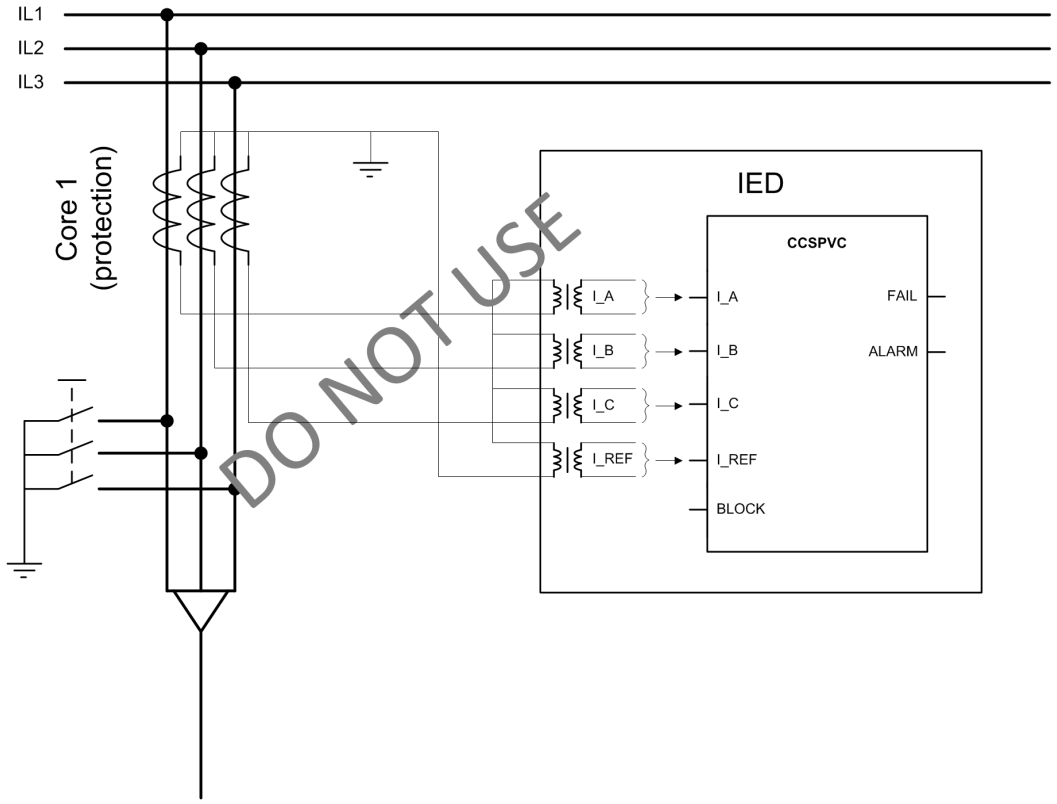

Figure 750: Example of incorrect reference current connection

Current transformer supervision for high-impedance protection scheme for phase C	HZCCCSPVC	MCS I_C	CCM_C

6.3.2 Function block

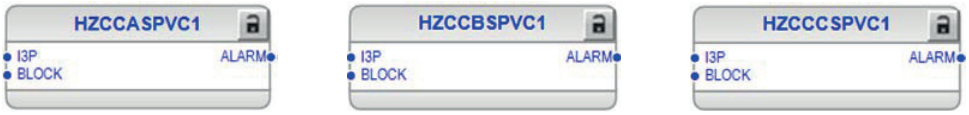

Figure 751: Function block

6.3.3 Functionality

The current transformer supervision for high-impedance protection scheme function HZCCxSPVC is a dedicated phase-segregated supervision function to be used along with the high-impedance differential protection for detecting the broken CT secondary wires. The differential current is taken as an input for the protection relay. During normal CT condition, the value of the differential current is zero. However, when the CT is broken, the secondary differential current starts flowing and it is used for generating alarms.

To avoid maloperation, HZCCxSPVC should have a sensitive setting, compared to the high-impedance differential protection. The function is likely to start under through-fault conditions. However, by incorporating a high time delay (3 s or more), the downstream protection clears the fault before an alarm is generated.

HZCCxSPVC generates an alarm when the differential current exceeds the set limit. The function operates within the DT characteristic.

HZCCxSPVC contains a blocking functionality. It is possible to block the function output, Timer or the whole function.

6.3.4 Analog channel configuration

HZCCxSPVC has one analog group input which must be properly configured.

Table 1253: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

6.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of HZCCxSPVC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

The module diagram illustrates all the phases of the function. However, the functionality is described only for phase A. The functionality for phase B and C is identical.

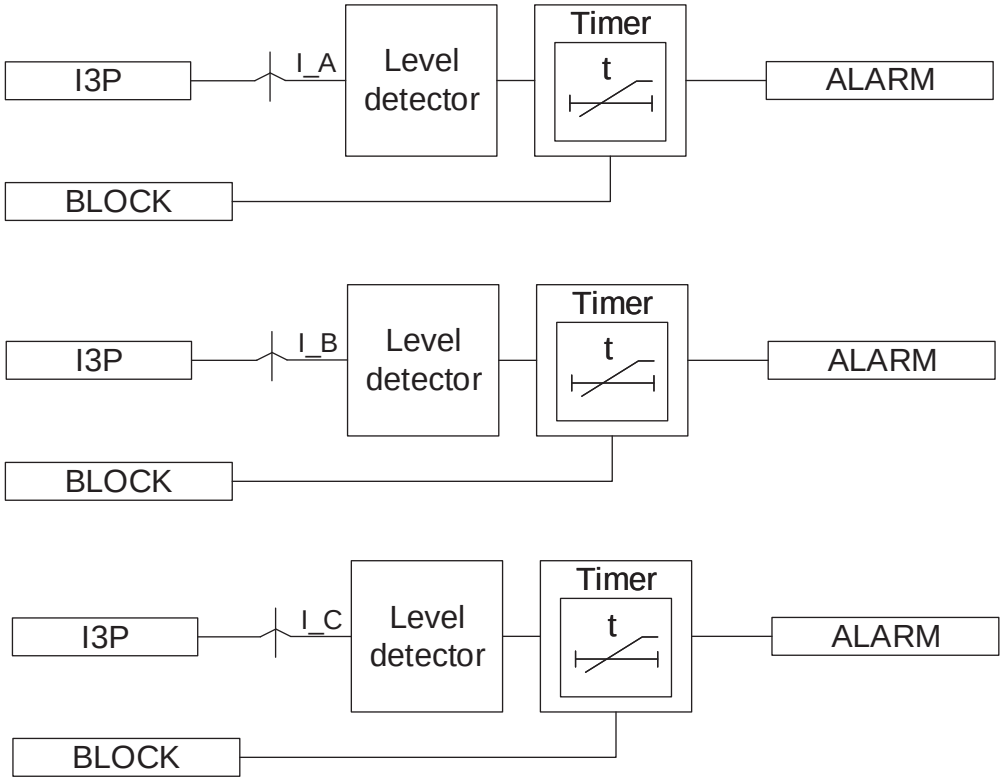

Figure 752: Functional module diagram

Level detector

This module compares the differential current `I_A` to the set *Start value*. The timer module is activated if the differential current exceeds the value set in the *Start value* setting.

Timer

The time characteristic is according to DT. When the alarm timer reaches the value set by *Alarm delay time*, the `ALARM` output is activated. If the fault disappears before the module generates an alarm signal, the reset timer is activated. If the reset timer reaches the value set by *Reset delay time*, the alarm timer resets. The activation of the `BLOCK` signal resets the Timer and deactivates the `ALARM` output.

Lockout logic

HZCCxSPVC is provided with the possibility to activate a lockout for the `ALARM` output depending on the *Alarm output mode* setting. In the "Lockout" mode, the `ALARM` must be reset manually from the LHMI Clear menu after checking the CT secondary circuit. In the "Non-latched" mode, the `ALARM` output functions normally, that is, it resets as soon as the fault is cleared.

6.3.6 Measuring modes

The function operates on two alternative measurement modes, DFT and Peak-to-Peak. The measurement mode is selected using the *Measurement mode* setting.

6.3.7 Application

HZCCxSPVC is a dedicated phase-segregated supervision function to be used along with the high-impedance differential protection for detecting the broken CT secondary wires. The operation principle of HZCCxSPVC is similar to the high-impedance differential protection function HIxPDIF. However, the current setting of HZCCxSPVC is set to be much more sensitive than HIxPDIF and it operates with a higher time delay. A typical example of the HZCCxSPVC *Start value* setting is 0.1 pu with an *Alarm delay time* of 3 s or more.

As the current setting of HZCCxSPVC is more sensitive than the actual differential stage, it can start internally under the through-fault conditions; however, a sufficient time delay prevents false alarm. If the bus wire is broken, differential current arises depending on the load of the feeder with the broken bus wire.

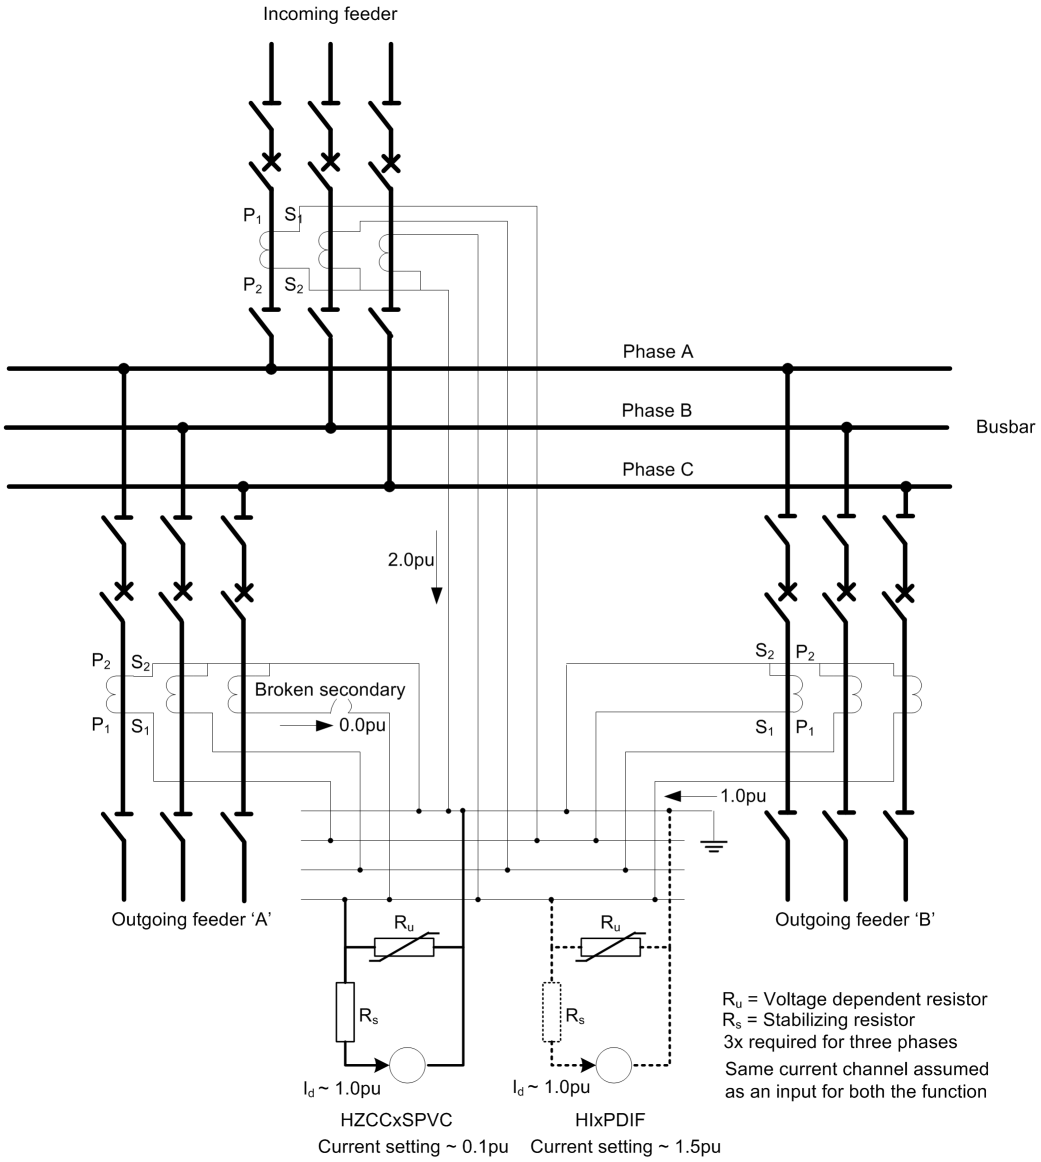

Figure 753: Broken secondary detection by HZCCxSPVC

In the example, the incoming feeder is carrying a load of 2.0 pu and both outgoing feeders carry an equal load of 1.0 pu However, both HIxPDIF and HZCCxSPVC consider the current as an increased differential or unbalance current because of the broken CT wire in phase C. Both HIxPDIF and HZCCxSPVC receive the differential current of approximately 1.0 pu The main differential protection HIxPDIF cannot operate because of the higher current setting.

All CTs must have the same ratio.

The ALARM output of the CT supervision function can be used to energize an auxiliary relay which can short-circuit the current CT wires, making the busbar differential protection inoperative. This arrangement does not prevent unwanted operation of HIxPDIF if the start setting is below the rated load. For example, if the start setting for HIxPDIF in the example is set as 0.8 pu HIxPDIF operate before HZCCxSPVC.

6.4 Protection communication supervision PCSITPC (ANSI PCS)

6.4.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Protection communication supervision	PCSITPC	PCS	PCS

6.4.2 Function block

Figure 754: Function block

6.4.3 Functionality

The protection communication supervision function PCSITPC monitors the protection communication channel. PCSITPC blocks the line differential protection functions when interference in the protection communication channel is detected. The blocking takes place automatically for the LNPLDF and BSTGAPC functions which are dependent on the continuous availability of the protection communication channel.

The protection communication channel is continuously monitored by PCSITPC. The function detects missing or delayed protection telegrams. Protection telegrams are used for transferring the sampled analog and other protection related data. Missing or delayed protection telegrams can jeopardize the demand operate speed of the differential protection.

When a short-term interference is detected in the protection communication channel, the function issues a warning and the line differential functions are automatically internally blocked. PCSITPC reacts fast for the protection communication interferences. The blocking takes place at the latest when a communication interruption lasting for two fundamental network periods is detected. When a severe and long lasting interference or total interruption in the protection communication channel is detected, an alarm is issued (after a five-second delay). The protection communication supervision quality status is exchanged continuously online by the local and remote PCSITPC instances. This ensures that both local and remote ends protection blocking is issued coordinately. This further enhances the security of the line differential protection by forcing both line end protection relays to the same blocking state during a protection communication interference, even in cases where the interference is detected with only one line end protection relay. There is also the *Reset delay time* settings parameter available which is used for changing the required interference-free time before releasing the line-differential protection back in operation after a blocking due to an interference in communication.

6.4.4 Operation principle

The operation of protection communication supervision can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

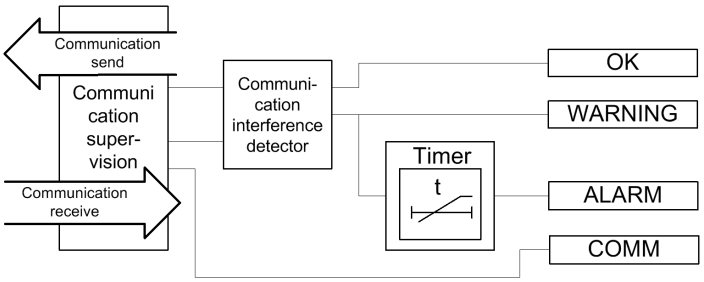

Figure 755: Functional module diagram

Communication supervision

The protection communication is supervised because the differential calculation is dependent on the refreshing of new analog phasor samples from the remote terminal within the protection telegram. The new protection telegram also updates the status of the binary signals sent by the remote terminal. The calculation of the differential current is based on comparing the remote and local terminal measured current samples. It is therefore essential that the protection communication telegrams are supervised and the result of the sample latency calculation can be used further in the differential current calculation. When the communication is able to receive telegrams correctly from the remote end via the communication media, the communication is assumed to be operating correctly and the COMM output is kept active.

Communication interference detector

The communication interference detector continuously measures and observes the sample latency of the protection telegrams. This value is also available as monitored data. The function provides three output signals of which only the corresponding one is active at a time depending on if the protection communication supervision is in OK, WARNING or ALARM. The OK state indicates the correct operation of the protection. The WARNING state indicates that the protection is internally blocked due to detected interference. The WARNING state is switched to ALARM if the interference lasts for a longer period. These output signals are set to the FALSE state until the first telegram is received over the communication link and supervision is started. The protection communication supervision can sometimes be in the WAITING state. This state indicates that the terminal is waiting for the communication to start or restart from the remote end terminal.

Timer

Once activated with the WARNING signal, the timer has a constant time delay value of five seconds. If the communication failure exists after the delay, the ALARM output is activated.

6.4.5 Application

Communication principle

Analog samples, trip-, start- and user programmable signals are transferred in each protection telegram and the exchange of these protection telegrams is done eight times per power system cycle (every 2.5 ms when F_n = 50 Hz).

Master-Master communication arrangement is used in the two-terminal line differential solution. Current samples are sent from both line ends and the protection algorithms are also executed on both line ends. The direct-intertrip, however, ensures that both ends are always operated simultaneously.

Time synchronization

In numerical line differential protection, the current samples from the protections which are located geographically apart from each other must be time coordinated so that the current samples from both ends of the protected line can be compared without introducing irrelevant errors. The time coordination requires an extremely high accuracy.

As an example, an inaccuracy of 0.1 ms in a 50 Hz system gives a maximum amplitude error of approximately around 3 percent. An inaccuracy of 1 ms gives a maximum amplitude error of approximately 31 percent. The corresponding figures for a 60 Hz system are 4 and 38 percent respectively.

In the protection relay, the time coordination is done with an echo method. The protection relays create their own time reference between each other so that the system clocks do not need to synchronize.

The figure shows that in the time synchronization the transmission time to send a message from station B to station A, T1→T2, and the time to receive a message from A to B, T4→T5, are measured. The station A protection relay delay from the sampling to the start of send, T3→T4, and the local delay from receive to the station B protection relay sampling T5→T6 time, are also measured for the station B protection relay, and vice versa. This way the time alignment factor for the local and remote samples is achieved.

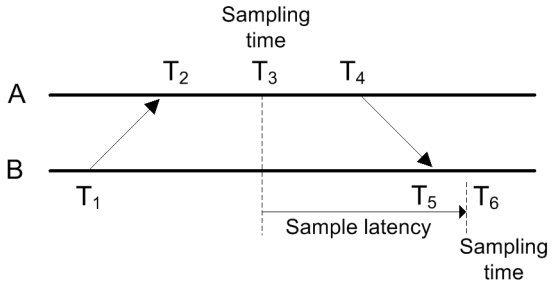

Figure 756: Measuring sampling latency

$$P_d = \frac{(T_2 - T_1) + (T_5 - T_4)}{2}$$

(Equation 317)

$$S_d = P_d + (T_4 - T_3) + (T_6 - T_5)$$

(Equation 318)

The sampling latency S_d is calculated for each telegram on both ends. The algorithm assumes that the one-way propagation delay P_d is equal for both directions.

The echo method without GPS can be used in telecommunication transmission networks as long as delay symmetry exists, that is, the sending and receiving delays are equal.

6.4.6 Signals

6.5 Fuse failure supervision SEQSPVC (ANSI VCM, 60)

6.5.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Fuse failure supervision	SEQSPVC	FUSEF	VCM, 60

6.5.2 Function block

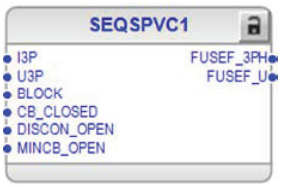

Figure 757: Function block

6.5.3 Functionality

The fuse failure supervision function SEQSPVC is used to block the voltage-measuring functions when failure occurs in the secondary circuits between the voltage transformer (or combi sensor or voltage sensor) and protection relay to avoid misoperations of the voltage protection functions.

SEQSPVC has two algorithms, a negative sequence-based algorithm and a delta current and delta voltage algorithm.

A criterion based on the delta current and the delta voltage measurements can be activated to detect three-phase fuse failures which usually are more associated with the voltage transformer switching during station operations.

6.5.4 Analog channel configuration

SEQSPVC has two analog group inputs which all must be properly configured.

Table 1273: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1274: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

6.5.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of SEQSPVC can be described with a module diagram. All the modules in the diagram are explained in the next sections.

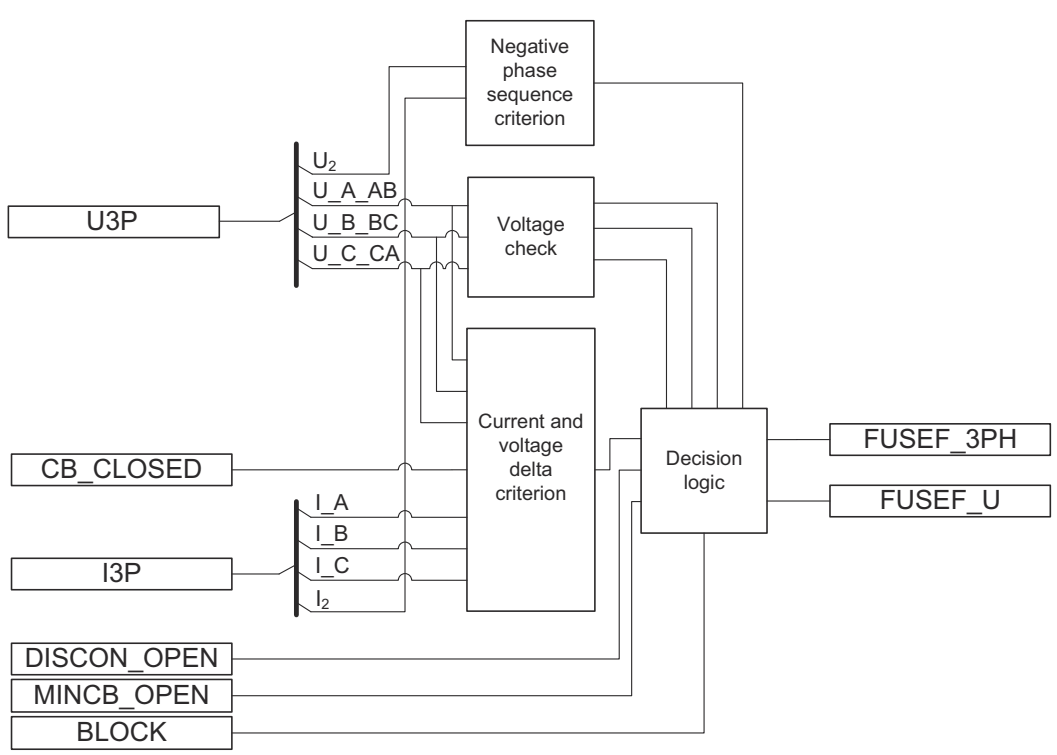

Figure 758: Functional module diagram

Negative phase-sequence criterion

A fuse failure based on the negative-sequence criterion is detected if the measured negative-sequence voltage exceeds the set *Neg Seq voltage Lev* value and the measured negative-sequence current is below the set *Neg Seq current Lev* value. The detected fuse failure is reported to the decision logic module.

Voltage check

The phase voltage magnitude is checked when deciding whether the fuse failure is a three, two or a single-phase fault.

The module makes a phase-specific comparison between each voltage input and the *Seal in voltage* setting. If the input voltage is lower than the setting, the corresponding phase is reported to the decision logic module.

Current and voltage delta criterion

The delta function can be activated by setting the *Change rate enable* parameter to "True". Once the function is activated, it operates in parallel with the negative sequence-based algorithm. The current and voltage are continuously measured in all three phases to calculate:

- Change of voltage dU/dt
- Change of current dI/dt

The calculated delta quantities are compared to the respective set values of the *Current change rate* and *Voltage change rate* settings.

The delta current and delta voltage algorithms detect a fuse failure if there is a sufficient negative change in the voltage amplitude without a sufficient change in

the current amplitude in each phase separately. This is performed when the circuit breaker is closed. Information about the circuit breaker position is connected to the CB_CLOSED input.

There are two conditions for activating the current and voltage delta function.

- The magnitude of dU/dt exceeds the corresponding value of the *Voltage change rate* setting and magnitude of dI/dt is below the value of the *Current change rate* setting in any phase at the same time due to the closure of the circuit breaker (CB_CLOSED = TRUE).
- The magnitude of dU/dt exceeds the value of the *Voltage change rate* setting and the magnitude of dI/dt is below the *Current change rate* setting in any phase at the same time and the magnitude of the phase current in the same phase exceeds the *Min Op current delta* setting.

The first condition requires the delta criterion to be fulfilled in any phase at the same time as the circuit breaker is closed. Opening the circuit breaker at one end and energizing the line from the other end onto a fault could lead to an improper operation of SEQSPVC with an open breaker. If this is considered to be an important disadvantage, the CB_CLOSED input is to be connected to FALSE. In this way only the second criterion can activate the delta function.

The second condition requires the delta criterion to be fulfilled in one phase together with a high current for the same phase. The measured phase current is used to reduce the risk of a false fuse failure detection. If the current on the protected line is low, a voltage drop in the system (not caused by the fuse failure) is not followed by a current change and a false fuse failure can occur. To prevent this, the minimum phase current criterion is checked.

The fuse failure detection is active until the voltages return above the *Min Op voltage delta* setting. If a voltage in a phase is below the *Min Op voltage delta* setting, a new fuse failure detection for that phase is not possible until the voltage returns above the setting value.

Decision logic

If voltages are Wye-connected, it is recommended to scale the default values of voltage-based settings with 1/sqrt(3) because the default setting values apply for Delta-connected settings.

The fuse failure detection outputs FUSEF_U and FUSEF_3PH are controlled according to the detection criteria or external signals.

Table 1275: Fuse failure output control

Fuse failure detection criterion	Conditions and function response
Negative-sequence criterion	If a fuse failure is detected based on the negative sequence criterion, the FUSEF_U output is activated.
	If the fuse failure detection is active for more than five seconds and at the same time all the phase voltage values are below the set value of the *Seal in voltage* setting with *Enable seal in* turned to "True", the function activates the FUSE_3PH output signal.

Table continues on the next page

Fuse failure detection criterion	Conditions and function response
	The FUSEF_U output signal is also activated if all the phase voltages are above the *Seal in voltage* setting for more than 60 seconds and at the same time the negative sequence voltage is above *Neg Seq voltage Lev* for more than 5 seconds, all the phase currents are below the *Current dead Lin Val* setting and the circuit breaker is closed, that is, CB_CLOSED is TRUE.
Current and voltage delta function criterion	If the current and voltage delta criterion detects a fuse failure condition, but all the voltages are not below the *Seal in voltage* setting, only the FUSEF_U output is activated.
	If the fuse failure detection is active for more than five seconds and at the same time all the phase voltage values are below the set value of the *Seal in voltage* setting with *Enable seal in* turned to "True", the function activates the FUSE_3PH output signal.
External fuse failure detection	The MINCB_OPEN input signal is supposed to be connected through a protection relay binary input to the N.C. auxiliary contact of the miniature circuit breaker protecting the VT secondary circuit. The MINCB_OPEN signal sets the FUSEF_U output signal to block all the voltage-related functions when MCB is in the open state.
	The DISCON_OPEN input signal is supposed to be connected through a protection relay binary input to the N.C. auxiliary contact of the line disconnector. The DISCON_OPEN signal sets the FUSEF_U output signal to block the voltage-related functions when the line disconnector is in the open state.

It is recommended to always set *Enable seal in* to "True". This secures that the blocked protection functions remain blocked until normal voltage conditions are restored if the fuse failure has been active for 5 seconds, that is, the fuse failure outputs are deactivated when the normal voltage conditions are restored.

The activation of the BLOCK input deactivates both FUSEF_U and FUSEF_3PH outputs.

6.5.6 Application

Some protection functions operate on the basis of the measured voltage value in the protection relay point. These functions can fail if there is a fault in the measuring circuits between the voltage transformer (or combi sensor or voltage sensor) and protection relay.

A fault in the voltage-measuring circuit is called a fuse failure. This term is misleading since a blown fuse is just one of the many possible reasons for a broken circuit. Since incorrectly measured voltage can result in a faulty operation of some of the protection functions, it is important to detect the fuse failures. A fast fuse failure detection is one of the means to block voltage-based functions before they operate.

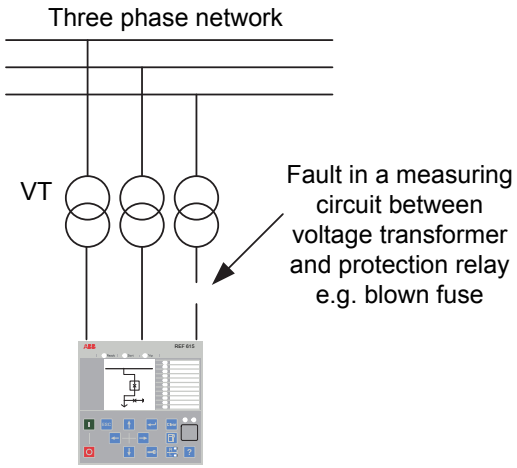

Figure 759: Fault in a circuit from the voltage transformer to the protection relay

A fuse failure occurs due to blown fuses, broken wires or intended substation operations. The negative sequence component-based function can be used to detect different types of single-phase or two-phase fuse failures. However, at least one of the three circuits from the voltage transformers must be intact. The supporting delta-based function can also detect a fuse failure due to three-phase interruptions.

In the negative sequence component-based part of the function, a fuse failure is detected by comparing the calculated value of the negative sequence component voltage to the negative sequence component current. The sequence entities are calculated from the measured current and voltage data for all three phases. The purpose of this function is to block voltage-dependent functions when a fuse failure is detected. Since the voltage dependence differs between these functions, SEQSPVC has two outputs for this purpose.

6.6 Runtime counter for machines and devices MDSOPT (ANSI OPTM)

6.6.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Runtime counter for machines and devices	MDSOPT	OPTS	OPTM

6.6.2 Function block

Figure 760: Function block

6.6.3 Functionality

The runtime counter for machines and devices function MDSOPT calculates and presents the accumulated operation time of a machine or device as the output. The unit of time for accumulation is hour. The function generates a warning and an alarm when the accumulated operation time exceeds the set limits. It utilizes a binary input to indicate the active operation condition.

The accumulated operation time is one of the parameters for scheduling a service on the equipment like motors. It indicates the use of the machine and hence the mechanical wear and tear. Generally, the equipment manufacturers provide a maintenance schedule based on the number of hours of service.

6.6.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of MDSOPT can be described using a module diagram. All the modules in the diagram are explained in the next sections.

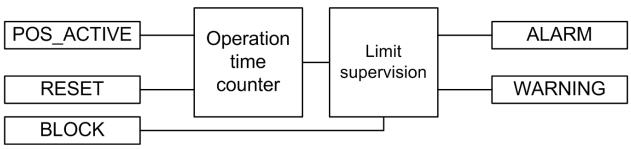

Figure 761: Functional module diagram

Operation time counter

This module counts the operation time. When POS_ACTIVE is active, the count is continuously added to the time duration until it is deactivated. At any time the OPR_TIME output is the total duration for which POS_ACTIVE is active. The unit of time duration count for OPR_TIME is hour. The value is available through the Monitored data view.

The OPR_TIME output is a continuously increasing value and it is stored in a non-volatile memory. When POS_ACTIVE is active, the OPR_TIME count starts increasing from the previous value. The count of OPR_TIME saturates at the final value of 299999, that is, no further increment is possible. The activation of RESET can reset the count to the *Initial value* setting.

Limit supervision

This module compares the motor run-time count to the set values of *Warning value* and *Alarm value* to generate the WARNING and ALARM outputs respectively when the counts exceed the levels.

The activation of the WARNING and ALARM outputs depends on the *Operating time mode* setting. Both WARNING and ALARM occur immediately after the conditions are met if *Operating time mode* is set to “Immediate”. If *Operating time mode* is set to “Timed Warn”, WARNING is activated within the next 24 hours at the time of the day set using the *Operating time hour* setting. If *Operating time mode* is set to “Timed Warn Alm”, the WARNING and ALARM outputs are activated at the time of day set using *Operating time hour*.

The *Operating time hour* setting is used to set the hour of day in Coordinated Universal Time (UTC). The setting has to be adjusted according to the local time and local daylight-saving time.

The function contains a blocking functionality. Activation of the BLOCK input blocks both WARNING and ALARM.

6.6.5 Application

The machine operating time since commissioning indicates the use of the machine. For example, the mechanical wear and lubrication requirement for the shaft bearing of the motors depend on the use hours.

If some motor is used for long duration runs, it might require frequent servicing, while for a motor that is not used regularly the maintenance and service are scheduled less frequently. The accumulated operating time of a motor together with the appropriate settings for warning can be utilized to trigger the condition based maintenance of the motor.

The operating time counter combined with the subsequent reset of the operating-time count can be used to monitor the motor's run time for a single run.

Both the long term accumulated operating time and the short term single run duration provide valuable information about the condition of the machine and device. The information can be co-related to other process data to provide diagnoses for the process where the machine or device is applied.

6.7 Motor start counter MSCPMRI (ANSI 66)

6.7.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Motor start counter	MSCPMRI	n<	66

6.7.2 Function block

Figure 762: Function block

[1] Of the reading, for a stand-alone relay, without time synchronization

6.7.3 Functionality

The motor start counter function MSCPMRI counts the number of motor starts and distinguishes between cold and warm starts. The allowed number is generally provided by the motor manufacturer. The motor starting MOT_START output of the motor start-up supervision function is used to count the starts. The motor thermal level TEMP_RL calculated by the thermal overload protection is used to distinguish between a cold and warm start.

The function contains a blocking functionality. It is possible to block the function outputs or the function itself.

6.7.4 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of MSCPMRI can be described with a module diagram. All the modules in the diagram are explained in the next sections.

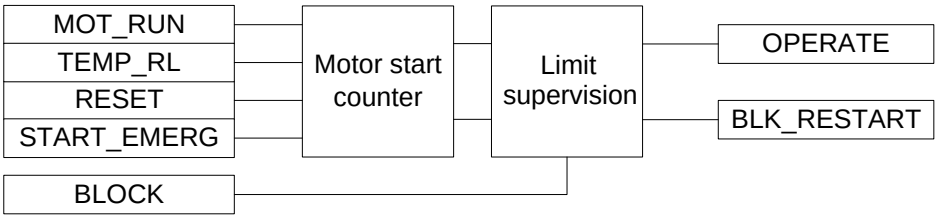

Figure 763: Functional module diagram

Motor start counter

This module counts the number of motor starts. The value of the cold count COLD_COUNT and warm count WARM_COUNT is available in the Monitored data view. On the rising edge of MOT_RUN, the module increments the cold start counter. If the thermal content available at the TEMP_RL input is above the set *Warm start level* when the rising edge of the MOT_RUN input is received, both cold and warm start counter values are incremented.

If *Operation* of the thermal overload protection for motors function MPTTR is set as "Off", the TEMP_RL value is not available. In this case, the warm start counter does not increase.

The counter decrease timer also starts at the first increment of the cold start counter (that is the first time when the counter increases from zero). When *Cnt decrease time* elapses, both cold and warm start counters decrease by one and the counter decrease timer restarts. This is repeated until both cold and warm counters are zero.

When the motor is not in operation, that is, the motor is in stop condition, it takes more time to cool. During such condition *Cnt decrease time* is multiplied by a *Cnt Dec timer Mult* setting.

The motor start detection is available at the MOT_START output of the motor start-up supervision function STTPMSU. The MOT_START output of STTPMSU must be connected to the MOT_RUN input of this function in Application Configuration

in PCM600. Similarly, the TEMP_RL output of MPTTR must be connected to the TEMP_RL input of this function in Application Configuration in PCM600.

When the emergency start signal START_EMERG is set high and if the value of the cold or warm counter is above its start value setting, the value of the counter is set one count less than the respective maximum number of start value setting. This disables BLK_RESTART and OPERATE which makes the restart of motor possible.

The values can be reset by activating the RESET binary input. The activation of the RESET input also resets the counter decrease timer. The counter value can also be reset on the Clear menu.

Limit supervision

This module compares the motor cold and warm count to the set *Max Num cold start* and *Max Num warm start*, respectively. The BLK_RESTART output is activated when either the cold or the warm start counter reaches the set *Max Num cold start* or *Max Num warm start*, respectively. The OPERATE output is activated when either the cold or the warm start counter exceeds the set *Max Num cold start* or *Max Num warm start*, respectively.

When the BLK_RESTART output is active, T_RST_ENA shows the possible time for the next restart. The value of T_RST_ENA is calculated as the time left for both counters to decrease below their maximum number of starts.

Activation of the BLOCK input blocks both OPERATE and BLK_RESTART outputs.

6.7.5 Application

Repeated motor starts increase the temperature to a high value in the stator or rotor windings, or both, unless enough time is allowed for the heat to dissipate. To ensure a safe operation, it is necessary to provide a fixed-time interval between starts or limit the number of starts within a period of time. This is why the motor manufacturers have restrictions on how many starts are allowed in a defined time interval.

This function counts the number of cold and warm starts and provides a block restart signal when the number of starts reaches the permitted limit. The customer can use this signal for blocking a new start operation. An operate signal is also available which can be used to disconnect the motor when the number of starts exceeds the limit.

6.7.6 Signals

6.7.6.1 MSCPMRI Input signals

6.8 Three-phase remanent undervoltage supervision MSVPR (ANSI 27R)

6.8.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Three-phase remanent undervoltage supervision	MSVPR	3U<R	27R

6.8.2 Function block

Figure 764: Function block

6.8.3 Functionality

The three-phase remanent undervoltage supervision function MSVPR is used to supervise the remanent voltage of the motor. The rotor with high inertia load may

continue to rotate after the primary supply voltage is switched off. Re-energizing the motor immediately can result in catastrophic failure.

MSVPR gives permissive output when the remanent voltage of the motor reaches a safe level to re-energize. Supervision can be selected for one-phase or for three-phase operation. MSVPR can also adapt to a frequency range of 10...70 Hz.

The function contains a blocking functionality. It is possible to block the function output, timer or the function itself.

6.8.4 Analog channel configuration

MSVPR has one analog group input which must be properly configured.

Table 1294: Analog inputs

Input	Description
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1295: Special conditions

Condition	Description
U3P connected to real measurements	The function can work with one voltage channel connected when *Phase supervision* is set to "A or AB", "B or BC" or "C or CA".
	The function requires that all three voltage channels are connected if *Phase supervision* is set to "A&B&C or AB&BC&CA".

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

6.8.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of MSVPR can be described with a module diagram. All the modules in the diagram are explained in the next sections.

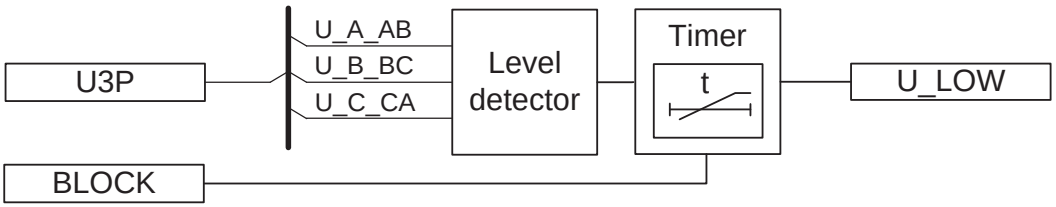

Figure 765: Functional module diagram

Level detector

The *Voltage selection* setting is used for selecting the phase-to-earth or phase-tophase voltages for supervision.

The voltage measurement can adapt the frequency to a range of 10...70 Hz.

Level detector supports one- or three-phase operation. Selection can be made with setting *Phase supervision*.

Table 1296: Functionality depending on Phase supervision

Value of *Phase supervision*	Functionality
1 = A or AB 2 = B or BC 4 = C or CA	This selection implements single-phase voltage supervision on the selected phase. If the measured voltage of the supervised phase is lower than the set value of the *Start value* setting, Level detector enables the Timer module.
7 = A&B&C or AB&BC&CA	This selection implements three-phase voltage supervision. The measured voltage of three supervised phases is compared against the *Start value* setting. If the number of phases where the voltage is below the setting matches the Num of phases setting, Level detector enables the Timer module.

Timer

Once activated, Timer runs until the value of *Operate delay time* has elapsed. The time characteristic is according to DT. When the operation timer has reached the value of *Operate delay time*, the U_LOW output is activated.

In a drop-off case, the remanent voltage returns to a value higher than the set value of *Start value* before *Operate delay time* is exceeded. Also, the timer reset state is activated. The reset timer runs until the *Reset delay time* value is exceeded. If the duration of the voltage drop-off exceeds the set Reset delay time, the operate timer is reset and the U_LOW output is deactivated.

The BLOCK input can be controlled with a binary input, a horizontal communication input or an internal signal of the relay program. The activation of the BLOCK input resets Timer and prevents the U_LOW output from being activated.

6.8.6 Application

Systems with critical motor applications provide a backup power source that can be switched in when the primary power source becomes faulty. When the power to a motor is suddenly lost, the motor terminal voltage does not immediately fall to zero because the rotating motor now acts as a generator producing its own voltage. Remanent voltage decays as the motor comes to a stop at a rate depending on the motor and load. Connecting the backup power source while the remanent voltage is at a high level can result in damage to the motor shaft and windings.

MSVPR is used to monitor the motor remanent voltage over a decaying frequency after power supply is lost, before allowing connection of backup power. It provides a permissive signal indicating when the backup power can be safely connected.

This application example describes the re-energization process. MSVPR is used to supervise the Bus1 remanent voltage. Control logic is used to detect the loss of primary power source and initiate the transfer to backup power. Normally, bus tie breaker CB5 is open and motor voltage power is supplied by incoming Feeder1 (see *Figure 766*).

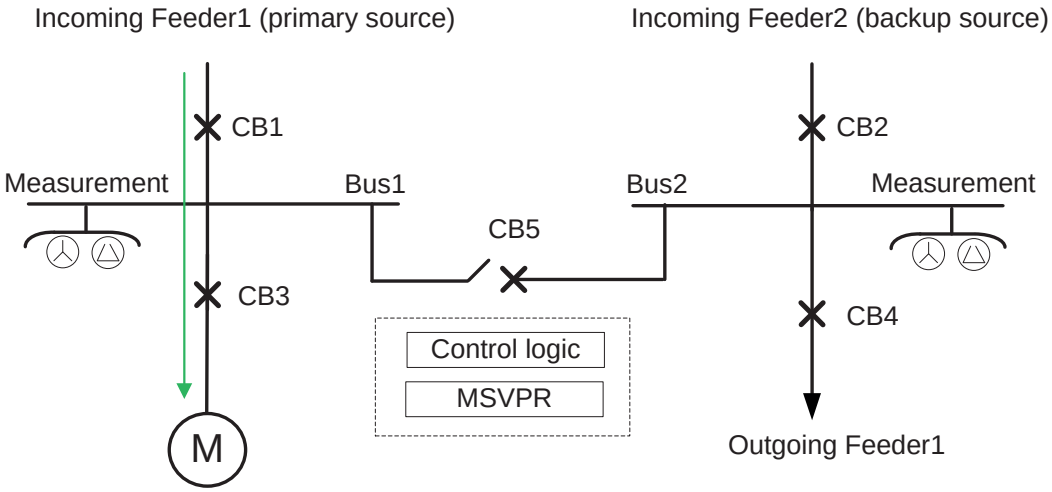

Figure 766: Example of remanent voltage supervision before fault

CB1 is tripped when a fault occurs on incoming Feeder1. MSVPR gives permission to control logic when the remanent voltage of the motor reaches a safe level on Bus1. Control logic closes the tie breaker CB5 if closing conditions are met. Finally, the motor is re-energized by incoming Feeder2 (see *Figure 767*).

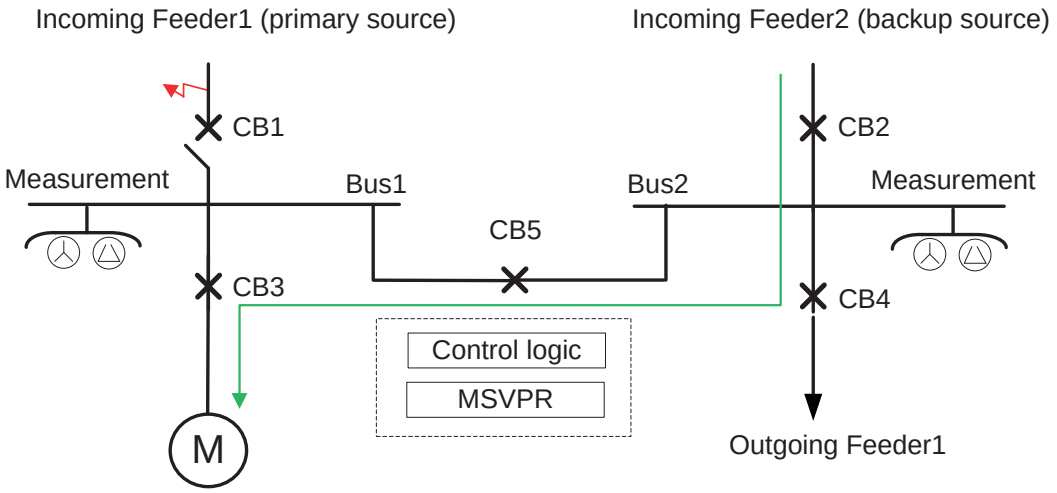

Figure 767: Example of remanent voltage supervision after fault

MSVPR runs in the range of 10...70 Hz. If the frequency is lower than 10 Hz, the motor terminal voltage is very low. The remanent voltage setting is typically set to 20...30 percent of the rated voltage.

Operation accuracy	Depending on the frequency of the measured voltage:
	20 Hz < f ≤ 70 Hz: ±1.5 % of the set value or ±0.002 × U_n
	10 Hz < f ≤ 20 Hz: ±4.0 % of the set value or ±0.002 × U_n
Reset time	Typically 40 ms
Reset ratio	Typically 1.04
Operate time accuracy in definite time mode	±1.0 % of the set value or ±20 ms

6.9 Current circuit supervision for transformers CTSRCTF (ANSI CCM 3I,I2)

6.9.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Current circuit supervision for transformers	CTSRCTF	MCS 3I,I2	CCM 3I,I2

6.9.2 Function block

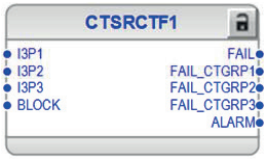

Figure 768: Function block

6.9.3 Functionality

The current circuit supervision for transformers function CTSRCTF is used for monitoring the current transformer secondary circuit where a separate reference current transformer input for comparison is not available or where a separate voltage channel for calculating or measuring the zero-sequence voltage is not available. CTSRCTF can be used for detecting the single-phase failure on the current transformer secondary for protection application involving two or three sets of the three-phase current transformers.

CTSRCTF detects a fault in the measurement circuit and issues an alarm which can be used for blocking the protection functions, for example, differential protection, to avoid unwanted tripping.

CTSRCTF is internally blocked in case of a transformer under no-load condition or if a current in any one phase exceeds the set maximum limit.

6.9.4 Analog channel configuration

CTSRCTF has three analog group inputs which must be properly configured.

Table 1303: Analog inputs

Input	Description
I3P1	Three-phase currents
I3P2	Three-phase currents
I3P3	Three-phase currents, can be connected to GRPOFF

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

6.9.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

The operation of CTSRCTF can be described with a module diagram. All the modules in the diagram are explained in the next sections.

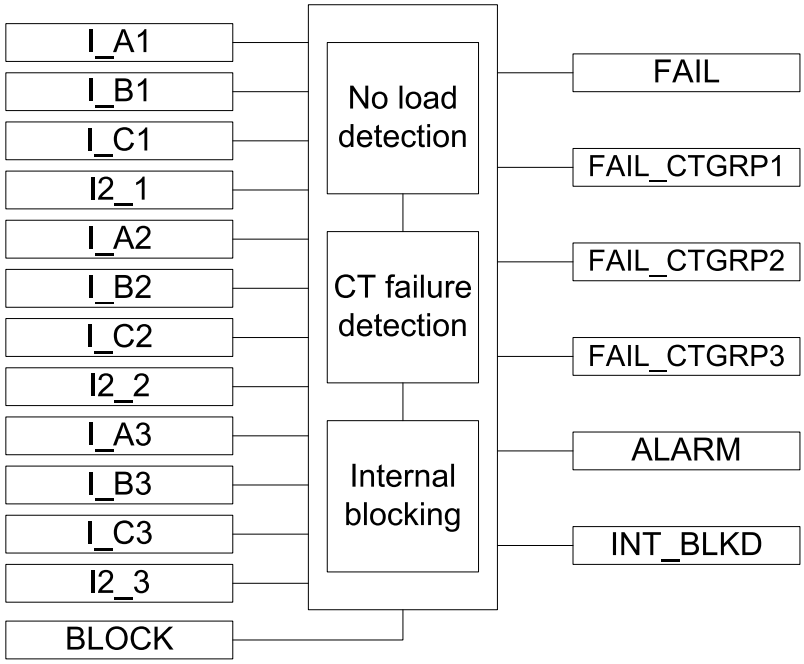

Figure 769: Functional module diagram

No-load detection

No-load detection module detects the loading condition. If all the three-phase currents of any two sets of current transformer are zero, the protected equipment is considered to be in the no-load condition and the function is internally blocked by activating the `INT_BLKD` output.

To avoid any false operation, the function is also internally blocked if any two-phase currents of any set of current transformers are below *Min operate current*. This activates `INT_BLKD`. The value of the Min operate current setting depends on the type of equipment to be protected. For example, in case of transformer protection, *Min operate current* depends on the no-load current rating. Typically, it can be set equal to the transformer no-load current rating.

CT failure detection

This module detects the CT secondary failure in any sets of current transformers. The module continuously scans the value of all the three-phase currents in all groups of current transformers to detect any sudden drop in the current value to zero. The detection of a zero current should not be the only criterion for considering a fault in the current transformer secondary. Two other criteria are evaluated to confirm the CT failure:

- A zero current due to the CT failure does not result in a negative-sequence current on healthy CT sets.

  On the detection of a zero current in any phase on either group of CT, the negative-sequence current I_2 is further evaluated. For a genuine CT secondary failure, the magnitude of I_2 changes only on the side where zero current has been detected. The change in the magnitude of I_2 (ΔI_2) on the other sets of the current transformer (other than where zero current is detected) is calculated. If

the change is detected on the healthy sets of CT, it is an indication of system failure.

- A zero current due to the CT failure does not result in a phase angle difference between the healthy phases.

  If a system faults happens on the phase A, it results in a change in the phase angle difference between phase B and phase C. This change in the phase angle difference between the healthy phases is evaluated in all three sets of current transformer, and if the change is detected in any set of CT, it is an indication of the system failure.

If both conditions are satisfied at zero current, the FAIL output is activated immediately. The ALARM output is activated after a fixed 200 ms delay. FAIL needs to be active during the delay. The outputs FAIL, CTGRP1, FAIL_CTGRP2 and FAIL_CTGRP3 are activated according to the CT group where the secondary failure is detected.

Activation of the BLOCK input deactivates the FAIL and ALARM outputs.

It is not possible to detect the CT secondary failure happening simultaneously with the system faults or failures or two simultaneous failures in the secondary circuit. The function resets if the zero current does not exist longer than 200 ms.

Internal blocking

This module blocks the function internally under specific condition to avoid any false operation during a system fault situation. When any of the following condition is satisfied, the function is internally blocked and the FAIL output is deactivated immediately.

- Magnitude of any phase current for any group of current transformers exceeds the *Max operate current* setting. The magnitude of phase current is calculated from the peak-to-peak value.
- Magnitude of the negative-sequence current I_2 on the healthy set of current transformer exceeds the *Max Nq Seq current* setting.

The INT_BLKD output is activated when FAIL is deactivated if any of the above conditions is satisfied. The ALARM output is also deactivated after a fixed three-second delay after the FAIL output is deactivated.

6.9.6 Application

Open or short-circuited current transformer secondary can cause unwanted operation in many protection functions, such as earth-fault current and differential. The simplest method for detecting the current transformer secondary failure is by comparing currents from two independent three-phase sets of CTs or the CT cores measuring the same primary currents. Another widely used method is the detection of a zero-sequence current and zero-sequence voltage. The detection of a zero-sequence current in the absence of a zero-sequence voltage is an indication of the current transformer secondary failure. However, both methods have disadvantages as they require an additional set of current transformer, or a voltage channel is needed for detecting a zero-sequence voltage.

The methods may not be applicable where additional current channels or voltage channels are not available. This CT secondary circuit supervision presents an algorithm that can be used as an example for detecting the CT secondary failure

used for the unit protection of a two-winding or three-winding transformer. However, the function has a limitation that it cannot detect failure in case of equipment under protection in no-load condition or when two simultaneous secondary CT failures occur.

The detection of a zero current in any one phase is a partial indication of failure in the current transformer secondary. Furthermore, if this current zero is due to the failure in the current transformer secondary, it results in a change in the magnitude of the negative-sequence current in the group only where current zero has been detected. However, changes in the negative-sequence current in other groups of three-phase current transformers at the instance of zero-current detection is an indication of a system problem. Also, it may happen that after the detection of a failure in the current transformer secondary, a fault may occur in the system. During such condition, functions are internally blocked.

Phase discontinuity

A zero current detected due to the phase discontinuity results in an asymmetry in all the sets of the current transformer, which then results in a change in the negative-sequence current (ΔI_2) in the healthy set. This change in the negative-sequence current on the healthy sides, that is, other than where a zero current has been detected, blocks the function.

In case of a lightly loaded transformer (up to 30 %) the change in the negative-sequence current may be very negligible. However, a phase discontinuity results in a change in the phase angle difference between two healthy phases in the set of CTs where a zero current has been detected as well as on the primary side of the transformer. This change in the value of the angle blocks the function internally.

Overload / System short circuit condition

It is required that any overload or short circuit conditions after a CT failure should block the function. During overload or short circuit condition, the phase current increases beyond its rated value; if any phase current on any set of current transformer exceeds the set limit, the function is blocked internally. Also in case of an unsymmetrical fault, the negative-sequence current increases. If the negative-sequence current increases beyond the set limit, the function is blocked internally. The overcurrent and negative-sequence current setting both can be set equal to the overcurrent and negative-sequence protection function start value.

The internal blocking is thus useful for avoiding false operation during a fault situation.

6.9.7 Signals

6.9.7.1 CTSRCTF Input signals

Table 1304: CTSRCTF Input signals

Name	Type	Default	Description
I3P1	SIGNAL	-	Three-phase currents 1
I3P2	SIGNAL	-	Three-phase currents 2
I3P3	SIGNAL	-	Three-phase currents 3

7.1.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Circuit-breaker condition monitoring	SSCBR	CBCM	52CM

7.1.2 Function block

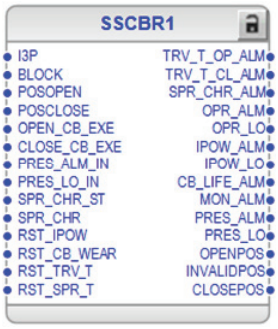

Figure 770: Function block

7.1.3 Functionality

The circuit-breaker condition monitoring function SSCBR is used to monitor different parameters of the circuit breaker. The breaker requires maintenance when the number of operations has reached a predefined value. The energy is calculated from the measured input currents as a sum of $I^{y}t$ values. Alarms are generated when the calculated values exceed the threshold settings.

The function contains a blocking functionality which can be used to block the function outputs.

7.1.4 Analog input configuration

SSCBR has one analog group input which must be properly configured.

Table 1309: Analog inputs

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

7.1.5 Operation principle

The circuit breaker condition monitoring function includes different metering and monitoring sub-functions. The functions can be enabled and disabled with the *Operation* setting. The corresponding parameter values are “On” and “Off”. The operation counters are cleared when *Operation* is set to “Off”.

The operation of SSCBR can be described with a module diagram. All the modules in the diagram are explained in the next sections.

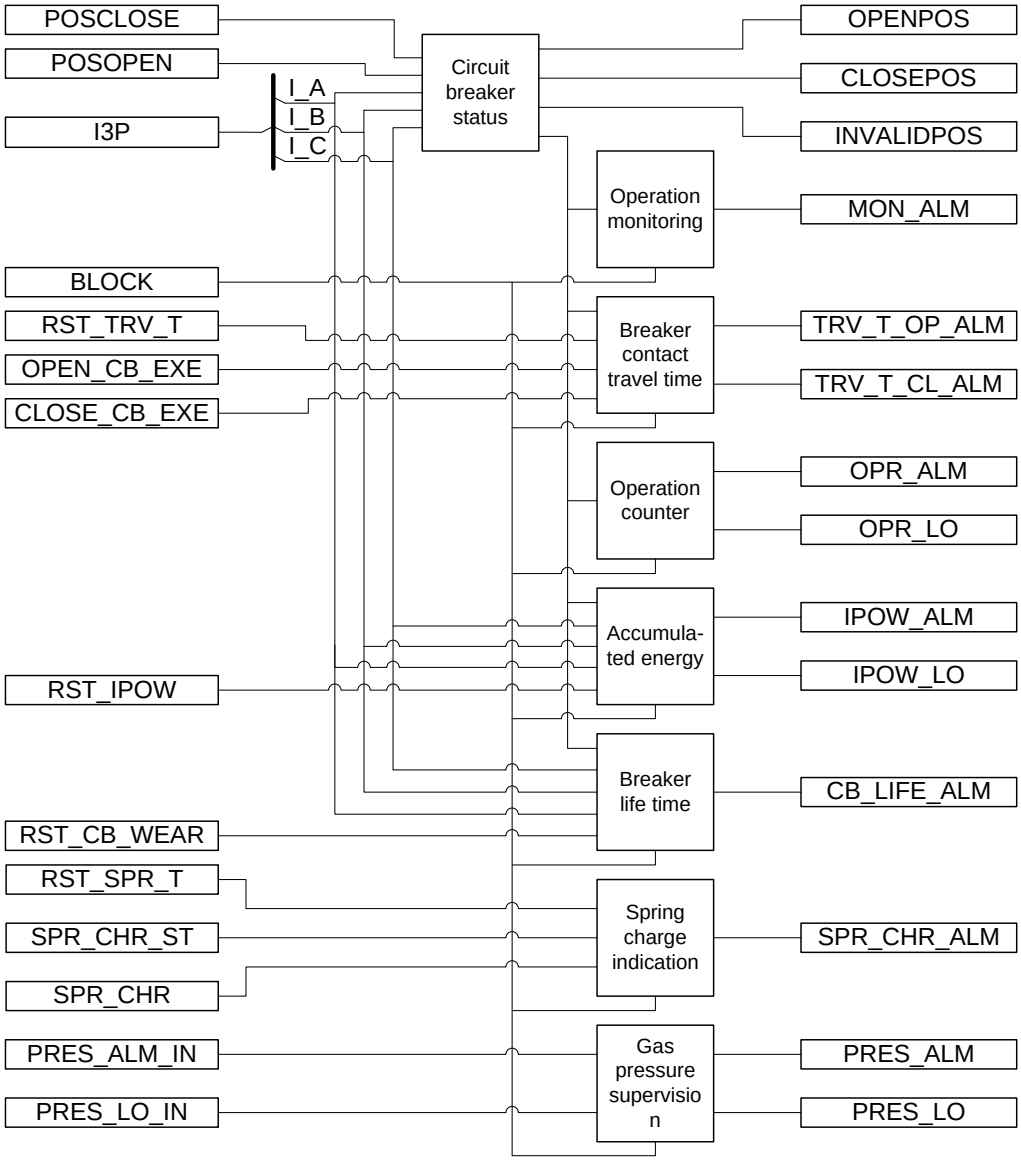

Figure 771: Functional module diagram

7.1.5.1 Circuit breaker status

The Circuit breaker status sub-function monitors the position of the circuit breaker, that is, whether the breaker is in open, closed or invalid position. The operation of the breaker status monitoring can be described by using a module diagram. All the modules in the diagram are explained in the next sections.

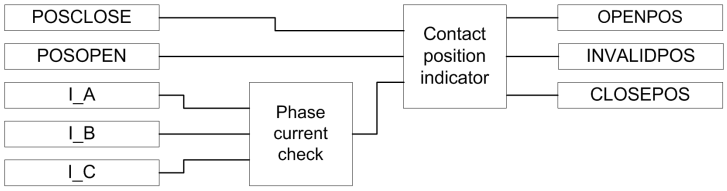

Figure 772: Functional module diagram for monitoring circuit breaker status

Phase current check

This module compares the three phase currents to the setting *Acc stop current*. If the current in a phase exceeds the set level, information about the phase is reported to the contact position indicator module.

Contact position indicator

The OPENPOS output is activated when the auxiliary input contact POSCLOSE is FALSE, the POSOPEN input is TRUE and all the phase currents are below the setting *Acc stop current*.

The CLOSEPOS output is activated when the auxiliary POSOPEN input is FALSE and the POSCLOSE input is TRUE.

The INVALIDPOS output is activated when both the auxiliary contacts have the same value, that is, both are in the same logical level, or if the auxiliary input contact POSCLOSE is FALSE and the POSOPEN input is TRUE and any of the phase currents exceed the setting Acc stop current.

The status of the breaker is indicated by the binary outputs OPENPOS, INVALIDPOS and CLOSEPOS for open, invalid and closed position respectively.

7.1.5.2 Circuit breaker operation monitoring

The purpose of the circuit breaker operation monitoring subfunction is to indicate if the circuit breaker has not been operated for a long time.

The operation of the circuit breaker operation monitoring can be described with a module diagram. All the modules in the diagram are explained in the next sections.

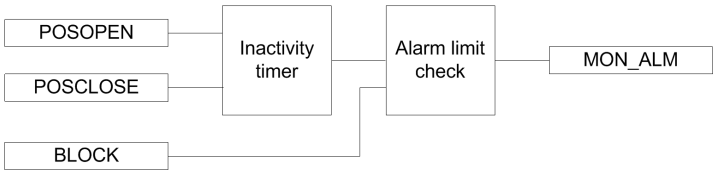

Figure 773: Functional module diagram for calculating inactive days and alarm for circuit breaker operation monitoring

Inactivity timer

The module calculates the number of days the circuit breaker has remained inactive, that is, has stayed in the same open or closed state. The calculation is done by monitoring the states of the POSOPEN and POSCLOSE auxiliary contacts.

The inactive days INA_DAYS is available in the monitored data view. It is also possible to set the initial inactive days with the *Ini inactive days* parameter.

Alarm limit check

When the inactive days exceed the limit value defined with the *Inactive Alm days* setting, the MON_ALM alarm is initiated. The time in hours at which this alarm is activated can be set with the *Inactive Alm hours* parameter as coordinates of UTC. The alarm signal MON_ALM can be blocked by activating the binary input BLOCK.

7.1.5.3 Breaker contact travel time

The Breaker contact travel time module calculates the breaker contact travel time for the closing and opening operation. The operation of the breaker contact travel time measurement can be described with a module diagram. All the modules in the diagram are explained in the next sections.

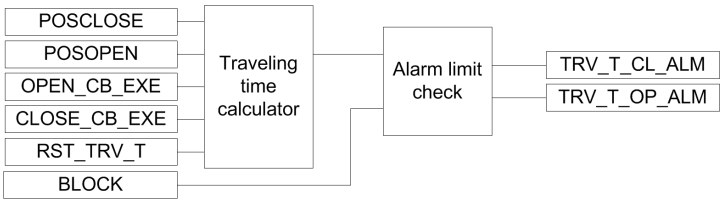

Figure 774: Functional module diagram for breaker contact travel time

Traveling time calculator

The travel time can be calculated using two different methods based on the setting *Travel time Clc mode*.

When the setting *Travel time Clc mode* is “From Pos to Pos”, the contact travel time of the breaker is calculated from the time between auxiliary contacts' state change. The opening travel time is measured between the opening of the POSCLOSE auxiliary contact and the closing of the POSOPEN auxiliary contact. The travel time is also measured between the opening of the POSOPEN auxiliary contact and the closing of the POSCLOSE auxiliary contact.

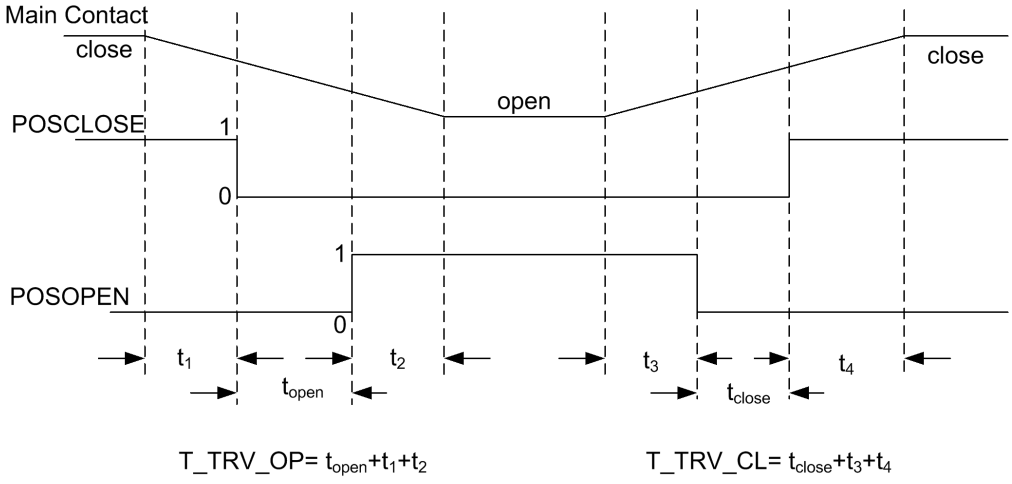

Figure 775: Travel time calculation when Travel time Clc mode is “From Pos to Pos”

There is a time difference t_1 between the start of the main contact opening and the opening of the POSCLOSE auxiliary contact. Similarly, there is a time gap t_2

between the time when the POSOPEN auxiliary contact opens and the main contact is completely open. To incorporate the time $t_1 + t_2$, a correction factor needs to be added with t_{open} to get the actual opening time. This factor is added with the *Opening time Cor* (= $t_1 + t_2$) setting. The closing time is calculated by adding the value set with the *Closing time Cor* ($t_3 + t_4$) setting to the measured closing time.

When the setting *Travel time Clc mode* is “From Cmd to Pos”, the contact travel time of the breaker is calculated from the time between the circuit breaker opening or closing command and the auxiliary contacts’ state change. The opening travel time is measured between the rising edge of the OPEN_CB_EXE command and the POSOPEN auxiliary contact. The closing travel time is measured between the rising edge of the CLOSE_CB_EXEC command and the POSCLOSE auxiliary contact.

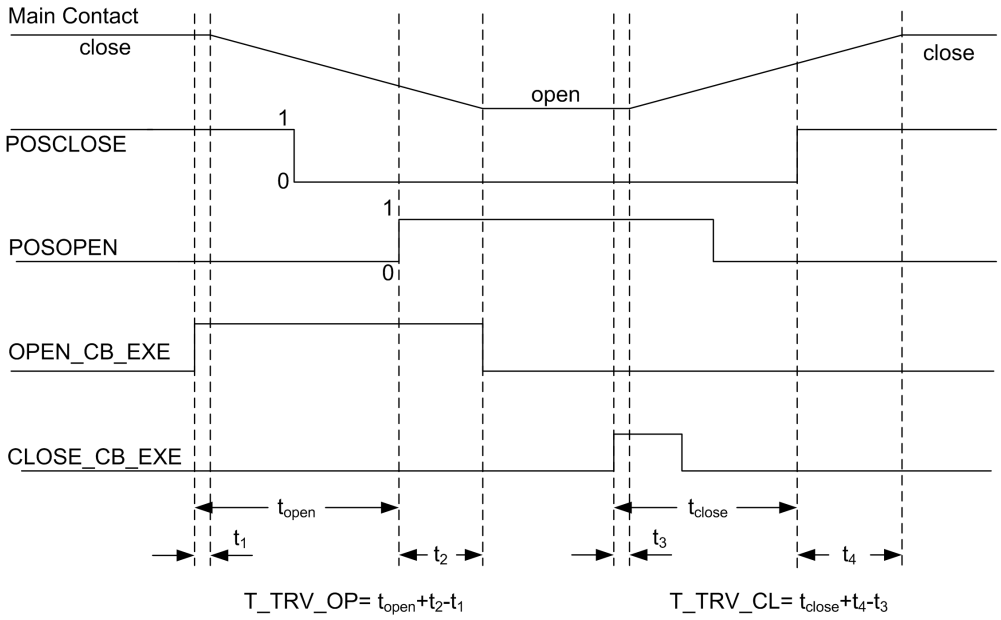

Figure 776: Travel time calculation when Travel time Clc mode is “From Cmd to Pos”

There is a time difference t_1 between the start of the main contact opening and the OPEN_CB_EXE command. Similarly, there is a time gap t_2 between the time when the POSOPEN auxiliary contact opens and the main contact is completely open. Therefore, to incorporate the times t_1 and t_2, a correction factor needs to be added with t_{open} to get the actual opening time. This factor is added with the *Opening time Cor* (= $t_2 - t_1$) setting. The closing time is calculated by adding the value set with the *Closing time Cor*($t_4 - t_3$) setting to the measured closing time.

The last measured opening travel time T_TRV_OP and the closing travel time T_TRV_CL are available in the monitored data view on the LHMI or through tools via communications.

Alarm limit check

When the measured opening travel time is longer than the value set with the *Open alarm time* setting, the TRV_T_OP_ALM output is activated. Respectively, when the measured closing travel time is longer than the value set with the *Close alarm time* setting, the TRV_T_CL_ALM output is activated.

It is also possible to block the TRV_T_CL_ALM and TRV_T_OP_ALM alarm signals by activating the BLOCK input.

7.1.5.4 Operation counter

The operation counter subfunction calculates the number of breaker operation cycles. The opening and closing operations are both included in one operation cycle. The operation counter value is updated after each opening operation.

The operation of the subfunction can be described with a module diagram. All the modules in the diagram are explained in the next sections.

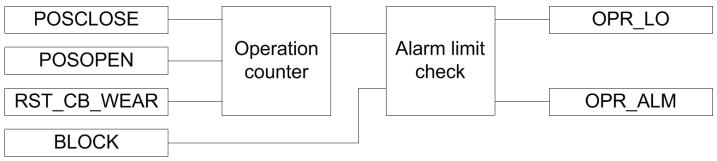

Figure 777: Functional module diagram for counting circuit breaker operations

Operation counter

The operation counter counts the number of operations based on the state change of the binary auxiliary contacts inputs POSCLOSE and POSOPEN.

The number of operations NO_OPR is available in the monitored data view on the LHMI or through tools via communications. The old circuit breaker operation counter value can be taken into use by writing the value to the *Counter initial Val* parameter and by setting the parameter *CB wear values* in the clear menu from WHMI or LHMI.

Alarm limit check

The OPR_ALM operation alarm is generated when the number of operations exceeds the value set with the *Alarm Op number* threshold setting. However, if the number of operations increases further and exceeds the limit value set with the *Lockout Op number* setting, the OPR_LO output is activated.

The binary outputs OPR_LO and OPR_ALM are deactivated when the BLOCK input is activated.

7.1.5.5 Accumulation of I y t

Accumulation of the $I^{y}t$ module calculates the accumulated energy.

The operation of the module can be described with a module diagram. All the modules in the diagram are explained in the next sections.

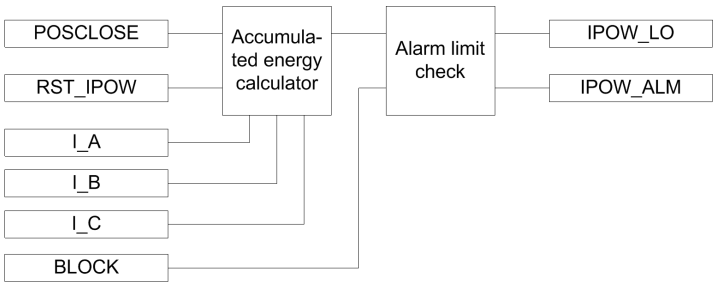

Figure 778: Functional module diagram for calculating accumulative energy and alarm

Accumulated energy calculator

This module calculates the accumulated energy $I^y t$ [(kA) ^{y}s]. The factor y is set with the *Current exponent* setting.

The calculation is initiated with the POSCLOSE input opening events. It ends when the RMS current becomes lower than the *Acc stop current* setting value.

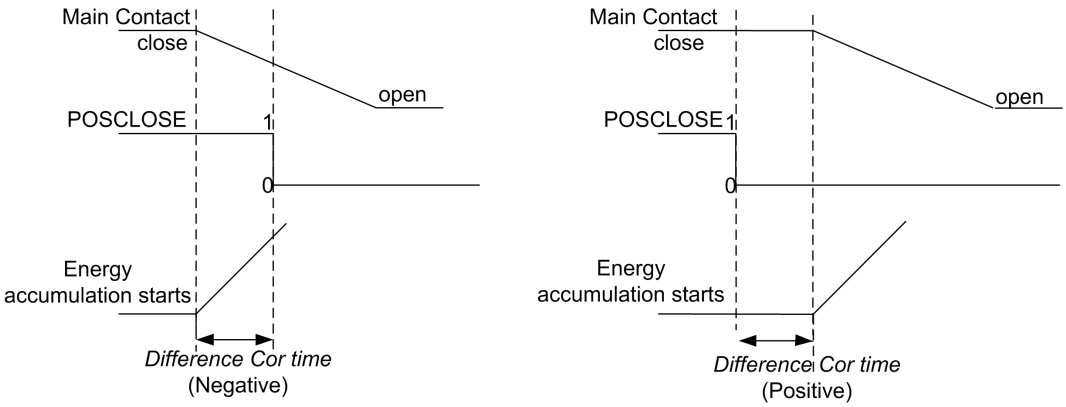

Figure 779: Significance of the Difference Cor time setting

The *Difference Cor time* setting is used instead of the auxiliary contact to accumulate the energy from the time the main contact opens. If the setting is positive, the calculation of energy starts after the auxiliary contact has opened and when the delay is equal to the value set with the *Difference Cor time* setting. When the setting is negative, the calculation starts in advance by the correction time before the auxiliary contact opens.

The accumulated energy outputs IPOW_A (_B, _C) are available in the monitored data view on the LHMI or through tools via communications. The values can be reset by setting the parameter *CB accum. currents power* setting to true in the clear menu from WHMI or LHMI.

Alarm limit check

The IPOW_ALM alarm is activated when the accumulated energy exceeds the value set with the *Alm Acc currents Pwr* threshold setting. However, when the energy exceeds the limit value set with the *LO Acc currents Pwr* threshold setting, the IPOW_LO output is activated.

The IPOW_ALM and IPOW_LO outputs can be blocked by activating the binary input BLOCK.

7.1.5.6 Remaining life of circuit breaker

Every time the breaker operates, the life of the circuit breaker reduces due to wearing. The wearing in the breaker depends on the tripping current, and the remaining life of the breaker is estimated from the circuit breaker trip curve provided by the manufacturer. The remaining life is decremented at least with one when the circuit breaker is opened.

The operation of the remaining life of the circuit breaker subfunction can be described with a module diagram. All the modules in the diagram are explained in the next sections.

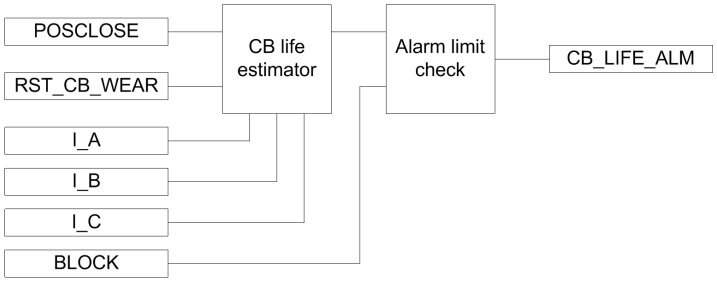

Figure 780: Functional module diagram for estimating the life of the circuit breaker

CB life estimator

CB life estimator module calculates the remaining life of the circuit breaker. The *Op number rated* and *Op number fault* parameters set the number of operations the breaker can perform at the rated current and at the rated fault current. If the tripping current is lower than the rated operating current set with the *Rated Op current* setting, the remaining operation of the breaker reduces by one operation. If the tripping current is higher than the rated fault current set with the *Rated fault current* setting, the remaining operation of the breaker reduces by *Op number rated* divided by *Op number fault*. The remaining life reduction of the tripping current in between these two values is calculated based on the trip curve given by the manufacturer.

$$Directional\ Coef = \frac{\log\left(\frac{Op\ number\ fault}{Op\ number\ rated}\right)}{\log\left(\frac{Rated\ fault\ current}{Rated\ Op\ current}\right)}$$

(Equation 319)

$$Remaining\ life\ reduction = \left(\frac{I_{fault}}{Rated\ Op\ current}\right)^{-Directional\ Coef}$$

(Equation 320)

The remaining life is calculated separately for all three phases and it is available as a monitored data value CB_LIFE_A (_B,_C). The values can be cleared by setting the parameter CB wear values in the clear menu from WHMI or LHMI.

Clearing *CB wear values* also resets the operation counter.

Alarm limit check

When the remaining life of any phase drops below the *Life alarm level* threshold setting, the corresponding circuit breaker life alarm CB_LIFE_ALM is activated.

It is possible to deactivate the CB_LIFE_ALM alarm signal by activating the binary input BLOCK. The old circuit breaker operation counter value can be taken into use by writing the value to the *Initial CB Rmn life* parameter and resetting the value via the clear menu from WHMI or LHMI.

7.1.5.7 Circuit breaker spring-charged indication

The circuit breaker spring-charged indication subfunction calculates the spring charging time.

The operation of the subfunction can be described with a module diagram. All the modules in the diagram are explained in the next sections.

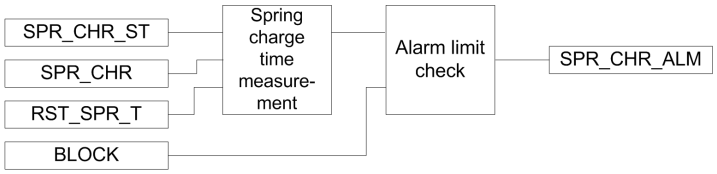

Figure 781: Functional module diagram for circuit breaker spring-charged indication and alarm

Spring charge time measurement

Two binary inputs, SPR_CHR_ST and SPR_CHR, indicate spring charging started and spring charged, respectively. The spring-charging time is calculated from the difference of these two signal timings.

The spring charging time T_SPR_CHR is available in the monitored data view on the LHMI or through tools via communications.

Alarm limit check

If the time taken by the spring to charge is more than the value set with the *Spring charge time* setting, the subfunction generates the SPR_CHR_ALM alarm.

It is possible to block the SPR_CHR_ALM alarm signal by activating the BLOCK binary input.

7.1.5.8 Gas pressure supervision

The gas pressure supervision subfunction monitors the gas pressure inside the arc chamber.

The operation of the subfunction can be described with a module diagram. All the modules in the diagram are explained in the next sections.

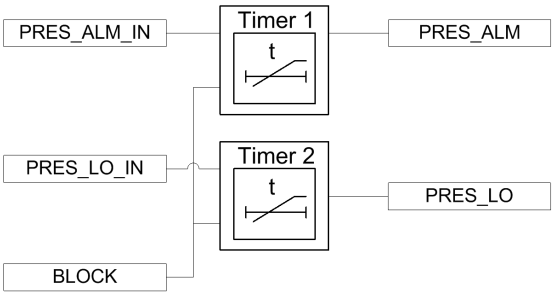

Figure 782: Functional module diagram for circuit breaker gas pressure alarm

The gas pressure is monitored through the binary input signals PRES_LO_IN and PRES_ALM_IN.

Timer 1

When the PRES_ALM_IN binary input is activated, the PRES_ALM alarm is activated after a time delay set with the *Pressure alarm time* setting. The PRES_ALM alarm can be blocked by activating the BLOCK input.

Timer 2

If the pressure drops further to a very low level, the PRES_LO_IN binary input becomes high, activating the lockout alarm PRES_LO after a time delay set with the *Pres lockout time* setting. The PRES_LO alarm can be blocked by activating the BLOCK input.

7.1.6 Application

SSCBR includes different metering and monitoring subfunctions.

Circuit breaker status

Circuit breaker status monitors the position of the circuit breaker, that is, whether the breaker is in an open, closed or intermediate position.

Circuit breaker operation monitoring

The purpose of the circuit breaker operation monitoring is to indicate that the circuit breaker has not been operated for a long time. The function calculates the number of days the circuit breaker has remained inactive, that is, has stayed in the same open or closed state. There is also the possibility to set an initial inactive day.

Breaker contact travel time

High traveling times indicate the need for the maintenance of the circuit breaker mechanism. Therefore, detecting excessive traveling time is needed. During the opening cycle operation, the main contact starts opening. The auxiliary contact A opens, the auxiliary contact B closes and the main contact reaches its opening position. During the closing cycle, the first main contact starts closing. The auxiliary contact B opens, the auxiliary contact A closes and the main contact reaches its

closed position. The travel times are calculated based on the state changes of the auxiliary contacts and the adding correction factor to consider the time difference of the main contact's and the auxiliary contact's position change.

Operation counter

Routine maintenance of the breaker, such as lubricating breaker mechanism, is generally based on a number of operations. A suitable threshold setting to raise an alarm when the number of operation cycle exceeds the set limit helps preventive maintenance. This can also be used to indicate the requirement for oil sampling for dielectric testing in case of an oil circuit breaker.

The change of state can be detected from the binary input of the auxiliary contact. There is a possibility to set an initial value for the counter which can be used to initialize this functionality after a period of operation or in case of refurbished primary equipment.

Accumulation of I y t

Accumulation of $I^{y}t$ calculates the accumulated energy $\Sigma I^{y}t$, where the factor y is known as the current exponent. The factor y depends on the type of the circuit breaker. For oil circuit breakers, the factor y is normally 2. In case of a high-voltage system, the factor y can be 1.4...1.5.

Remaining life of the breaker

Every time the breaker operates, the life of the circuit breaker reduces due to wearing. The wearing in the breaker depends on the tripping current, and the remaining life of the breaker is estimated from the circuit breaker trip curve provided by the manufacturer.

Example for estimating the remaining life of a circuit breaker

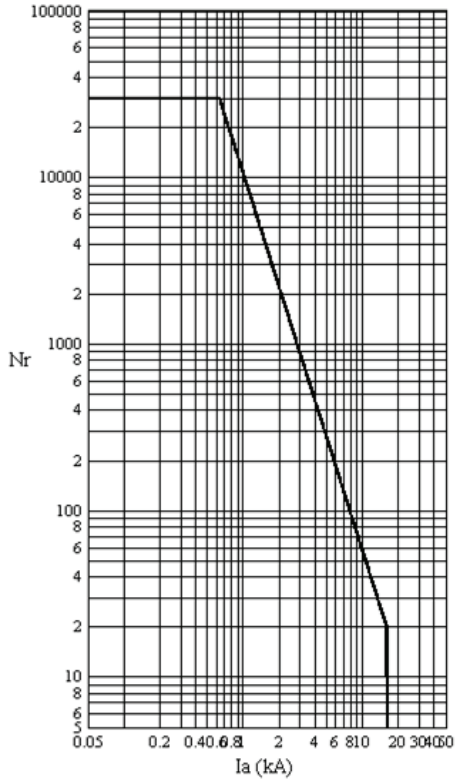

Figure 783: Trip Curves for a typical 12 kV, 630 A, 16 kA vacuum interrupter

Nr	the number of closing-opening operations allowed for the circuit breaker
Ia	the current at the time of tripping of the circuit breaker

Calculation for estimating the remaining life

Figure 783 shows that there are 30,000 possible operations at the rated operating current of 630 A and 20 operations at the rated fault current 16 kA. Therefore, if the tripping current is 10 kA, one operation at 10 kA is equivalent to 30,000/60=500 operations at the rated current. It is also assumed that prior to this tripping, the remaining life of the circuit breaker is 15,000 operations. Therefore, after one operation of 10 kA, the remaining life of the circuit breaker is 15,000-500=14,500 at the rated operating current.

Spring-charged indication

For normal operation of the circuit breaker, the circuit breaker spring should be charged within a specified time. Therefore, detecting long spring-charging time indicates that it is time for the circuit breaker maintenance. The last value of the spring-charging time can be used as a service value.

Gas pressure supervision

The gas pressure supervision monitors the gas pressure inside the arc chamber. When the pressure becomes too low compared to the required value, the circuit breaker operations are locked. A binary input is available based on the pressure levels in the function, and alarms are generated based on these inputs.

7.1.7 Signals

7.1.7.1 SSCBR Input signals

Table 1310: SSCBR Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
BLOCK	BOOLEAN	0=False	Block input status
POSOPEN	BOOLEAN	0=False	Signal for open position of apparatus from I/O
POSCLOSE	BOOLEAN	0=False	Signal for closeposition of apparatus from I/O
OPEN_CB_EXE	BOOLEAN	0=False	Signal for open command to coil
CLOSE_CB_EXE	BOOLEAN	0=False	Signal for close command to coil
PRES_ALM_IN	BOOLEAN	0=False	Binary pressure alarm input
PRES_LO_IN	BOOLEAN	0=False	Binary pressure input for lockout indication
SPR_CHR_ST	BOOLEAN	0=False	CB spring charging started input
SPR_CHR	BOOLEAN	0=False	CB spring charged input
RST_IPOW	BOOLEAN	0=False	Reset accumulation energy
RST_CB_WEAR	BOOLEAN	0=False	Reset input for CB remaining life and operation counter
RST_TRV_T	BOOLEAN	0=False	Reset input for CB closing and opening travel times
RST_SPR_T	BOOLEAN	0=False	Reset input for the charging time of the CB spring

7.1.7.2 SSCBR Output signals

Table 1311: SSCBR Output signals

Name	Type	Description
TRV_T_OP_ALM	BOOLEAN	CB open travel time exceeded set value
TRV_T_CL_ALM	BOOLEAN	CB close travel time exceeded set value
SPR_CHR_ALM	BOOLEAN	Spring charging time has crossed the set value
OPR_ALM	BOOLEAN	Number of CB operations exceeds alarm limit
OPR_LO	BOOLEAN	Number of CB operations exceeds lockout limit
IPOW_ALM	BOOLEAN	Accumulated currents power (Iyt),exceeded alarm limit
IPOW_LO	BOOLEAN	Accumulated currents power (Iyt),exceeded lockout limit
CB_LIFE_ALM	BOOLEAN	Remaining life of CB exceeded alarm limit
MON_ALM	BOOLEAN	CB 'not operated for long time' alarm
PRES_ALM	BOOLEAN	Pressure below alarm level
PRES_LO	BOOLEAN	Pressure below lockout level
OPENPOS	BOOLEAN	CB is in open position
INVALIDPOS	BOOLEAN	CB is in invalid position (not positively open or closed)
CLOSEPOS	BOOLEAN	CB is in closed position

7.1.8 SSCBR Settings

Table 1312: SSCBR Non group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Operation	1=on 5=off			1=on	Operation Off / On
Acc stop current	5.00...500.00	A	0.01	10.00	RMS current setting below which engy acm stops
Open alarm time	0...200	ms	10	40	Alarm level setting for open travel time in ms
Close alarm time	0...200	ms	10	40	Alarm level Setting for close travel time in ms
Spring charge time	0...60	s	1	15	Setting of alarm for spring charging time of CB in s

Table continues on the next page

Parameter	Values (Range)	Unit	Step	Default	Description
Alarm Op number	0...99999		1	200	Alarm limit for number of operations
Lockout Op number	0...99999		1	300	Lock out limit for number of operations
Current exponent	0.00...5.00		0.01	2.00	Current exponent setting for energy calculation
Difference Cor time	-10...10	ms	1	5	Corr. factor for time dif in aux. and main contacts open time

7.2 Motor controlled earthing switch and disconnector supervision ESDCSSWI (ANSI 29CM)

7.2.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Motor controlled earthing switch and disconnector supervision	ESDCSSWI	ESDCCM	29CM

7.2.2 Function block

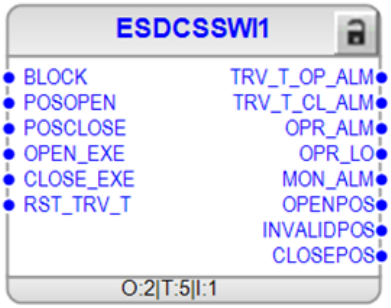

Figure 784: Function block

7.2.3 Functionality

The motor controlled earthing switch and disconnector supervision (ESDCSSWI) is used for monitoring switch status, inactivity, contact travel time and operation counter. Function can be used for condition monitoring and as indicator for maintenance need.

7.2.4 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of ESDCSSWI is described by using a module diagram (see figure below). All the modules in the diagram are explained in the next sections.

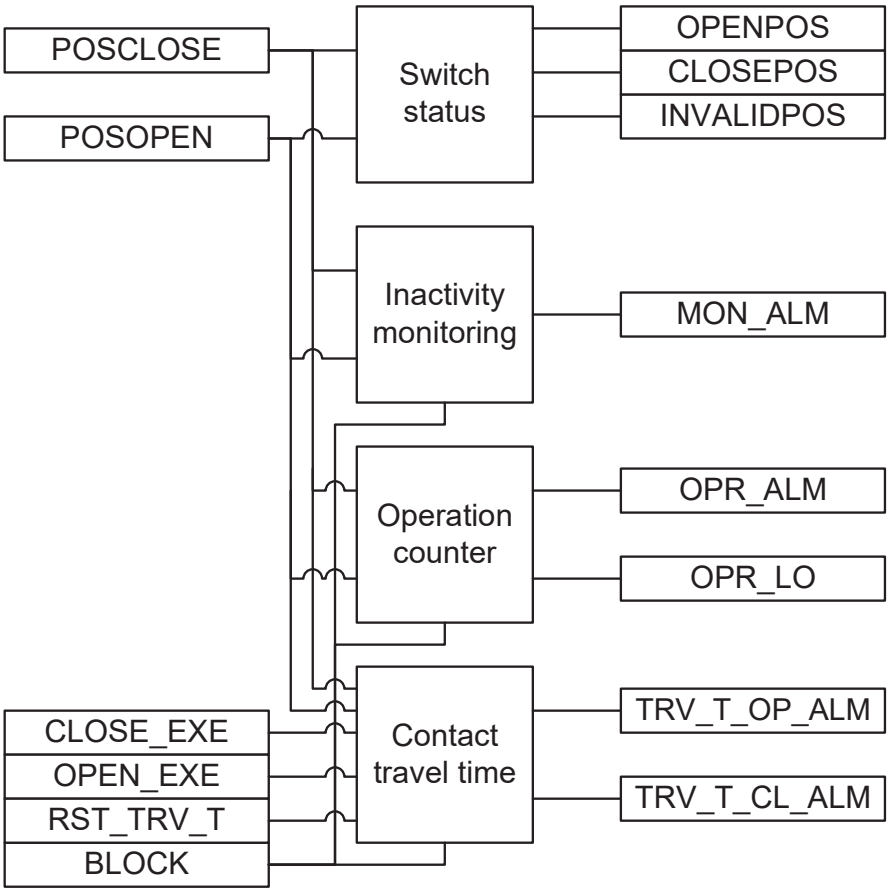

Figure 785: Functional module diagram

7.2.4.1 Switch status

This module monitors the position of the earthing switch or disconnector, that is, whether the switch is in an open, closed, intermediate or faulty position.

The OPENPOS output is activated when the auxiliary input contact POSCLOSE input is FALSE and the POSOPEN input is TRUE. The CLOSEPOS output is activated when the POSOPEN input is FALSE and the *POSCLOSE* input is TRUE.

The INVALIDPOS output is activated when both auxiliary contacts have the same value, that is, both are in the same logical level.

7.2.4.2 Inactivity monitoring

The purpose of the inactivity monitoring is to indicate if the earthing switch or disconnector has not been operated for a long time.

This module calculates the number of days the earthing switch or disconnector has remained inactive, that is, has stayed in the same open, closed and intermediate or faulty state. The calculation is done by monitoring the states of the POSOPEN, POSCLOSE auxiliary contacts. The inactive days INA_DAYS is available in the monitored data view. For relay retrofit installations, it is possible to initialize

INA_DAYS to certain value with *Ini inactive days* setting. The inactive days INA_DAYS will reset to zero when there is change in auxiliary contact.

When the INA_DAYS exceeds the limit value defined with the *Inactive Alm days* setting, the MON_AL alarm is activated. The time during the day when alarm is forwarded can be set with the *Inactive Alm hours* parameter. The warning signal MON_ALM can be blocked by activating the binary input BLOCK.

7.2.4.3 Operation counter

This module calculates the number of operation cycles which means the combination of opening and closing operation of switch. The operation counter is increased on each opening operation of the switch.

The number of operations NO_OPR is available in the monitored data view. The former operation counter value can be taken into use by writing the value to the *Counter initial Val* parameter setting and can be cleared by setting the parameter *Operation counter* in the clear menu from WHMI or LHMI.

The OPR_ALM operation warning is generated when the number of operations exceeds the value set with the *Alarm Op number* threshold setting. However, if the number of operations increases further and exceeds the limit value set with the Lockout Op number setting, the OPR_LO output is activated.

The binary outputs OPR_ALM and OPR_LO are deactivated when the BLOCK input is activated.

7.2.4.4 Contact travel time

This module calculates the contact travel time for the closing and opening operation. the travel time can be calculated in two different ways based on setting *Travel time Clc* mode.

When setting *Travel time Clc* mode is “From Pos to Pos”, the contact travel time of the earthing switch or disconnector is calculated from the time between auxiliary contacts’ state change. The opening travel time is measured between the opening of the POSCLOSE auxiliary contact and the closing of the POSOPEN auxiliary contact. The closing travel time is measured between the opening of the POSOPEN auxiliary contact and the closing of the POSCLOSE auxiliary contact.

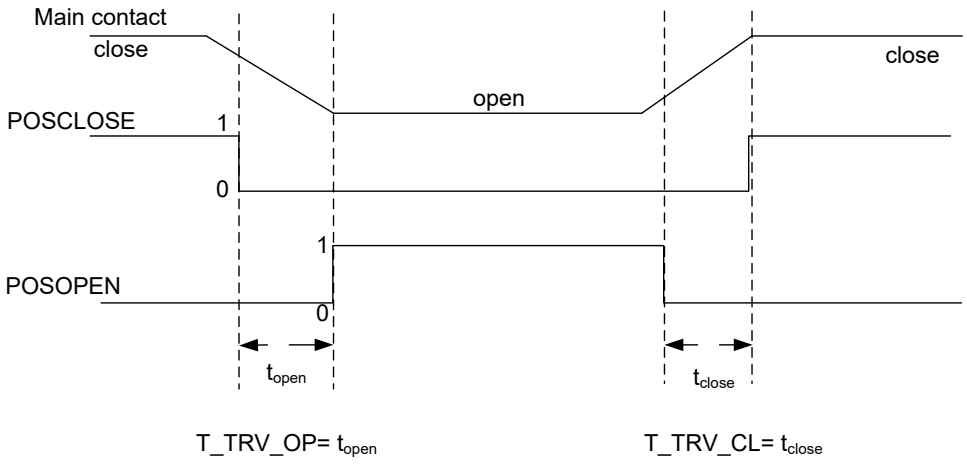

Figure 786: Travel time calculation when Travel time Clc mode is "From Pos to Pos

When setting *Travel time Clc* mode is "From Cmd to Pos", the contact travel time of the earthing switch or disconnector is calculated from the time between opening or closing command and auxiliary contacts' state change. The opening travel time is measured between rising edge of OPEN_EXE command and POSOPEN auxiliary contact. The closing travel time is measured between rising edge of the CLOSE_EXE command and POSCLOSE auxiliary contact.

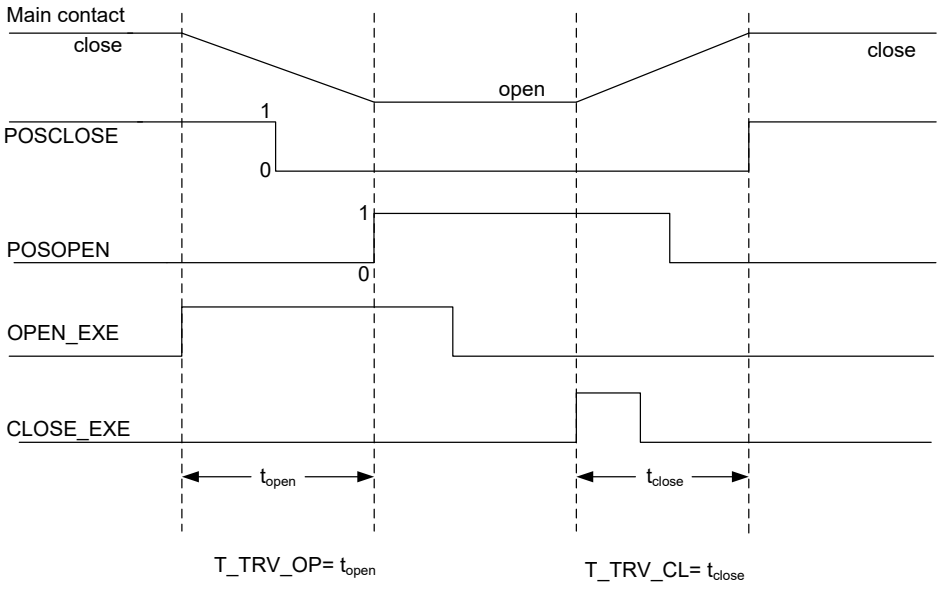

Figure 787: Travel time calculation when Travel time Clc mode is "From Cmd to Pos"

The last measured opening travel time T_TRV_OP and the closing travel time T_TRV_CL are available in the monitored data.

The maximum measured opening travel time T_TRV_MAX_OP and the maximum measured closing travel time T_TRV_MAX__CL are available in the monitored data.

The last measured and maximum travel time are stored in nonvolatile memory and these values are not cleared until the reset input (RST_TRV_ T) is set to TRUE or reset from the clear menu.

When the measured opening travel time is longer than the value set with the *Open alarm time* setting, the TRV_T_OP_ALM output is activated. Respectively, when the measured closing travel time is longer than the value set with the *Close alarm time* setting, the TRV_T_CL_ALM output is activated.

It is also possible to block the TRV_T_CL_ALM and TRV_T_OP_ALM alarm signals by activating the BLOCK input.

7.2.5 Application

Earthing switches or disconnectors are usually located either in metal- clad draw out switchgear or outside in switch yard or pole mounted pole mounted. These switches are operated on no load when circuit breaker is opened. Mechanical actuation is affected due to continued exposure of varying weather conditions. Supervision of following parameters helps understanding the mechanical condition and need for maintenance:

- Increasing contact travel time might be indication e.g., of mechanical wear or lubrication problem.
- Certain maintenance actions are dependent on operation counter value.
- Mechanism may be stuck if switch is in same position long period of time. Inactivity time measurement guides operator for periodic movement.

7.2.6 Signals

7.2.6.1 ESDCSSWI Input signals

Table 1316: ESDCSSWI Input signals

Name	Type	Default	Description
BLOCK	BOOLEAN	0=False	Block all the alarm and lockout indications
POSOPEN	BOOLEAN	0=False	Signal for open position of apparatus from I/O
POSCLOSE	BOOLEAN	0=False	Signal for close position of apparatus from I/O
OPEN_EXE	BOOLEAN	0=False	Signal for open command to coil
CLOSE_EXE	BOOLEAN	0=False	Signal for close command to coil
RST_TRV_T	BOOLEAN	0=False	Reset input for switch closing and opening travel times

7.2.6.2 ESDCSSWI Output signals

Table 1317: ESDCSSWI Output signals

Name	Type	Description
TRV_T_OP_ALM	BOOLEAN	Switch open travel time exceeded set value
TRV_T_CL_ALM	BOOLEAN	Switch close travel time exceeded set value
OPR_ALM	BOOLEAN	Number of switch operations exceeds alarm limit
OPR_LO	BOOLEAN	Number of switch operations exceeds lockout limit
MON_ALM	BOOLEAN	Switch not operated for long time alarm
OPENPOS	BOOLEAN	Apparatus open position
INVALIDPOS	BOOLEAN	Apparatus position is invalid
CLOSEPOS	BOOLEAN	Apparatus closed position

7.2.7 ESDCSSWI Settings

Table 1318: ESDCSSWI Non group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description

7.3 Hot-spot and insulation ageing rate monitoring for transformers HSARSPTR (ANSI 26/49HS)

7.3.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Hot-spot and insulation ageing rate monitoring for transformers	HSARSPTR	3Ihp>T	26/49HS

7.3.2 Function block

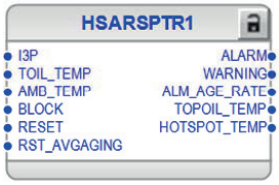

Figure 788: Function block

7.3.3 Functionality

The hot-spot and insulation ageing rate monitoring for transformers function HSARSPTR is used for online monitoring of transformers. The function monitors the hot-spot temperature of the transformer winding and the ageing rate of the insulation caused by thermal stress. The function can be applied for new transformers as well as for transformers already in service.

The hot-spot temperature and loss of life of transformer are calculated for one winding of the transformer from three phase currents and RTD inputs for top oil temperature and ambient temperature.

The hot-spot temperature and the momentary ageing rate are calculated based on the IEC 60076-7 or the IEEE C57.91-2011 standard, depending upon a user defined setting. The total ageing and loss of transformer insulation life is calculated in years.

The function generates `WARNING` and `ALARM` signals if the calculated hot-spot temperature exceeds the set value.

7.3.4 Analog channel configuration

HSARSPTR has one analog group input which must be properly configured.

Table 1322: Analog signals

Input	Description
I3P	Three-phase currents

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings.

For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

7.3.5 Operation principle

The function can be enabled and disabled with the *Operation* setting. The corresponding parameter values are "on" and "off".

The operation of HSARSPTR can be described with a module diagram. All modules in the diagram are explained in the next sections.

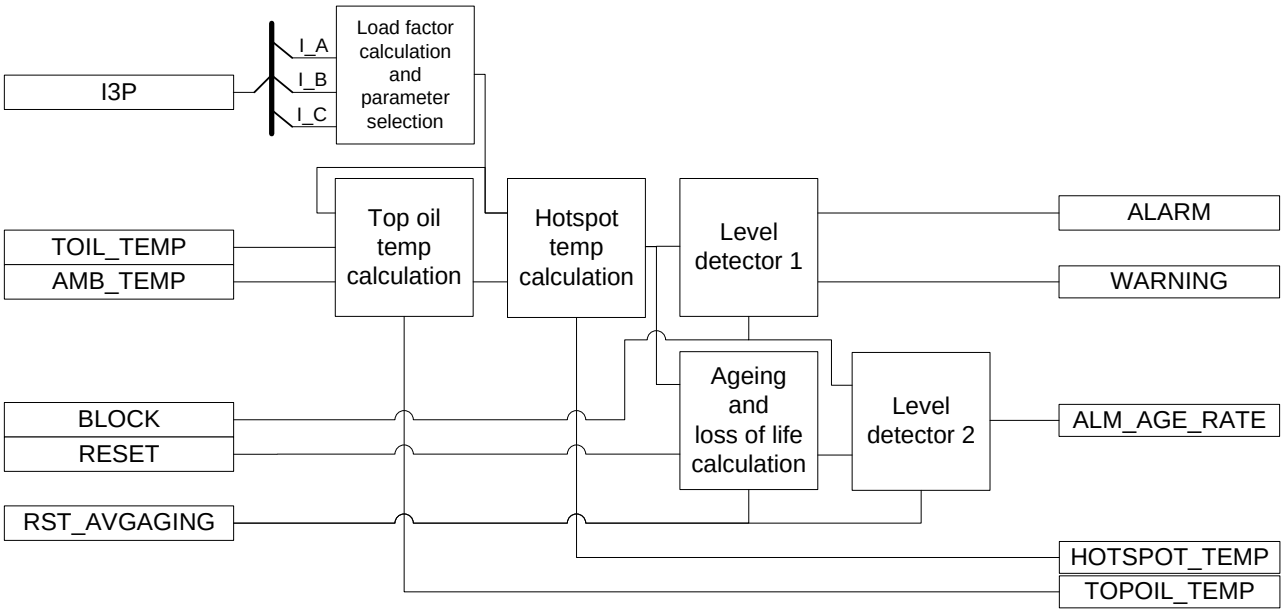

Figure 789: Functional module diagram

7.3.5.1 Load factor calculation and parameter selection

The transformer top oil and hot-spot temperatures are dependent on the load factor, the winding conductor properties and the cooling oil properties of the transformer. This module calculates the load factor based on the measured phase currents and selects the transformer parameters based on user defined settings.

Load factor calculation

Load factor is a ratio of the load current to the rated current. Since the thermal content of all the three phase currents influence the temperature inside the transformer, the load factor is calculated as a ratio of the root of sum of squared phase currents to three times the rated current.

$$K = \sqrt{\frac{I_A^2 + I_B^2 + I_C^2}{3 \cdot I_{rated}^2}}$$

(Equation 321)

Where

K	Load factor
I_A, I_B and I_C	RMS value of input phase currents (Amperes)
I_{rated}	Rated current (Amperes)

If *Transformer type* is set to “Single phase”, the denominator consists only of I^2_{rated} instead of $3\times I^2_{rated}$.

Equation 321 assumes that voltage is constant and tap changer position is not considered.

For a star-delta transformer, it is recommended to use the function on the star winding, since the circulating zero sequence currents (in case of unbalance) cannot be measured on the delta winding of the transformer.

Transformer parameter selection

The transformer parameters are selected based on the *Parameter Sel method*, *Cooling mode*, *Transformer type*, and *Transformer rating* settings.

If the *Parameter Sel method* setting is set to "IEC", the transformer parameters' values are automatically selected as per the IEC 60076-7 guidelines based on *Table 1323*.

Table 1323: Constants based IEC guidelines

	Distribution Transformers	**Medium and Large power transformers**			
Cooling mode	**ONAN**	**ONAN**	**ONAF**	**OFAF**	**ODAF**
Oil Exponent (x)	0.8	0.8	0.8	1.0	1.0
Winding Exponent (y)	1.6	1.3	1.3	1.3	2.0
Constant K11 (k_{11})	1.00	0.50	0.50	1.00	1.00
Constant K21 (k_{21})	1.00	2.00	2.00	1.30	1.00
Constant K22 (k_{22})	2.00	2.00	2.00	1.00	1.00
Oil Time Constant (τ_0) [minutes]	180	210	150	90	90
Winding Tm Constant (τ_w) [minutes]	4	10	7	7	7

If *Parameter Sel method* is set to "IEEE", the constants are selected as per the IEEE C57.91™-2011 standard based on *Table 1324*.

Table 1324: Constants based on IEEE guidelines

	Distribution Transformers	**Medium and Large power transformers**			
Cooling mode	**ONAN**	**ONAN**	**ONAF**	**OFAF**	**ODAF**
Oil Exponent (x)	0.8	0.8	0.8	0.8	1.0
Winding Exponent (y)	0.8	0.8	0.9	0.9	1.0
Constant K11 (k_{11})	1.00	1.00	1.00	1.00	1.00

Table continues on the next page

	Distribution Transformers	Medium and Large power transformers			
Cooling mode	**ONAN**	**ONAN**	**ONAF**	**OFAF**	**ODAF**
Constant K21 (k_{21})	1.00	1.00	1.00	1.00	1.00
Constant K22 (k_{22})	1.00	1.00	1.00	1.00	1.00
Oil Time Constant (τ_0) [minutes]	180	210	150	90	90
Winding Tm Constant (τ_w) [minutes]	4	10	7	7	7

A transformer is a distribution transformer if the *Transformer rating* setting < 2.5 MVA and *Transformer type* is set to "Three phase" or if the *Transformer rating* setting < 0.833 MVA and *Transformer type* is set to "Single phase".

Transformer parameters vary with the material used for winding and insulating oil. The *Parameter Sel method* setting can be set to "Manual" and the constants can be set individually through the *Oil exponent*, *Winding exponent*, *Constant K11*, *Constant K21*, *Constant K22*, *Oil time constant* and *Winding Tm constant* settings.

If *Parameter Sel method* is set to "Manual", the *Cooling mode* setting has no effect on the transformer parameters.

Since there is no direct *Cooling mode* based time constants' selection mentioned in the IEEE Std C57.91™- 2011 standard, the oil time constant (τ_0) and winding time constant (τ_w) in *Table 1324* are kept same as in *Table 1323*.

For more accuracy, the values of the constants can be entered manually by setting *Parameter Sel method* to "Manual".

7.3.5.2 Top oil temp calculation

The function receives two sensor inputs for measuring top oil temperature and ambient temperature.

The top oil temperature of the tank is obtained through a sensor placed at the upper inner turn of the winding. If the top oil temperature sensor status TOIL_SNSFLT is FALSE, the top oil temperature is directly obtained from the TOIL_TEMP input.

If the status of TOIL_SNSFLT is TRUE, indicating that the sensor is faulty, the top oil temperature is calculated with the help of measured ambient temperature.

The status of the ambient temperature sensor is obtained through the AMB_SNSFLT binary input. If AMB_SNSFLT is FALSE, indicating the healthy status of the sensor, the ambient temperature is directly measured through the AMB_TEMP input. Else, if AMB_SNSFLT is TRUE, the ambient temperature is taken from the *Average ambient Tmp* setting.

The formula for calculating the top oil temperature from the measured or set ambient temperature is shown in *Equation 322*.

$$D\theta_{0(n)} = \frac{Dt}{(k_{11} \cdot \tau_o)} \cdot \left(\left[\frac{1 + (K^2 \cdot R)}{1 + R} \right]^x \cdot \Delta\theta_{or} - \left[\theta_{0(n-1)} - \theta_a \right] \right)$$

(Equation 322)

Where

$\theta_{0(n)}$	Top oil temperature in the tank at n^{th} time step
θ_a	Ambient temperature [°C]
$\Delta\theta_{or}$	Top oil temperature rise over ambient temperature at rated load, given by the setting *Top oil Tmp rise*
R	Ratio of losses at rated current to no load losses, given by the setting *Ratio of losses*

k_{11}, τ_0, K and x are as defined in the Parameter selection module in *Figure 789*.

The D operator implies a difference in the associated variable that corresponds to each time step Dt. At each time step, the n^{th} value of $D\theta_{0(n)}$ is calculated from the $(n-1)^{th}$ value.

The initial conditions are calculated by setting the time derivative equal to zero in $D\theta_{0(n)}$ equation, resulting in the following equations.

$$\theta_{0(0)} = \left[\frac{1 + (K^2 \cdot R)}{1 + R} \right]^x \cdot \Delta\theta_{or} + \theta_a$$

(Equation 323)

The top oil temperature at the n^{th} time step is calculated as shown below.

$$TOPOIL_TEMP = \theta_{0(n-1)} + D\theta_{0(n)}$$

(Equation 324)

The measured/calculated top oil temperature TOPOIL_TEMP is available in the Monitored data view.

If the top oil temperature sensor is valid, the TOPOIL_TEMP output is equal to the measured top oil temperature TOIL_TEMP input.

7.3.5.3 Hot-spot temp calculation

Winding hot-spot temperature depends on the winding temperature rise due to the load factor and oil flow. These two factors act complimentary to each other in the influence of temperature rise.

The differential equations for hot-spot temperature rise above top oil temperature is solved as the sum of two differential equations.

$$\Delta\theta_{h(n)} = \Delta\theta_{h1(n)} - \Delta\theta_{h2(n)}$$

(Equation 325)

The two differential equations are shown in *Equation 326* and *Equation 327*.

$$D\Delta\theta_{h1(n)} = \frac{Dt}{(k_{22} \cdot \tau_w)} \cdot \left(k_{21} \cdot \Delta\theta_{hr} \cdot K^y - \Delta\theta_{h1(n-1)}\right)$$

(Equation 326)

$$D\Delta\theta_{h2(n)} = \frac{Dt}{\left(\left(\frac{1}{k_{22}}\right) \cdot \tau_o\right)} \cdot \left((k_{21} - 1) \cdot \Delta\theta_{hr} \cdot K^y - \Delta\theta_{h2(n-1)}\right)$$

(Equation 327)

Where

$\Delta\theta_{hr}$ Hot-spot-to-top-oil gradient at rated current [°C]

The constants τ_w, k_{21}, k_{22} and y are varying according to the *Cooling mode* setting and are obtained from the Load factor calculation and parameter selection module.

The rated hot-spot to top oil gradient, HS_TOIL_GRA ($\Delta\theta_{hr}$), is calculated using the formula as shown in *Equation 328*.

$$\Delta\theta_{hr} = \frac{Hotspot\ \ Tmp\ rise - Top\ oil\ \ Tmp\, rise}{\left(\frac{Current\, type\, test}{I_{rated}}\right)^y}$$

(Equation 328)

Where

I_{rated}	Rated current of the transformer
Hotspot Tmp rise	Hot-spot temperature rise over ambient at rated load
Top oil Tmp rise	Top oil temperature rise over ambient at rated load
Current type test	Current applied in type testing to reach rated hot-spot temperature

At each time step, the n^{th} value of $D\Delta\theta_{h1(n)}$ and $D\Delta\theta_{h2(n)}$ are calculated from the (n-1) value; the solutions of which are combined in accordance with the hot-spot temperature rise equation.

$$\Delta\theta_{h1(n)} = \Delta\theta_{h1(n-1)} + D\Delta\theta_{h1(n)}$$

(Equation 329)

$$\Delta\theta_{h2(n)} = \Delta\theta_{h2(n-1)} + D\Delta\theta_{h2(n)}$$

(Equation 330)

The initial conditions are calculated by setting the time derivative equal to zero in$D\Delta\theta_{h1(n)}$ and $D\Delta\theta_{h2(n)}$ equations, resulting in the following equations.

$$\Delta\theta_{h1(0)} = k_{21} \cdot \Delta\theta_{hr} \cdot K^{y}$$

(Equation 331)

$$\Delta\theta_{h2(0)} = (k_{21} - 1) \cdot \Delta\theta_{hr} \cdot K^{y}$$

(Equation 332)

The final hot-spot temperature is calculated as the sum of top oil temperature and the rise of hot-spot temperature over the top oil temperature.

The hot-spot temperature at the nth time step is calculated as shown in *Equation 333*.

$$HOTSPOT_TEMP = \theta_{o(n)} + \Delta\theta_{h(n)}$$

(Equation 333)

The calculated hot-spot temperature HOTSPOT_TEMP and rated hot-spot to top oil gradient, HS_TOIL_GRA are available in the Monitored data view.

7.3.5.4 Level detector 1

This module compares the calculated hot-spot temperature, HOTSPOT_TEMP value with the *Alarm level* and *Warning level* settings.

If HOTSPOT_TEMP is greater than the *Warning level*, the module activates the WARNING output after a settable *Warning delay time*.

If HOTSPOT_TEMP is greater than the *Alarm level*, the module activates the ALARM output after a settable *Alarm delay time*.

Assuming existing conditions, as long as the alarm/warning conditions are not reached, the module calculates the available load reserve in percentage to reach the alarm condition LD_RSV_ALM_PCT and to reach the warning condition, LD_RSV_WRN_PCT. These outputs can be obtained from the Monitored data view.

If the warning condition is reached, the LD_RSV_WRN_PCT output is forced to zero and if the alarm condition is reached, LD_RSV_ALM_PCT is forced to zero.

The load reserve outputs are only indicative and are calculated based on rated current, assuming the same ambient temperature and cooling modes. If, for any reason, the load reserve calculation is not feasible, the load reserve outputs are shown as zero.

The binary input BLOCK can be used to block the function. The activation of the BLOCK input deactivates WARNING and ALARM outputs and resets the internal timers.

7.3.5.5 Ageing and loss of life calculation

This module calculates the rate at which transformer insulation ageing is accelerating compared with the ageing rate at rated hot-spot temperature and equivalent ageing over a time period.

If transformer insulation paper is not upgraded, that is, if setting *Insul paper type* is set to "Normal", the setting *Ageing rate method* selects between the IEC and IEEE

methods of calculation. If *Ageing rate method* is set to "IEC", the relative ageing rate is calculated as shown in *Equation 334*.

$$V_{IEC} = 2^{\frac{(\theta_h - 98)}{6}}$$

(Equation 334)

If the setting *Ageing rate method* is set to "IEEE", the ageing rate is calculated as shown in *Equation 335*.

$$V_{IEEE} = e^{\frac{15000}{110+273} - \frac{15000}{\theta_h + 273}}$$

(Equation 335)

Where

V_{IEC}	Momentary ageing rate as per IEC method
V_{IEEE}	Momentary ageing rate as per IEEE method
θ_h	The calculated hot-spot temperature

If the setting *Insul paper type* is set to "Upgraded", the IEEE method is used for calculating the ageing rate irrespective of the value of *Ageing rate method* setting.

The calculated value of the relative ageing rate, AGEING_RATE is given as an output in the Monitored data view.

The module also calculates the average ageing rate, AVG_AGE_RATE, over a specified time period given by the *Avg Age rate period* setting. The setting *Avg Age rate period* can be set to "DAY", "WEEK", "MONTH" or "YEAR".

For example, if the *Avg Age rate period* is set to "MONTH", the output AVG_AGE_RATE is updated every day with the average ageing rate since the day the calculation started. Once a month is completed, the AVG_AGE_RATE is calculated over the previous 30 days. That is, after the 31st day, the average ageing rate is calculated from day 2 to day 31 and so on.

If the *Avg Age rate period* is set to "DAY", "WEEK" or "MONTH", the calculated AVG_AGE_RATE is refreshed every day at 12:00 hours, but if it is set to "YEAR", the AVG_AGE_RATE is refreshed once in 30 days.

The calculated AVG_AGE_RATE is given as an output in the Monitored data view.

The function considers month as 30 days and correspondingly a year as 12 months or 360 days.

Loss of life calculation

The momentary loss of life can be calculated as the product of the momentary ageing rate and the time step over which the momentary ageing is calculated.

$$DL_n = V_n \cdot Dt$$

(Equation 336)

The total loss of life is the sum of the momentary loss of life and the total loss of life until time, n-1.

$$L_n = L_{n-1} + DL_n$$

(Equation 337)

The initial loss of life L_0, is taken from the setting *Initial loss of life*.

For new transformer installations, the *Initial loss of life* setting should be “0”. For previously installed transformers, the *Initial loss of life* can be set to the consumed transformer life in months.

The calculated value of the loss of life in years, LOSS_OF_LIFE, is given as an output in the Monitored data view.

The calculated value of LOSS_OF_LIFE can be reset through the input RESET.

7.3.5.6 Level detector 2

This module compares the ALM_AGE_RATE output with the setting *Alarm level Age Rte*.

If the calculated AVG_AGE_RATE over the *Avg Age rate period* setting is greater than *Alarm level Age Rte*, the module activates the binary output ALM_AGE_RATE.

The binary input RST_AVGAGING can be used to reset the output ALM_AGE_RATE and also the calculated value of AVG_AGE_RATE.

Once the RST_AVGAGING input is active, the average ageing rate values stored over the *Avg Age rate period* setting is erased and the calculation of AVG_AGE_RATE is restarted.

If the *Avg Age rate period* is set to "YEAR", the output AVG_AGE_RATE is refreshed once in 30 days starting from the time the relay is installed or since the last activation of binary input RST_AVGAGING.

The activation of the BLOCK input deactivates the ALM_AGE_RATE output.

7.3.6 Application

The insulation used in transformer windings is paper oil insulation that can degrade over a period of time. The deterioration of insulation is a time function of temperature, moisture and oxygen content. With modern oil preservation systems, the moisture and oxygen contributions to insulation deterioration can be minimized, leaving insulation temperature as the controlling parameter.

Since, in most of the transformers the temperature distribution is not uniform, the part that is operating at the highest (hot-spot) temperature normally undergoes the greatest deterioration. Hot-spot temperature of winding needs to be monitored continuously in order to not exceed the flashover value of transformer insulation oil. The first step in monitoring the insulation age is the calculation of hot-spot temperature of the transformer.

A simplified representation of the variation of temperature inside the transformer is shown in *Figure 790* (IEC 60076-7).

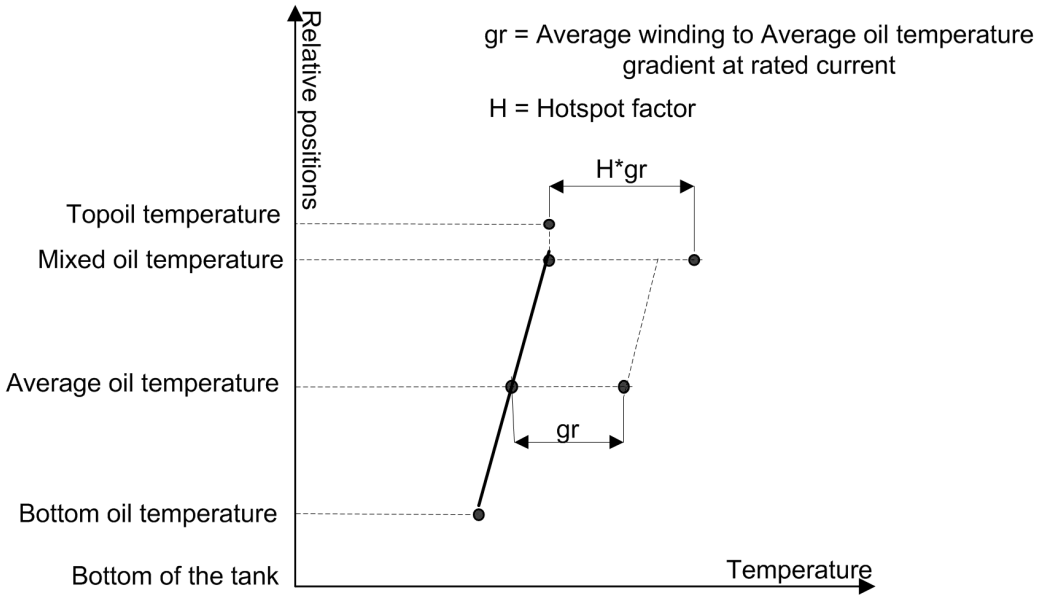

Figure 790: Transformer thermal diagram

The winding hot-spot temperature depends on the load losses, type of cooling and ambient temperature. Usually the conductors near the top of the winding experience the maximum leakage field and the highest surrounding oil temperature (due to convection effect). It is natural to consider that the top conductors contain the hottest spot. Measurements have shown that the hottest spot can also be moved to lower conductors.

Direct measurement of hot-spot temperature with fiber optic probes became available in mid 1980s. Experience has shown that there might be gradients of more than 10 °C between different locations at the top of a transformer winding. It is unlikely that the insertion of one to three sensors detect the real hot-spot. Direct measurement of hot-spot temperature is difficult and it is calculated using the empirical formulae.

The hot-spot temperature calculation is dependent upon the thermal properties of the winding material, cooling oil and the cooling mode of the transformer. The thermal model may also differ from IEC and IEEE markets, though the underlying principle of temperature calculation remains the same. The transformer constants are decided based on a user defined setting to select the preferred type of thermal model (IEC, IEEE or Manual).

For most transformers in service, the top oil temperature inside a winding is difficult to measure. On the other hand, the top oil temperature at the top of the tank is well known, either by measurement or by calculation. The winding hot-spot temperature rise above the top oil temperature is calculated. By adding this value to the measured or calculated top oil temperature, the winding hot-spot temperature is obtained. A pictorial representation of the location of top oil temperature sensor is shown in *Figure 791*.

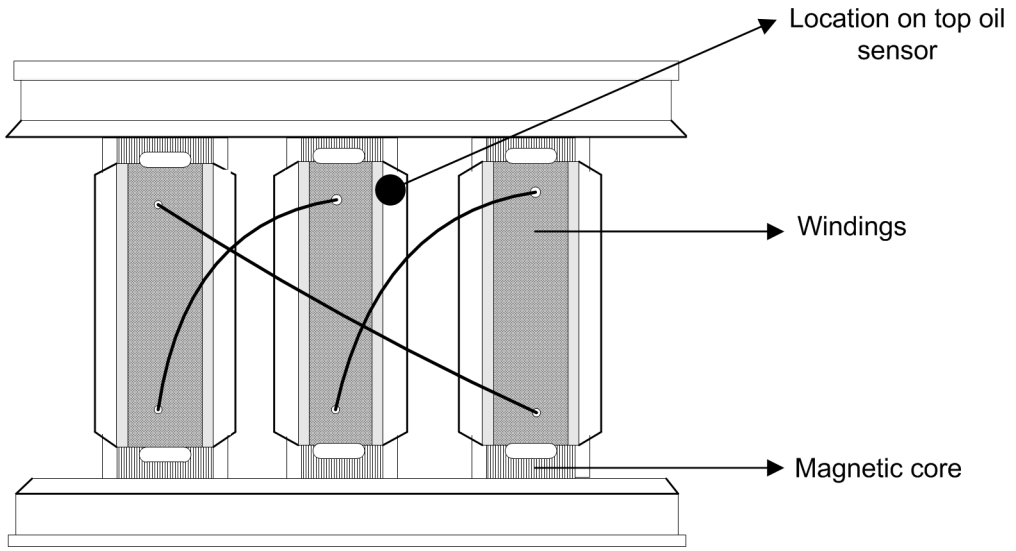

Figure 791: Location of top oil sensor

WARNING and ALARM signals are provided for the operator to take corrective actions to reduce the temperature inside the transformer. Corrective actions include switching on coolers, reducing the load on the transformers and so on.

Normally, warning level is set to indicate if the temperature is nearing the limiting value and alarm is generated when the limiting condition has reached. Hence, alarm level is set at a higher value than the warning level.

The function only calculates hot-spot temperature based on the load factor of the winding. This function does not calculate the rise in actual hot-spot temperature, which occurs due to oil flow blockage or malfunction of cooler groups. That said, the set oil and winding properties can be updated manually to indicate this change.

Based on the calculated hot-spot temperature, the function calculates the relative ageing, that is, the accelerated or decelerated ageing of the insulation at current load compared to its ageing at rated load. The variation of ageing acceleration factor with respect to the hot-spot temperature for a sample transformer is plotted in *Figure 792*. Here, 110 °C is taken as the rated hot-spot temperature at which point an ageing acceleration factor of 1.0 is achieved.

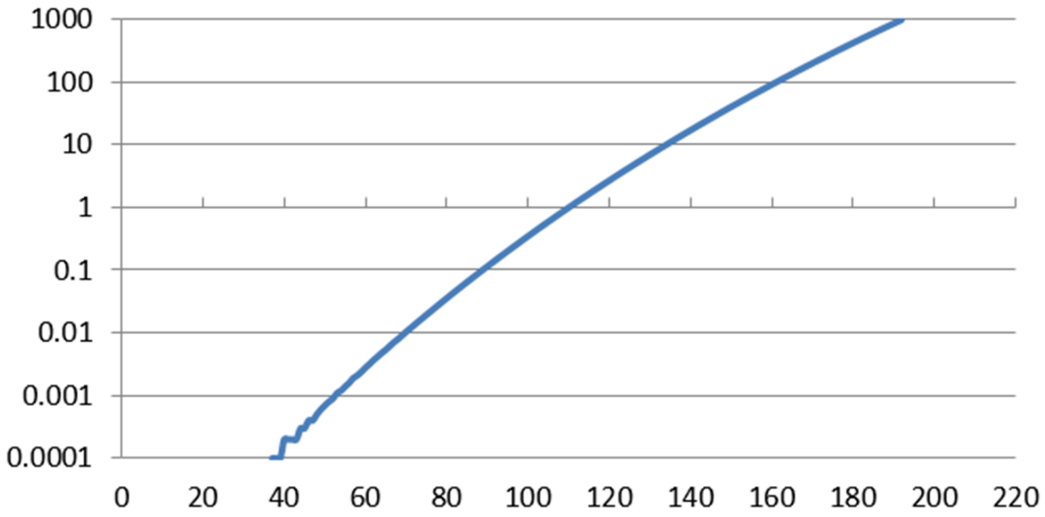

Figure 792: Variation of insulation ageing factor with hot-spot temperature (Graph produced using values from Table 11 of IEEE Std. C57.91-1995)

The variation of insulation life with respect to the hot-spot temperature depends upon the type of insulation paper used. Thermally upgraded insulation paper neutralizes the production of acids caused by the hydrolysis of the material over the lifetime of the transformer and slows down insulation ageing when compared to the normal insulation paper (IEC 60076-7). The proper selection of insulation paper type is needed for better accuracy of loss of life calculation.

In certain cases, it is necessary to monitor the loading of the transformer over a defined time period. For example, during a planned overloading of a transformer for a period of one month. In such cases it is important to know the ageing rate during that period of overload rather than the overall loss of life transformer. Hence, an additional output on average ageing rate over a settable average ageing period is provided in the function.

The function can be applied for new transformers and also for transformers already in service using the *Initial loss of life* setting.

7.3.7 Signals

7.3.7.1 HSARSPTR Input signals

Table 1325: HSARSPTR Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
TOIL_TEMP	FLOAT32	0	Measured top oil temperature
AMB_TEMP	FLOAT32	0	Measured ambient temperature

Table continues on the next page

Name	Type	Default	Description
BLOCK	BOOLEAN	0=False	Block signal for activating the blocking mode
RESET	BOOLEAN	0=False	Reset loss of life calculation
RST_AVGAGING	BOOLEAN	0=False	Reset average ageing rate calculation

7.3.7.2 HSARSPTR Output signals

Table 1326: HSARSPTR Output signals

Name	Type	Description
ALARM	BOOLEAN	Alarm signal
WARNING	BOOLEAN	Warning signal
ALM_AGE_RATE	BOOLEAN	Alarm signal for Avg ageing rate over set time period
TOPOIL_TEMP	FLOAT32	Calculated value of top oil temperature
HOTSPOT_TEMP	FLOAT32	Calculated value of hot spot temperature

7.3.8 HSARSPTR Settings

Table 1327: HSARSPTR Group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Cooling mode	1=ONAN 2=ONAF 3=OFAF 4=ODAF			1=ONAN	Transformer cooling method
Alarm level	50.0...350.0	°C	0.1	120.0	Alarm level for hotspot temperature
Warning level	50.0...350.0	°C	0.1	100.0	Warning level for hotspot temperature
Alarm delay time	0...3600000	ms	10	10000	Time delay for hotspot temperature alarm
Warning delay time	0...3600000	ms	10	10000	Time delay for hotspot temperature warning
Average ambient Tmp	-20.00...70.00	°C	0.01	20.00	Average ambient temperature

7.4 Cable fault detection RCFD (ANSI CFD)

7.4.1 Identification

Function description	IEC 61850 identification	IEC 60617 identification	ANSI/IEEE C37.2 device number
Cable fault detection	RCFD	CFD	CFD

7.4.2 Function block

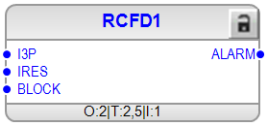

Figure 793: Function block

7.4.3 Functionality

The self-clearing fault detection function (RCFD) calculates half cycle DFT of the current signal for all the three phases and earth and uses it to detect a self-clearing fault pronounced primarily in cable networks.

The function provides individual counter values for number of times a self-clearing fault is observed in each phase and earth. The function determines the self-clearing fault is detected in all three phases or earth.

7.4.4 Analog input configuration

RCFD has two analog group inputs which must be properly configured.

Table 1332: Analog inputs

Input	Description
I3P	Three-phase currents.
IRES	Measured residual current

See the preprocessing function blocks in this document for the possible signal sources.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. For troubleshooting, check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

7.4.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "On" the function is enabled and respectively "Off" means function is disabled.

The operation of RCFD can be described by using a module diagram (see Figure *Figure 794* below). All the modules in the diagram are explained in the next sections.

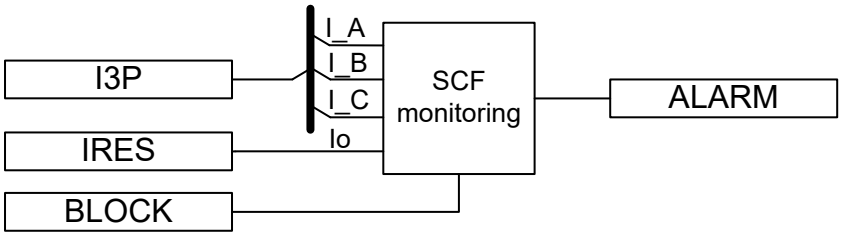

Figure 794: Functional module diagram

7.4.5.1 SCF monitoring

The SCF(Self Clearing Fault) monitoring module provides measurement channel specific monitoring for phase and residual currents. Following table lists the options for monitoring and available monitored data values.

Table 1333: SCF monitoring options and data values

Measurement channel	Calculated ½ cycle DFT current	Start detection	SCF indication	SCF counter
Phase A current (I_A)	I_CLC_AMPL_A	STR_DET_A	SLFCLR_FLT_A	SLFCLR_CNT_A
Phase B current (I_B)	I_CLC_AMPL_B	STR_DET_B	SLFCLR_FLT_B	SLFCLR_CNT_B
Phase C current (I_C)	I_CLC_AMPL_C	STR_DET_C	SLFCLR_FLT_C	SLFCLR_CNT_C
Residual current (Io)	I_CLC_AMPL_N	STR_DET_N	SLFCLR_FLT_N	SLFCLR_CNT_N

Half cycle DFT values are calculated for the SCF detection. Values are available in monitored data. If the calculated phase current (or residual current) exceeds above set *Phase start value* (or *Residual start value*), then the corresponding start

detection in monitored data is set to TRUE. Monitored data is set to FALSE once fault current has dropped below start value.

The module calculates the duration for currents continuously staying above the set *Phase start value* (or *Residual start value*). If the calculated duration is between ¼ cycles and cycles set by *Maximum fault cycle*, then it is regarded as the SCF and corresponding SCF indication in monitored data is set to TRUE. Simultaneously corresponding SCF counter in monitored data is increased.

The parameter settings *Residual start value*, *Residual current limit* are dimmed when *Ena selfclear Det EF* setting is set to “FALSE”. And also Monitoring for residual current (Io), can be disabled by setting *Ena selfclear Det EF* to “FALSE”.

If the setting *Adaptive Str Val Ena* is set to TRUE. the adaptive phase and residual start value are defined based on the one-minute phase and residual averages, the *Minimum load current* (for phase) and *Residual current limit* (for earth) setting.

At end of the every healthy state one-minute period, new one-minute phase and residual current averages are calculated. If it is greater than the *Minimum load current* (for phase) and *Residual current limit* (for earth) setting, then the adaptive start value will be updated as twice the calculated value.

If one-minute phase and ground averages are less than the *Minimum load current* and *Residual current limit*, then the adaptive start value are set to twice the *Minimum load current* and *Residual current limit*.

In case fault is detected, the adaptive start value will hold the last updated one-minute average of phase and residual current.

The adaptive start values of corresponding phases (or residual) are displayed in monitored data ADP_ST_VAL_A, ADP_ST_VAL_B, ADP_ST_VAL_C and ADP_ST_VAL_N.

If the SCF is detected in at least one phase or residual current channel, the `ALARM` output is set to TRUE. When one phase detects a fault, the algorithm waits for 1 cycle time and if during this period two other phases also detect fault, then the fault is considered as three phase SCF and the SLFCLR_3PH in monitored data is set to TRUE.

The counter type monitored data can be reset to their initial value along with the all the outputs in the monitored data via a control parameter RCFD1 reset that is located under the clear menu.

When `BLOCK` input is activated, the `ALARM` output is set to FALSE, and also the Boolean type monitored data are set to FALSE and ADP_ST_VAL_x (phase A,B and C) are defaulted to *Phase start value* setting (ADP_ST_VAL_N is defaulted to *Residual start value* setting), Counter type monitored data are not affected and will retain last SCF fault count.

7.4.6 Application

The self-clearing fault will not the damage the cable initially, but if the frequency of the self-clearing fault slowly increases and causes the cable insulation breakdown.

[1] Results based on statistical distribution of 1000 measurements
[2] Measured with static signal output (SSO)

7.5.2 Function block

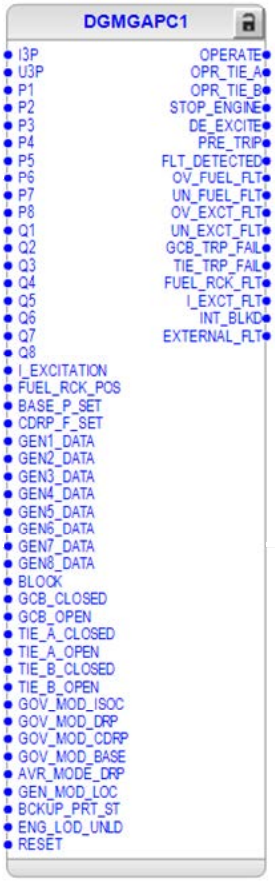

Figure 795: Function block

7.5.3 Functionality

The Diesel generator monitoring and protection DGMGAPC function protects industrial power plants and vessels from faults which are not easily detected by normal protection functions. The most important of such faults are the over/under fueling of diesel engines and over/under excitation of generators.

DGMGAPC protects the generators in isochronous load sharing, droop load sharing and base load modes. The function performs topology determination to identify the components connected in its own electrical network and exchanges relevant data with all other relays having DGMGAPC function and present in the same IEC61850 network.

The DGMGAPC identifies a fault in the generator by comparing its behavior to its current governor mode or with reference to other generators in the network. When a fault is detected, the function will signal the fault to the Power Management System (PMS). If the fault condition deteriorates, the function issues commands to stop the engine or to de-excite the generator. It then issues a trip command to the Generator Circuit Breaker (GCB).

7.5.4 Analog channel configuration

DGMGAPC has two analog group inputs which must be properly configured.

Table 1341: Analog inputs

Input	Description
I3P	Three-phase currents
U3P	Three-phase voltages

See the preprocessing function blocks in this document for the possible signal sources.

There are a few special conditions which must be noted with the configuration.

Table 1342: Special conditions

Condition	Description
U3P connected real measurements	The function can work with any two voltage channels connected but it is recommended to connect all three voltage channels.

Improper analog channel configuration causes a validation error if the analog channels are not completely configured or they do not match with certain settings. check the contents of this chapter and also the preprocessing blocks in this document. The configuration can be written to the protection relay once the mismatch is corrected.

7.5.5 Operation principle

The *Operation* setting is used to enable or disable the function. When selected "on" the function is enabled and respectively "off" means function is disabled.

The operation of DGMGAPC can be described by using a module diagram (see *Figure 796*). All the modules in the diagram are explained in the next sections.

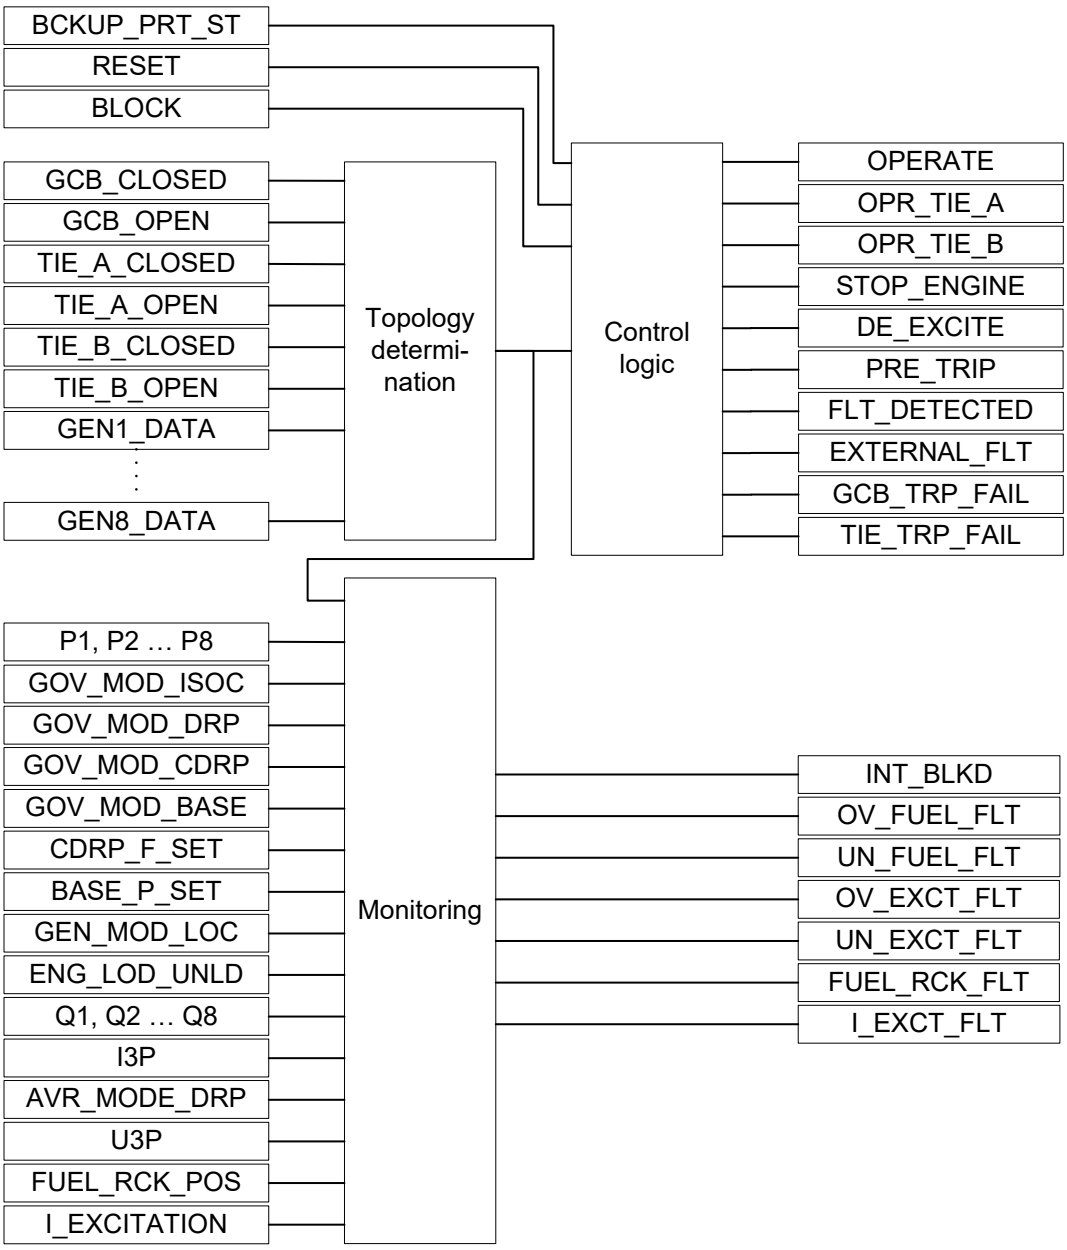

Figure 796: Functional module diagram

7.5.5.1 Topology determination

The Topology determination module identifies the group of busbar and generators that are electrically connected and calculates the subnetwork number for each group. The maximum network configuration considered is 8 generators, 8 GCBs and 8 tie breakers.

Some typical busbar arrangements in a Diesel Generator Monitoring and protection System (DGMS) are shown in *Figure 797* and *Figure 798*.

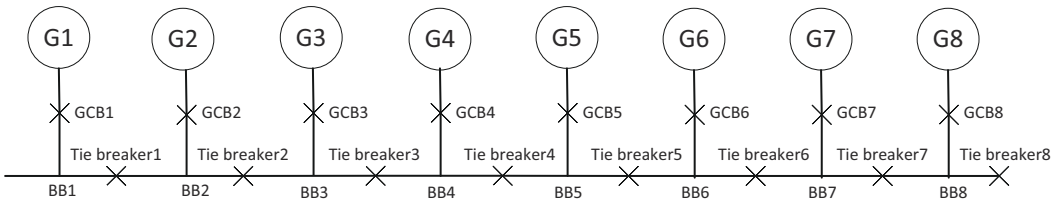

Figure 797: Topology of a DGMS system with all generators in a single network

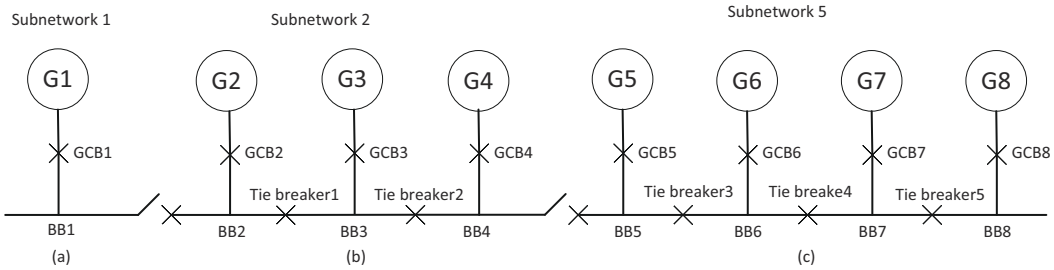

Figure 798: Topology of a DGMS system with 3 subnetworks

The connection of a generator to a particular busbar can be configured by using corresponding settings, *Gn 1 busbar Num* to *Gn 8 busbar Num*. Each of the settings can be set to values “Bus 1” to “Bus 8” or to “Not configured”.

For example, if generator 1 is connected to busbar1, then *Gn 1 busbar Num* is set to “Bus 1”. If suppose there are only four generators in the system, then settings *Gn 5 busbar Num* to *Gn 8 busbar Num* are set to “Not configured”.

The numbering of each GCB is assumed to be same as the number given to the generator it is connected to. That is, GCB1 assumed to be connected to generator 1, GCB2 to generator 2 and so on.

The tie breaker connects different busbar to form the different subnetwork groups. Each tie breaker connects two busbars and these are referred to as bus A and bus B. Hence, two settings are used to indicate the connection of a tie breaker to the two busbars.

For example: If tie breaker 1 connects busbar1 and busbar2, then setting *Tie 1 busbar A Num* is set to “Bus 1” and *Tie 1 busbar B Num* is set to “Bus 2”. If a tie breaker is not configured in the network, it is set to “Not configured”.

The entire network configuration can be modeled in a similar method using settings *Tie 2 busbar A Num, Tie 2 busbar B Num … Tie 8 busbar A Num and Tie 8 busbar B Num*.

Once the entire network has been defined using the settings as mentioned above, the module identifies the existing network topology through the status of GCBs and the tie breakers. The status of the local GCB is obtained through confirmed closed and open inputs `GCB_CLOSED` and `GCB_OPEN`, whereas the adjacent tie breaker statuses are received through inputs, `TIE_A_CLOSED`, `TIE_A_OPEN`, `TIE_B_CLOSED` and `TIE_B_OPEN`. The status of other GCBs and tie breakers are obtained from corresponding weighted integer inputs `GEN1_DATA … GEN8_DATA`.

The module expects that the tie breaker which connects to the lower numbered busbar is configured as tie breaker A and the tie breaker which connects to the higher numbered busbar as tie breaker B.

For example, if Generator 2 is connected to busbar2 and the busbar2 connects to busbars 1 and 3 through tie breakers 1 and 2 as shown in *Figure 796*. Then the status of tie breaker1 shall be received through inputs TIE_A_CLOSED and TIE_A_OPEN and the status of tie breaker 2 is shall be received as TIE_B_CLOSED and TIE_B_OPEN.

If one of the tie breakers of the generator under consideration is not configured or connects to a non-configured busbar, then the module expects the status of the other tie breaker through inputs TIE_B_CLOSED and TIE_B_OPEN.

The inputs GEN1_DATA to GEN8_DATA are received from other generators in the system. Each of these inputs contain information on the status of GCB, status of the adjacent tie breakers, governor and Automatic Voltage Regulator (AVR) modes, generator local mode status, backup protection status, fault status and tie breaker trip failure indication in the respective generators from where the information is being received.

The setting *Local generator Num* is used to set the local generator number. Based on this setting the local active/reactive power, circuit breaker statuses, governor and excitation system information are associated to the corresponding generator.

Though 8 inputs, GEN1_DATA ... GEN8_DATA, are provided to receive information from other generators, the input corresponding to the local generator need not be connected.

That is, if *Local generator Num* is set to "5", then GEN5_DATA needs to be left unconnected and any information connected to this input would not be used by the function.

Based on this information, the Topology determination module determines the different subnetwork groups. Each network group is assigned a network number which is the lowest busbar number in the sub group.

For example in *Figure 798* (c), the subnetwork group has busbar 5, 6, 7 and 8. Hence the subnetwork number of this group is 5.

If an element is not electrically connected to any busbar, then a zero subnetwork number is assigned. The DGMGAPC function will be disabled in those networks whose subnetwork number will be zero.

When the quality bit of local GCB status input indicates that the data is not reliable, then the corresponding breaker status is considered open and rest of the modules in the function are disabled. If the quality bits of the local tie breakers status indicate that data is not reliable, then that tie breaker is considered as open and the generators connected through that tie breaker are suspended from participating in the monitoring function.

In case the quality of the status of the adjacent tie breakers are not reliable, then the module may identify the status of the same tie breaker using the data received from the adjacent generator sharing the same tie breaker.

The subnetwork numbers of eight generators are available in monitored data SBNW_GEN1 to SBNW_GEN8. The subnetwork numbers of tie breakers are available in monitored data SBNW_TIE_CB1 to SBNW_TIE_CB8.

If the inputs GEN1_DATA ... GEN8_DATA indicate that a network generator is faulty, then it is indicated in the respective monitored data output FAULT_GEN1 ... FAULT_GEN8 and the data corresponding to those generators are not used in other modules of DGMGAPC.

7.5.5.2 Monitoring

Monitoring module consists of Fuel fault detection, Excitation fault detection, Fuel rack monitoring and Excitation current monitoring as shown in *Figure 799*.

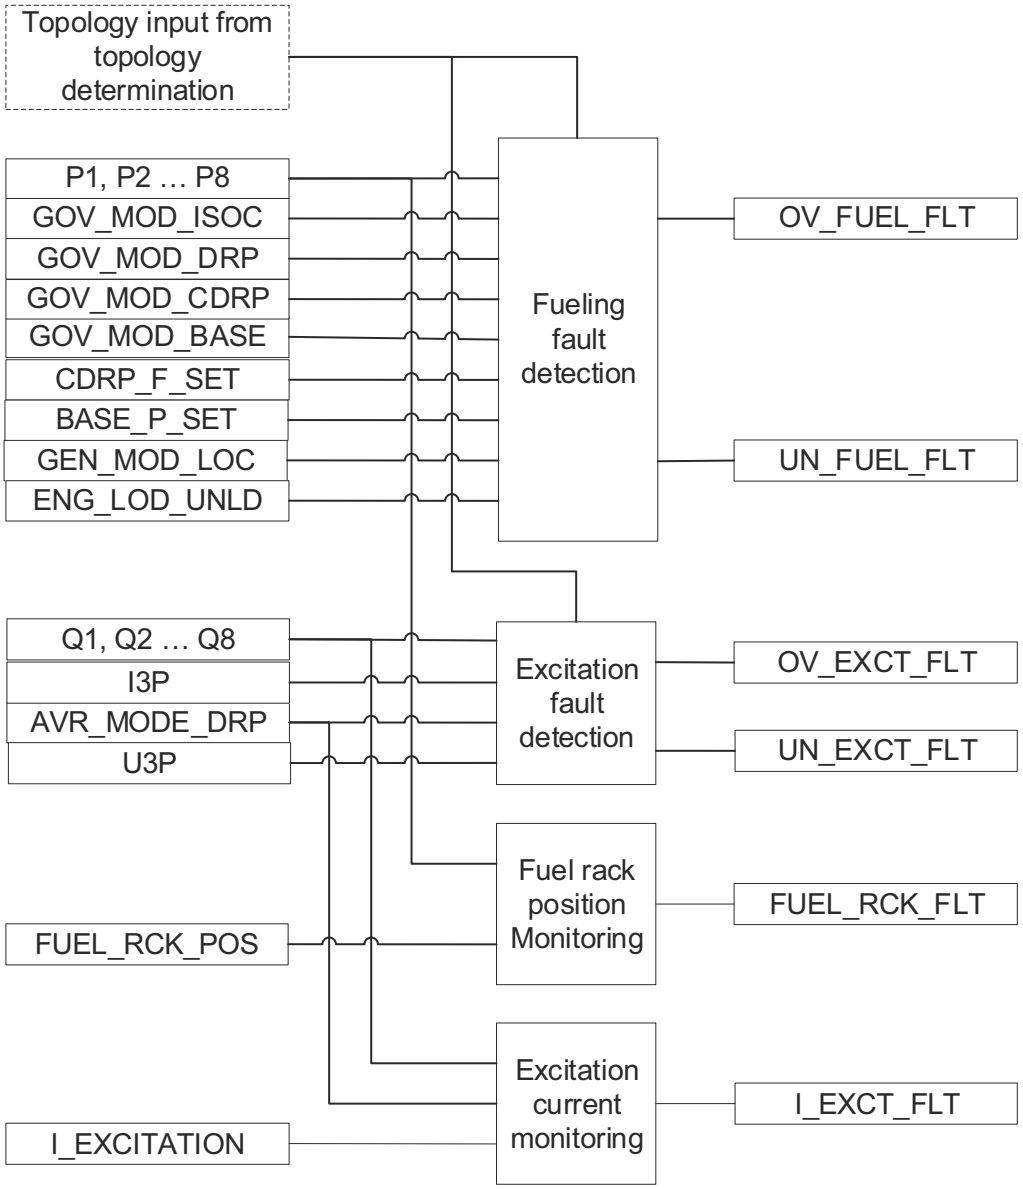

Figure 799: Submodules of Monitoring

Fueling fault detection

This module detects over/under fueling faults in the fuel system or engine governor, which result in the generator producing excessive active power (over fueling condition) or insufficient active power (under fueling condition).

Fueling faults are detected by two methods which are Correlation algorithm and Voting algorithm. The module activates `OV_FUEL_FLT` output in case of over fueling fault detection and `UN_FUEL_FLT` output in case of under fueling fault. Fueling faults are reported to Control logic module.

If the input GEN_MOD_LOC is 1, indicating that the generator is in local mode, then the Fueling fault detection module is disabled. If the quality status of the local active power input is faulty, then the module is disabled and INT_BLKD output is activated.

If one of the generators present in the same subnetwork is faulty, then that generator is removed from comparison in the Fueling fault detection module.

The input ENG_LOD_UNLD suggests whether the engine is in loading or unloading condition. When the engine is in loading condition (confirmed by GCB position change from open to close) the fueling fault detection is disabled until the generated power reaches 80% of the average loading of generators in the same subnetwork or until the elapsing of *Disable time*, whichever is faster. When the function is in unloading condition (i.e. GCB continues to remain in closed position), then the module is blocked until the elapsing of *Disable time*. As the GCB status change and ENG_LOD_UNLD input may not come together, by using settings (*Wait time signal status* - Wait time for Load/Unload signal and *Wait time status signal* - Wait time for GCB status and Load/Unload signal) the confirmation of loading/unloading of engine is done.

Correlation algorithm:

The Correlation algorithm compares the active power of the local generator, to its expected behavior in the current governor mode.

The algorithm can be disabled through the setting *Disable Fuel Crl*.

The function has 8 active power inputs, P1 ... P8. The input corresponding to the setting *Local generator Num*, would be considered as the local active power.

For example, if *Local generator Num* is set to “1”, then P1 is considered as the local generator active power output.

Correlation algorithm uses different criteria based on the governor mode.
The governor mode information is obtained through the four binary inputs GOV_MOD_ISOC, GOV_MOD_DRP, GOV_MOD_CDRP and GOV_MOD_BASE. The governor and AVR modes of other generators are obtained through inputs GEN1_DATA ... GEN8_DATA. In case any generator in the same subnetwork is communicated to be faulty, through the inputs GEN1_DATA ... GEN8_DATA, then that generator is not considered in the Correlation algorithm.

If the input GOV_MOD_ISOC is active, the function monitors the system frequency and active power of all generators in the same subnetwork and with the same governor mode. If the frequency of the network exceeds the set *Expected frequency* over and above the margin *Max Freq Dev Isoc*, and if the local active power is more than the rest of the generators by a margin *Max P Dev Crl*, then the generator is deemed faulty and OV_FUEL_FLT output is activated.

If the frequency of the network is below the set *Expected frequency* over and above the margin *Max Freq Dev Isoc*, and if the local active power is less than the rest of the generators by a margin *Max P Dev Crl*, then the generator is deemed faulty and UN_FUEL_FLT output is activated. The fueling fault detection algorithm in isochronous mode needs at least 2 generators in parallel and operating in same mode.

When the input GOV_MOD_DRP is active, the function compares the local active power and system frequency with the set droop curve. Deviation above or below this curve (for over and under fueling conditions respectively) by a margin greater than *Max Freq deviation*, indicates a failure of the governor or the fuel system. The

droop curve is set using the settings *F set point no load* and *Frequency droop*. A sample droop characteristics and the associated settings are shown in *Figure 800*.

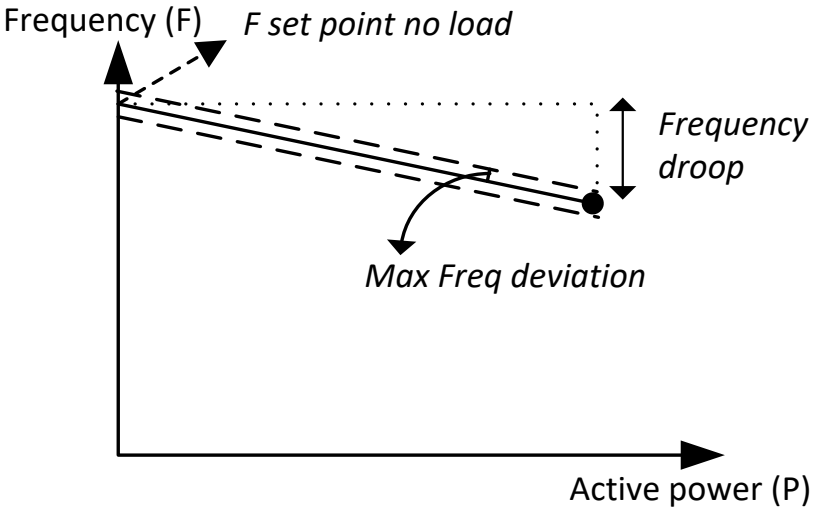

Figure 800: Frequency vs. Active power droop characteristics

When the input GOV_MOD_CDRP is active, then the central PMS shifts the droop curve parallel to the existing curve, through inputs CDRP_F_SET. The CDRP_F_SET input is a 0-20mA signal obtained through an RTD input, directly gives the no load set point frequency for the generator, using which the droop characteristic is generated. The calculated frequency limit at a particular load is displayed in monitored data F_CALC_LIMIT. If the network frequency value deviates over/under the F_CALC_LIMIT by a margin greater than set *Max Freq deviation*, the OV_FUEL_FLT or UN_FUEL_FLT outputs are activated. When the generator is in compensated droop mode and if the quality of the signal CDRP_F_SET is not reliable, the module is disabled and INT_BLKD output is activated.

When input GOV_MOD_BASE is active, the local active power is compared to the load set point received from PMS, BASE_P_SET. The BASE_P_SET input is a 0-20mA signal obtained through an RTD input. If the local active power deviates from this set point by a margin greater than the set *Max P Dev Crl*, it indicates an over/under fueling fault. In case the quality of the signal BASE_P_SET is not reliable when generator is in base mode, then the correlation module is disabled and INT_BLKD output is activated.

Any one among the binary inputs from governor, for example, GOV_MOD_ISOC, GOV_ MOD_DRP, GOV_MOD_CDRP and GOV_MOD_BASE can be active at a given time. If more than one of them is active or if none of them is active, then the output INT_BLKD is activated and the Correlation algorithm is stopped.

Table 1343 indicates the method of detecting over/under fueling faults in a diesel generator system. For simplicity, the local active power will simply be called P in the tables below.

Table 1343: Correlation algorithm for detecting fueling faults

Type of fault	Governor mode	Fault detection criteria	Output activation
Over fueling fault	GOV_MOD_ISOC = TRUE	F > (*Expected frequency* + *Max Freq Dev Isoc*) AND Local active power (P) > MAX(P1, P2, … P8) + *Max P Dev Crl* Note: Only generators within the same subnetwork are considered for comparison.	OV_FUEL_FLT
	GOV_MOD_DRP = TRUE	F > *F set point no load* – ((*Frequency droop**0.01) * P) + *Max Freq deviation*	
	GOV_MOD_CDRP = TRUE	F > F_CALC_LIMIT + *Max Freq deviation*	
	GOV_MOD_BASE = TRUE	P > BASE_P_SET + *Max P Dev Crl*	
Under fueling fault	GOV_MOD_ISOC = TRUE	F < (*Expected frequency* - *Max Freq Dev Isoc*) AND P < MIN(P1, P2, … P8) - *Max P Dev Crl* Note: Only generators within the same subnetwork are considered for comparison.	UN_FUEL_FLT
	GOV_MOD_DRP = TRUE	F < *F set point no load* - ((*Frequency droop**0.01) * P) - *Max Freq deviation*	
	GOV_MOD_CDRP = TRUE	F < F_CALC_LIMIT - *Max Freq deviation*	
	GOV_MOD_BASE = TRUE	P < BASE_P_SET - *Max P Dev Crl*	

Voting algorithm:

Voting algorithm is applied to groups of generators running in parallel. Voting algorithm compares the behavior of the local generator with rest of the generators in the connected network and if the load on local generator deviates excessively from the others, it is identified as faulty.

The algorithm needs minimum three generators (including the local generator) running in parallel.

The algorithm can be disabled through the setting *Disable Fuel voting*. *Table 1344* shows the method of detecting fueling faults using the voting algorithm.

Table 1344: Voting algorithm for detecting fueling faults

Type of fault	Fault detection criteria	Output activation
Over fueling fault	Number of generators in parallel with same governor mode >= 3 AND MAX(P1, P2, … P8) – MIN(P1, P2 … P8) < *Max P Dev Vot* (This check ensures that the network generators, **excluding local generator**, are operating with similar load) AND P > MAX (P1, P2… P8) + *Max P Dev Vot* (This is to check if the local generator load (P) is deviating significantly from other generators in the same network)	OV_FUEL_FLT
Under fueling fault	Number of generators in parallel with same governor mode >= 3 AND MAX(P1, P2, … P8) – MIN(P1, P2 … P8) < *Max P Dev Vot* AND P < MIN (P1, P2… P8) - *Max P Dev Vot*	UN_FUEL_FLT

If the generator is identified as faulty by the Correlation algorithm, then the generator is removed from the Voting algorithm. Similarly if a network generator is communicated to be faulty via inputs GEN1_DATA … GEN8_DATA, or if the quality of any of the inputs GEN1_DATA … GEN8_DATA is unreliable, then that generator is also removed from the Voting algorithm. This prevents misdiagnosis by Voting algorithm in the event that several generators should suffer from a common mode failure.

Excitation fault detection

This module detects problems with the generator excitation or AVR, which result in excessive reactive power (over excitation) or insufficient reactive power (under excitation) production by the generator.

As in Fueling fault detection block, the excitation faults are also detected by Correlation algorithm and Voting algorithm. The module activates OV_EXCT_FLT in case of over excitation fault detection and UN_EXCT_FLT output in case of under excitation fault. These two signals are available as outputs. Once an excitation fault is detected, the module initiates the Control logic module.

If the input AVR_MODE_DRP is FALSE, indicating that the automatic voltage regulator is not in droop mode, then the module is disabled. If the quality status of the local reactive power input is faulty, then the module is disabled and INT_BLKD output is activated. If generator present in the same subnetwork is faulty or if the quality status of reactive power of a generator is faulty, then that generator is removed from comparison in the Fueling fault detection module. INT_BLKD_STS

enumerated monitored data indicates the effect of signal loss (quality faulty) on all the four algorithms (i.e. Fueling Fault-Correlation, Fueling Fault-Voting, Excitation Fault-Correlation and Excitation Fault-Voting).

Correlation algorithm:

The generator excitation system normally follows the droop characteristic. Hence, the average generator phase-phase bus voltage (Uavg), derived from the three phase input `U3P`, and local generator reactive power are compared to the set droop curve. Deviation above/below this curve indicates over/under excitation condition.

The Correlation algorithm for excitation faults can be disabled through the setting *Disable Ext Crl*. The droop curve is set through the settings *U set point no load* and *Voltage droop*.

Table 1345 shows the criteria for detecting excitation faults using Correlation algorithm.

Table 1345: Correlation algorithm for identifying excitation faults

Type of fault	Fault detection criteria	Output activation
Over excitation fault	Uavg > *U set point no load* - ((*Voltage droop* *0.01) * Q) + *Max Volts deviation*	OV_EXCT_FLT
Under excitation fault	Uavg < *U set point no load* - ((*Voltage droop* * 0.01) * Q) - *Max Volts deviation*	UN_EXCT_FLT

Voting algorithm:

As in Fueling fault detection block, the Voting algorithm for excitation faults is also applied when at least 3 generators (including the local generator) are running in parallel. Whenever necessary, the algorithm can be disabled through the setting *Disable Ext Voting*.

Table 1346 shows the criteria for identifying excitation faults using Voting algorithm.

Table 1346: Voting algorithm for identifying excitation faults

Type of fault	Fault detection criteria	Output activation
Over excitation fault	Number of generators in parallel with same governor mode >= 3 AND MAX(Q1, Q2, … Q8) – MIN(Q1, Q2 … Q8) < *Max Q Dev Vot* (Check to ensure that the network generators, **excluding local generator**, are operating with similar load) AND Q > MAX(Q1, Q2 … Q8) + *Max Q Dev Vot*	OV_EXCT_FLT

Table continues on the next page

Type of fault	Fault detection criteria	Output activation
	(Check if the local reactive power (**Q**) is deviating significantly from other generators in the same network)	
Under excitation fault	Number of generators in parallel with same governor mode >= 3 AND MAX(Q1, Q2, … Q8) – MIN(Q1, Q2 … Q8) < *Max Q Dev Vot* AND Q < MIN(Q1, Q2 … Q8) - *Max Q Dev Vot*	UN_EXCT_FLT

Among the 8 reactive power inputs, `Q1 … Q8`, the input corresponding to the setting *Local generator Num*, would be considered as the local reactive power. For example, if *Local generator Num* is set to "1", then `Q1` is considered as the local generator reactive power output.

Fuel rack position monitoring

This module compares the position of the engine's fuel rack, obtained as input `FUEL_RCK_POS`, to the active power, P. The `FUEL_RCK_POS` input is a 0-20mA signal obtained through an `RTD` input. An offset linear relationship, refer *Figure 801*, is assumed between the fuel rack position and the generator active power.

The droop characteristics can be parameterized using the settings *Rack Pos no load* and *Rack Pos gain*. If the performance of the generator set deviates over/under the set droop curve, the fuel rack system is identified as faulty and the output `FUEL_RCK_FLT` is activated. The module can be disabled using the setting *Disable Fuel Rck Mon*.

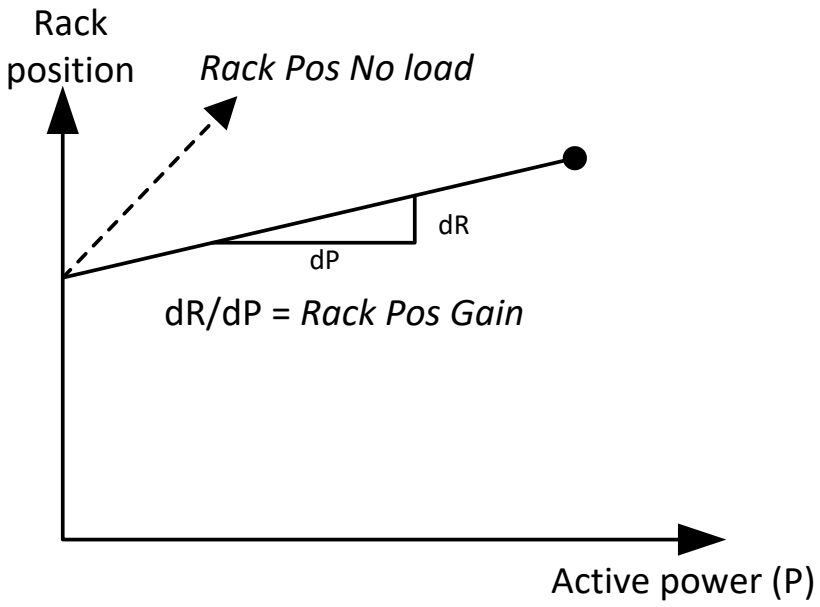

Figure 801: Rack position vs. Active power output of the generator

Excitation current monitoring

The excitation current, I_EXCITATION, produced by the AVR is compared to the reactive power output, Q, of the generator. A linear relationship is assumed between I_EXCITATION and Q. The I_EXCITATION input is a 0-20mA signal obtained through an RTD input and is in primary Amperes.

The droop characteristics can be parameterized using the settings *Ext current no load* and *Ext current gain*. If the performance of the generator deviates from this relationship, the module activates the output I_EXCT_FLT. The module can be disabled using the setting *Disable Ext Cur Mon*.

For both the Fuel rack position monitoring and the Excitation current monitoring modules, an internal delay of 100ms is assumed before activation of FUEL_RCK_FLT and I_EXCT_FLT outputs. This delay is to enable the generator mechanics to respond to the changes in fuel rack position and excitation current.

7.5.5.3 Control logic

Once activated by either the Fuel fault detection module or by the Excitation fault detection module, the Control logic module activates the FLT_DETECTED output. This output serves as an indication for the operator or the central PMS to start standby engines or alter the power sharing between healthy diesel generators.

If the network frequency and voltage deteriorate beyond control, the module activates the STOP_ENGINE (incase of fueling faults) and DE_EXCITE (incase of

excitation faults) to protect the system. The logic for the same has been shown in *Table 1347* and *Table 1348*.

The over/under fueling and over/under excitation logic will be checked only if the local active and reactive power are above 2% of nominal value respectively. When the local active and reactive power are less than 2%, the OPERATE output is issued instantaneously.

Table 1347: Criteria for activation of STOP_ENGINE output

Fault type	Criteria	Output
Over fueling fault	MIN (P1 … P8) < *Min active power* That is, One among the **network generators (excluding the local generator)** enter reverse power OR F > *Max Freq limit* + *Max Freq deviation*	STOP_ENGINE
Under fueling fault	(MAX (P1 … P8) > *Max active power* That is, One among the **network generators** enter over power region OR F < *Min Freq limit* – *Max Freq deviation*) AND P < 0.0 That is, **local generator** enters reverse power zone.	

Table 1348: Criteria for activation of DE_EXCITE output

Fault type	Criteria	Output
Over excitation fault	MIN(Q1 … Q8) <*Min reactive power* OR Uavg > *Max voltage limit* + *Max Volts deviation*	DE_EXCITE
Under excitation fault	(Uavg < *Min voltage limit* – *Max Volts deviation* OR I_MAX > 100% of nominal value I_MAX = Maximum of the three phase currents obtained from input I3P) AND Q < 0.0 That is, **local generator** enters reverse reactive power zone.	

The activation of STOP_ENGINE or DE_EXCITE outputs, activates the PRE_TRIP output and initiates the operate delay timer. The timer characteristic is based on DT. Once the time set by *Operate delay time* elapses or when active power (for fueling

faults)/ reactive power (for excitation faults) falls below 2% of nominal value, the OPERATE output is activated to open the generator circuit breaker.

In case the active or reactive power does not fall below 2% of nominal value within the set *Operate delay time*, after the activation of STOP_ENGINE or DE_EXCITE outputs respectively, the EXTERNAL_FLT output is activated along with OPERATE output.

The *Min active power*, *Max active power*, *Min reactive power* and *Max reactive power* settings should be set such that the faulty generator is tripped by its own DGMGAPC function before a healthy generator is tripped on over/under power/excitation condition.

The opening of the generator circuit breaker is monitored through the inputs GCB_CLOSED and GCB_OPEN. If the confirmation of GCB opening is not obtained with in the set *Max CB trip delay*, from the instant of activating OPERATE output, the OPR_TIE_A and OPR_TIE_B outputs are activated to trip the tie breakers and GCB_TRP_FAIL output is activated.

If any of the inputs GEN1_DATA ... GEN8_DATA indicate that backup protection is triggered in one of the generators in its own subnetwork, then the module activates the outputs OPR_TIE_A and OPR_TIE_B after the set *Backup delay time*, to protect the local diesel generator from tripping due to faults in other network generators.

The module continues to monitor the tie breaker status through inputs TIE_A_CLOSED, TIE_A_OPEN, TIE_B_CLOSED and TIE_B_OPEN. If after another *Max CB trip delay*, the confirmed opening information of tie breakers is not obtained then the module activates TIE_TRP_FAIL output.

The information on tie A or tie B side breaker tripping failure is shared with other DGMGAPC functions in the network through output GEN_DATA to initiate tripping of tie breaker. If the DGMGAPC function receives tie breaker trip failure indication from a generator which shares a tie breaker with the local generator, then the module initiates tripping of that shared tie breaker through either or both outputs OPR_TIE_A and OPR_TIE_B to protect the local generator.

The activated binary outputs, OPERATE, OPR_TIE_A, OPR_TIE_B and EXTERNAL_FLT, will remain active unless the RESET input is activated either from LHMI or through communication.

The module combines the binary information, namely, the GCB status, adjacent tie breaker statuses, Governor Mode, AVR mode, Generator local mode information, backup protection activation (BCKUP_PRT_ST), fault status of the generator (PRE_TRIP activation), A or B side tie breaker trip failure indication into output GEN_DATA. This output is available in the monitored data and is communicated to other DGMGAPC functions in the network on GOOSE. The active and reactive power inputs of the local generator are also communicated over GOOSE for usage as inputs in other DGMGAPC functions.

The binary input BLOCK can be used to block the function, for example, during synchronization of switchboard sections and when the engine is placed in manual control. The activation of the BLOCK input deactivates all module binary outputs, binary monitored data and resets the internal timers.

7.5.6 Application

The function is intended towards a set of diesel generators with similar characteristics interconnected with busbar and tie-breakers.

The DGMGAPC function is mainly used to protect the diesel generator from the over/under fueling of the diesel engines and over/under excitation of the generators. These faults are not easily detected by the traditional protection relay algorithms, which can result in healthy generators behaving abnormally in an attempt to maintain the system voltage and frequency within acceptable limits. This can lead to a cascade fault in which all the healthy generators are disconnected, leaving only the faulty unit running. Without the healthy generators to maintain the frequency and voltage, the faulty generator will also be tripped, resulting in a complete blackout of that part of the industrial network.

The DGMGAPC function identifies the existing network topology and the generators are compared with the expected behavior corresponding to their operation mode or with other generators with in the network.

Two algorithms are used to detect fueling and excitation faults, namely, Correlation and Voting algorithms. The Correlation algorithm compares the generator behavior with the set operation mode of the governor. If the local generator is deviating significantly then it is identified as faulty. The Voting algorithm works on the assumption that, generators share the load similarly. Hence a generator is identified as faulty, if the local generation is moving significantly away from the rest of the generators in the network. Any generator identified as faulty will not be used in either of the algorithms.

Real and reactive power for the local generator is obtained from power measurement function PEMMXU and for the network generator over GOOSE. As an example, a part of application configuration with two generators is shown in *Figure 802*. Here, Generator1 is the local generator whose real and reactive power is obtained from PEMMXU and Generator2 is the network generator whose real and reactive power are obtained over GOOSE.

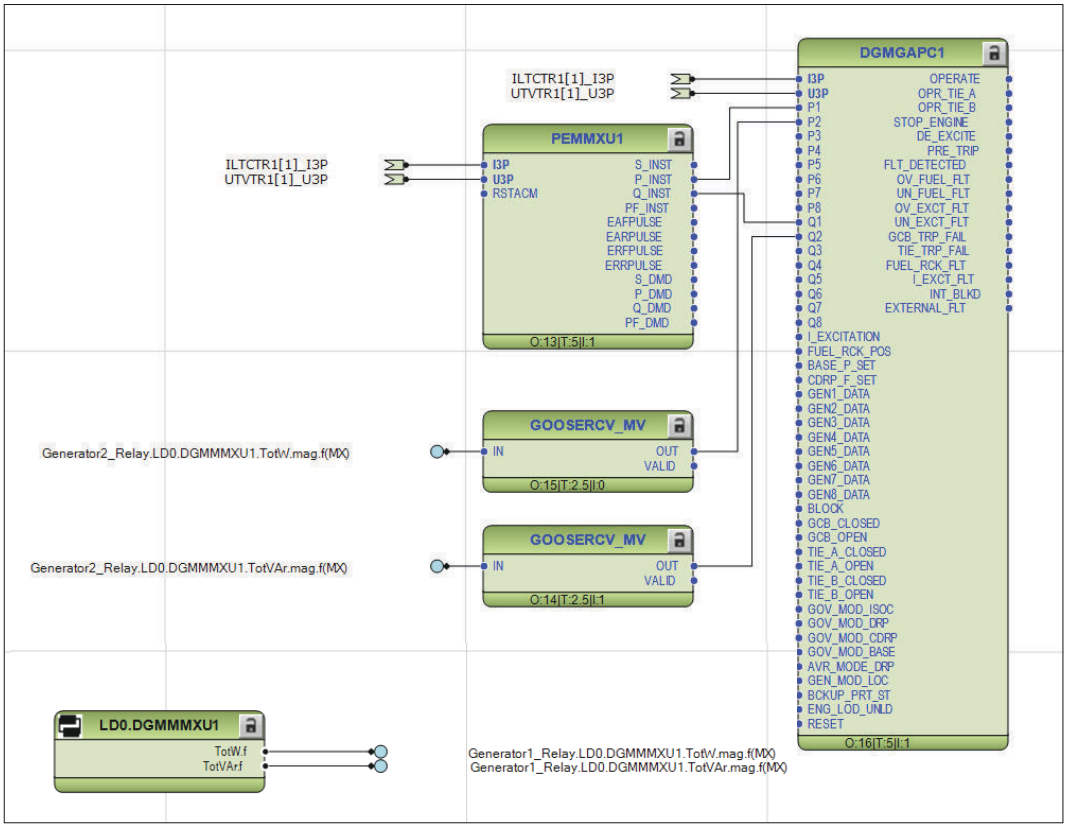

Figure 802: Example application configuration for real and reactive power connection

Once a generator is identified faulty an indication is sent to PMS for starting the backup generators, or to alter the power sharing between healthy generators, which would allow the faulty generator to be offloaded and tripped. But in case the system deteriorates, the function issues commands to shut down the engine or de-excite the generator. It then issues the command to open the GCB. In case the GCB tripping is unsuccessful, the function opens the neighboring tie breakers.

The network topology identification enables the function to locate a particular fault in the network and trip the neighboring tie breakers of healthy generators in case a network generator is faulty and is still not tripped.

The application configuration needs to ensure that in case any protection functions like, over speed protection or over voltage protection or if generator operates outside stability limit then a signal needs to be sent to shut down the diesel engine and open the GCB.

This needs to be configured outside the DGMGAPC function block.

The function monitors the fuel rack position and excitation current of the generator and rises an alarm in case they are deviating from the set operation mode.

7.5.7 Signals

7.5.7.1 DGMGAPC Input signals

Table 1349: DGMGAPC Input signals

Name	Type	Default	Description
I3P	SIGNAL	-	Three-phase currents
U3P	SIGNAL	-	Three-phase voltages
P1	FLOAT32	0.0	Active power of network generator 1
P2	FLOAT32	0.0	Active power of network generator 2
P3	FLOAT32	0.0	Active power of network generator 3
P4	FLOAT32	0.0	Active power of network generator 4
P5	FLOAT32	0.0	Active power of network generator 5
P6	FLOAT32	0.0	Active power of network generator 6
P7	FLOAT32	0.0	Active power of network generator 7
P8	FLOAT32	0.0	Active power of network generator 8
Q1	FLOAT32	0.0	Reactive power of network generator 1
Q2	FLOAT32	0.0	Reactive power of network generator 2
Q3	FLOAT32	0.0	Reactive power of network generator 3
Q4	FLOAT32	0.0	Reactive power of network generator 4
Q5	FLOAT32	0.0	Reactive power of network generator 5
Q6	FLOAT32	0.0	Reactive power of network generator 6
Q7	FLOAT32	0.0	Reactive power of network generator 7
Q8	FLOAT32	0.0	Reactive power of network generator 8
I_EXCITATION	FLOAT32	0.0	Excitation current of the generator
FUEL_RCK_POS	FLOAT32	0.0	Fuel rack position of the governor
BASE_P_SET	FLOAT32	0.0	Set active power limit in generator base load mode

Table continues on the next page

Name	Type	Default	Description
CDRP_F_SET	FLOAT32	0.0	Compensated droop no load set point frequency from PMS
GEN1_DATA	INT32	0	Data received from network generator 1
GEN2_DATA	INT32	0	Data received from network generator 2
GEN3_DATA	INT32	0	Data received from network generator 3
GEN4_DATA	INT32	0	Data received from network generator 4
GEN5_DATA	INT32	0	Data received from network generator 5
GEN6_DATA	INT32	0	Data received from network generator 6
GEN7_DATA	INT32	0	Data received from network generator 7
GEN8_DATA	INT32	0	Data received from network generator 8
BLOCK	BOOLEAN	0=False	Block input to block all binary outputs
GCB_CLOSED	BOOLEAN	0=False	Local generator circuit breaker closed position status
GCB_OPEN	BOOLEAN	0=False	Local generator circuit breaker open position status
TIE_A_CLOSED	BOOLEAN	0=False	Adjacent tie breaker A closed position
TIE_A_OPEN	BOOLEAN	0=False	Adjacent tie breaker A open position
TIE_B_CLOSED	BOOLEAN	0=False	Adjacent tie breaker B closed position
TIE_B_OPEN	BOOLEAN	0=False	Adjacent tie breaker B open position
GOV_MOD_ISOC	BOOLEAN	0=False	Governor isochronous mode status
GOV_MOD_DRP	BOOLEAN	0=False	Governor droop mode status
GOV_MOD_CDRP	BOOLEAN	0=False	Governor compensated droop mode status
GOV_MOD_BASE	BOOLEAN	0=False	Governor base load mode status

Table continues on the next page

Name	Type	Default	Description
AVR_MODE_DRP	BOOLEAN	0=False	Automatic voltage regulator mode
GEN_MOD_LOC	BOOLEAN	0=False	Generator in local mode
BCKUP_PRT_ST	BOOLEAN	0=False	Backup protection activated
ENG_LOD_UNLD	BOOLEAN	0=False	Engine loading or unloading in progress
RESET	BOOLEAN	0=False	Reset the correlation and voting algorithms and timer

7.5.7.2 DGMGAPC Output signals

Table 1350: DGMGAPC Output signals

Name	Type	Description
OPERATE	BOOLEAN	Operate
OPR_TIE_A	BOOLEAN	Operate tie breaker A
OPR_TIE_B	BOOLEAN	Operate tie breaker B
STOP_ENGINE	BOOLEAN	Stop fuel inflow to the engine
DE_EXCITE	BOOLEAN	De excite the generator
PRE_TRIP	BOOLEAN	Pre-trip signal indicating imminent trip of generator
FLT_DETECTED	BOOLEAN	Fault detected in the local generator
OV_FUEL_FLT	BOOLEAN	Over fueling fault detected
UN_FUEL_FLT	BOOLEAN	Under fueling fault detected
OV_EXCT_FLT	BOOLEAN	Over excitation fault detected
UN_EXCT_FLT	BOOLEAN	Under excitation fault detected
GCB_TRP_FAIL	BOOLEAN	Trip command to generator circuit breaker failed
TIE_TRP_FAIL	BOOLEAN	Trip command to tie breaker failed
FUEL_RCK_FLT	BOOLEAN	Fault in fuel rack of the governor
I_EXCT_FLT	BOOLEAN	Fault in excitation system of the generator
INT_BLKD	BOOLEAN	Internal block status
EXTERNAL_FLT	BOOLEAN	Gen P/Q not controlled due to fault in external system

7.5.8 Settings

7.5.8.1 DGMGAPC Settings

Table 1351: DGMGAPC Group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Disable Fuel Crl	0=False 1=True			0=False	Disable correlation algorithm for fueling faults
Disable Fuel voting	0=False 1=True			0=False	Disable voting algorithm for fueling faults
Disable Ext Crl	0=False 1=True			0=False	Disable correlation algorithm for excitation faults
Disable Ext voting	0=False 1=True			0=False	Disable voting algorithm for excitation faults
Disable Fuel Rck Mon	0=False 1=True			0=False	Disable fuel rack position monitoring
Disable Ext Cur Mon	0=False 1=True			0=False	Disable excitation current monitoring
Min Freq limit	0.95...1.00	xFn	0.01	0.95	Minimum Freq limit below which STOP_ENGINE is activated
Max Freq limit	1.00...1.05	xFn	0.01	1.05	Maximum Freq limit above which STOP_ENGINE is activated
Min voltage limit	0.5...1.5	xUn	0.1	0.8	Minimum voltage limit below which DE_EXCITE is activated
Max voltage limit	0.5...1.5	xUn	0.1	1.2	Maximum voltage limit above which DE_EXCITE is activated
Operate delay time	10...300000	ms	10	600	Operate delay time
Max CB trip delay	10...300000	ms	10	600	Maximum time delay for detection of CB status
Disable time	10...3600000	ms	10	60000	Function disable time during engine loading/unloading
Backup delay time	10...300000	ms	10	100	Operate delay time for backup protection

Table 1352: DGMGAPC Group settings (Advanced)

Parameter	Values (Range)	Unit	Step	Default	Description
Min active power	0.01...1.00	xSn	0.01	0.05	Active power limit below which STOP_ENGINE is activated
Max active power	0.10...2.00	xSn	0.01	1.00	Active power limit above which STOP_ENGINE is activated

Table continues on the next page

Parameter	Values (Range)	Unit	Step	Default	Description
Min reactive power	0.01...1.00	xSn	0.01	0.05	Reactive power limit below which DE_EXCITE is activated
Max reactive power	0.10...2.00	xSn	0.01	1.00	Reactive power limit above which DE_EXCITE is activated
Expected frequency	0.95...1.05	xFn	0.01	1.00	Expected frequency of the network in isochronous mode
F set point no load	0.10...2.00	xFn	0.01	1.00	No load frequency of the generator for droop characteristics
Frequency droop	0.00...100.00	%Fn	0.01	5.00	Percentage frequency droop from no load to full load
U set point no load	0.10...2.00	xUn	0.01	1.00	No load voltage of the generator
Voltage droop	0.00...100.00	%Un	0.01	10.00	Percentage voltage droop from no load to full load
Rack Pos no load	0.00...100.00	%	0.01	0.00	Fuel rack position on no load
Rack Pos gain	0.01...10.00		0.01	1.00	Rate of change of rack position from no load to full load
Ext current no load	0.0010...1.0000	xIn	0.0005	0.0100	Excitation current when generator is on no load
Ext current gain	0.0100...10.0000		0.0005	1.0000	Rate of change of excitation Curr from no load to full load

Table 1353: DGMGAPC Non group settings (Basic)

Parameter	Values (Range)	Unit	Step	Default	Description
Operation	1=on 5=off			1=on	Operation Off / On
Total Num of Gn	1...8		1	8	Total number of generators
Total Num of tie	1...8		1	8	Total number of tie
Reset delay time	20...15000	ms	10	100	Reset delay time

Table 1354: DGMGAPC Non group settings (Advanced)

Parameter	Values (Range)	Unit	Step	Default	Description
Max Freq deviation	0.00...0.10	xFn	0.01	0.01	Maximum allowed deviation in frequency
Max Freq Dev Isoc	0.00...0.10	xFn	0.01	0.01	Maximum allowed deviation in frequency for isochronous mode
Max Volts deviation	0.00...0.10	xUn	0.01	0.01	Maximum allowed deviation in voltage
Max P Dev Crl	0.00...0.10	xSn	0.01	0.01	Maximum allowed deviation in active power for correlation
Max P Dev Vot	0.00...0.10	xSn	0.01	0.01	Maximum allowed deviation in active power for voting

Table continues on the next page

Parameter	Values (Range)	Unit	Step	Default	Description

7.5.10 Technical data

Table 1356: Technical data

Characteristic	Value
Operation accuracy	Depending on the frequency of the measured voltage and current: f_n ±2 Hz
	Voltage: ±1.5% of the set value or 0.002 xU_n Frequency: ±5 mHz Active power: ±3% of the set value or 0.002 xS_n Reactive power: ±3% of the set value or 0.002 xS_n
Operate time accuracy	±1.0% of the set value or ±20 ms
Reset ratio	Typically 0.96/1.04

8 Measurement functions

8.1 Basic measurements

8.1.1 Functions

The three-phase current measurement function CMMXU is used for monitoring and metering the phase currents of the power system.

The three-phase voltage measurement function VMMXU is used for monitoring and metering the phase-to-phase voltages of the power system. The phase-to-earth voltages are available in VPHMMXU.

Single-phase voltage measurement function VAMMXU is used for monitoring and metering the single-phase voltage of the power system.

The residual current measurement function RESCMMXU is used for monitoring and metering the residual current of the power system.

The residual voltage measurement function RESVMMXU is used for monitoring and metering the residual voltage of the power system.

The frequency measurement function FMMXU is used for monitoring and metering the frequency of the power system.

The sequence current measurement CSMSQI is used for monitoring and metering the phase sequence currents.

The sequence voltage measurement VSMSQI is used for monitoring and metering the phase sequence voltages.

The frequency measurement FMMXU is used for monitoring and metering the power system frequency.

The three-phase power and energy measurement PEMMXU is used for monitoring and metering the active power (P), reactive power (Q), apparent power (S) and power factor (PF) and for calculating the accumulated energy separately as forward active, reversed active, forward reactive and reversed reactive. PEMMXU calculates these quantities using the fundamental frequency phasors, that is, the DFT values of the measured phase current and phase voltage signals.

The information of the measured quantity is available for the operator both locally in LHMI or WHMI and remotely to a network control center with communication.

If the measured data in LHMI or WHMI is within parentheses, there are some problems to express the data.

8.1.2 Measurement functionality

The functions can be enabled or disabled with the *Operation* setting. The corresponding parameter values are "On" and "Off".

Some of the measurement functions operate on two alternative measurement modes: "DFT" and "RMS". The measurement mode is selected with the *X Measurement mode* setting. Depending on the measuring function if the measurement mode cannot be selected, the measuring mode is "DFT".

Demand value calculation

The demand values are calculated separately for each measurement function and per phase when applicable. The available measurement modes are "Linear" and "Logarithmic". The "Logarithmic" measurement mode is only effective for phase current and residual current demand value calculations. The demand value calculation mode is selected with the setting parameter **Configuration** > **Measurements** > **A demand Av mode**. The time interval for all demand value calculations is selected with the setting parameter **Configuration** > **Measurements** > **Demand interval**.

The demand time interval is synchronized to the real-time clock of the protection relay. When the demand time interval or calculation mode is changed, it initializes the demand value calculation. For the very first demand value calculation interval, the values are stated as invalid until the first refresh is available.

The "Linear" calculation mode uses the periodic sliding average calculation of the measured signal over the demand time interval. A new demand value is obtained once in a minute, indicating the analog signal demand over the demand time interval proceeding the update time. The actual rolling demand values are stored in the memory until the value is updated at the end of the next time interval.

The "Logarithmic" calculation mode uses the periodic calculation using a log10 function over the demand time interval to replicate thermal demand ammeters. The logarithmic demand calculates a snapshot of the analog signal every 1/15 x demand time interval.

Each measurement function has its own recorded data values. In protection relay, these are found in **Monitoring** > **Recorded data** > **Measurements**. In the technical manual these are listed in the monitored data section of each measurement function. These values are periodically updated with the maximum and minimum demand values. The time stamps are provided for both values.

Reset of Recorded data initializes a present demand value to the minimum and maximum demand values.

Value reporting

The measurement functions are capable of reporting new values for network control center (SCADA system) based on various functions.

- Zero-point clamping
- Deadband supervision
- Limit value supervision

In the three-phase voltage measurement function VMMXU the supervision functions are based on the phase-to-phase voltages. However, the phase-to-earth voltage values are also reported with the phase-to-phase voltages.

GOOSE is an event based protocol service. Analog GOOSE uses the same event generation functions as vertical SCADA communication for updating the measurement values. Update interval of 500 ms is used for data that do not have zero-point clamping, deadband supervision or limit value supervision.

Zero-point clamping

A measured value under the zero-point clamping limit is forced to zero. This allows the noise in the input signal to be ignored. The active clamping function forces both the actual measurement value and the angle value of the measured signal to zero. In the three-phase or sequence measuring functions, each phase or sequence component has a separate zero-point clamping function. The zero-value detection operates so that once the measured value exceeds or falls below the value of the zero-clamping limit, new values are reported.

Table 1357: Zero-point clamping limits

Function	Zero-clamping limit
Three-phase current measurement (CMMXU)	1 % of nominal (In)
Three-phase voltage measurement (VMMXU)	1 % of nominal (Un)
Phase-to-earth voltage measurement (VPHMMXU)	1 % of nominal (Un)
Residual current measurement (RESCMMXU)	1 % of nominal (In)
Residual voltage measurement (RESVMMXU)	1 % of nominal (Un)
Phase sequence current measurement (CSMSQI)	1 % of the nominal (In)
Phase sequence voltage measurement (VSMSQI)	1 % of the nominal (Un)
Three-phase power and energy measurement (PEMMXU)	1.5 % of the nominal (Sn)

When the frequency measurement function FMMXU is unable to measure the network frequency in the undervoltage situation, the measured values are set to the nominal and also the quality information of the data set accordingly. The undervoltage limit is fixed to 10 percent of the nominal for the frequency measurement.

Limit value supervision

The limit value supervision function indicates whether the measured value of `X_INST` exceeds or falls below the set limits. The measured value has the corresponding range information `X_RANGE` and has a value in the range of 0 to 4:

- 0: "normal"
- 1: "high"
- 2: "low"
- 3: "high-high"
- 4: "low-low"

The range information changes and the new values are reported.

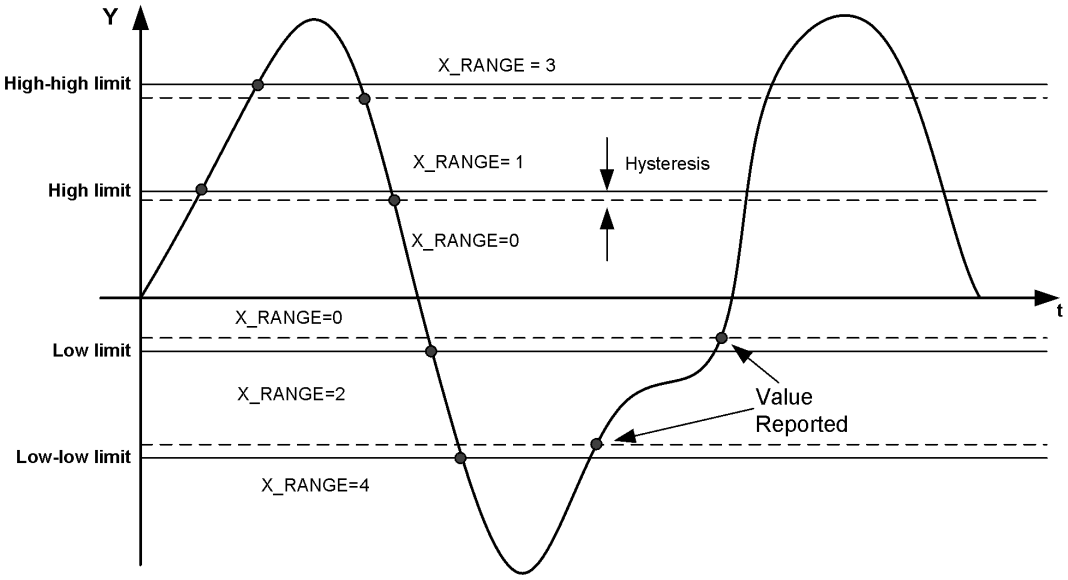

Figure 803: Presentation of operating limits

The range information can also be decoded into boolean output signals on some of the measuring functions and the number of phases required to exceed or undershoot the limit before activating the outputs and can be set with the *Num of phases* setting in the three-phase measurement functions CMMXU and VMMXU. The limit supervision boolean alarm and warning outputs can be blocked.

Table 1358: Settings for limit value supervision

Function	Settings for limit value supervision	
Three-phase current measurement (CMMXU)	High limit	*A high limit*

Three-phase power and energy measurement (PEMMXU)	High limit	–
	Low limit	–
	High-high limit	–
	Low-low limit	–

Deadband supervision

The deadband supervision function reports the measured value according to integrated changes over a time period. In *Figure 804* the values are reported at points Y1, Y2, Y3 and Y4. There is no value report at the end of |A3 + A4 + A5 + A6 + A7| because the positive and negative areas counteract each other. The integrated changes, |A3 + A4 + A5 + A6 + A7|, equal approximately zero.

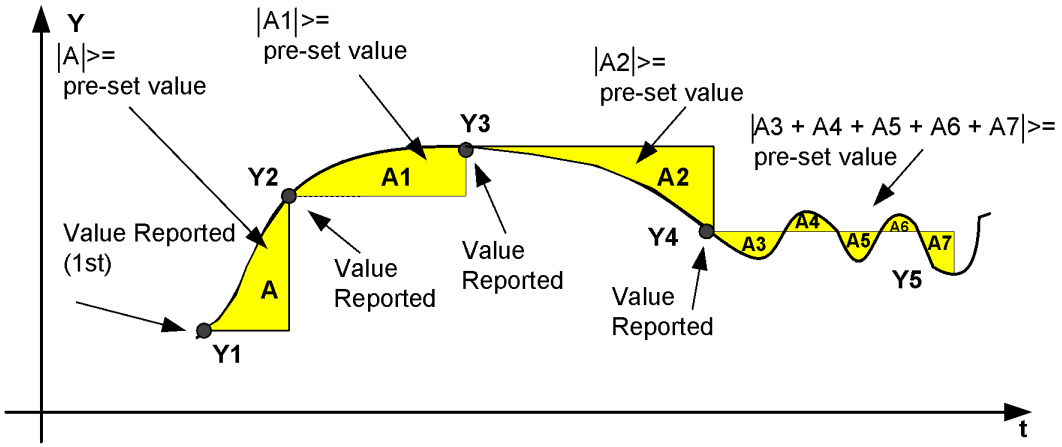

Figure 804: Integral deadband supervision

The deadband value used in the integral calculation is configured with the *X deadband* setting. The value represents the percentage of the difference between the maximum and minimum limit in the units of 0.001 percent x seconds.

The reporting delay of the integral algorithms in seconds is calculated with the formula:

$$t(s) = \frac{(\max - \min) \times deadband / 1000}{|\Delta Y| \times 100\%}$$

(Equation 338)

Example for CMMXU:

A deadband = 2500 (2.5 % of the total measuring range of 40)

`I_INST_A` = `I_DB_A` = 0.30

If `I_INST_A` changes to 0.40, the reporting delay is:

$$t(s) = \frac{(40 - 0) \times 2500 / 1000}{|0.40 - 0.30| \times 100\%} = 10s$$

Table 1359: Parameters for deadband calculation

Function	Settings	Minimum/maximum
Three-phase current measurement (CMMXU)	*A deadband*	*0.04/40*
Three-phase voltage measurement (VMMXU)	*V deadband*	*0.004/4*
Phase voltage measurement (VMHMMXU)	*V deadband*	*0.004/4*
Single-phase voltage measurement (VAMMXU)	*V deadband*	*0.004/4*
Residual current measurement (RESCMMXU)	*A deadband res*	*0.04/40*
Residual voltage measurement (RESVMMXU)	*V deadband res*	*0.004/4*
Frequency measurement (FMMXU)	*F deadband*	*0.04/40*

Table continues on the next page

Function	Settings	Minimum/maximum
Phase sequence current measurement (CSMSQI)	*Ps Seq A deadband*, *Ng Seq A deadband*, *Zro A deadband*	*0.04/40*
Phase sequence voltage measurement (VSMSQI)	*Ps Seq V deadband*, *Ng Seq V deadband*, *Zro V deadband*	*0.004/4*
Three-phase power and energy measurement (PEMMXU)	*Power deadband*	*0.01/0.1*

Power and energy calculation

The three-phase power is calculated from the selected voltage and current measurements as described in *Table 1360*. The setting *Measurement mode* determines which voltage and current measurements are used.

It is also possible to use positive-sequence components for calculating the apparent power, which makes the determination of power insensitive to any asymmetry in currents or voltages.

Table 1360: Measured apparent power

***Measurement mode* setting values**	**Power calculation**
PhsA, PhsB, PhsC	$\overline{S} = \overline{U_A} \cdot \overline{I_A}^* + \overline{U_B} \cdot \overline{I_B}^* + \overline{U_C} \cdot \overline{I_C}^*$ (Equation 339)
